In many regions, sugarcane is the target of insect pests and some of them are very damaging. On Reunion Island, which is a French department, the two major pests are the white grub, Hoplochelus marginalis (Coleoptera: Scarabaeidae), introduced from Madagascar in the seventies and the spotted stemborer, Chilo sacchariphagus, originally from Java. Control of the white grub by the entomopathogenic fungus, Beauveria brongniartii, has been successful, but the spotted stemborer remains problematic.

In the past few years the problem has been increasing due to adoption of a susceptible variety (R579) which often is less productive than the resistant one, R570. Stalk and internodes bored by larval stages result in productivity loss (tonnes cane per ha) of 30% in case of severe infestations (Goebel et al., 1999). Today, it is estimated that at least 10 000 ha of sugarcane (40% of the overall sugarcane area in Reunion) are at medium or high infestation risk.
Because chemical treatments are generally ineffective, expensive and, at the present, none are registered for use, biological control represents a good option that combines environmental preservation and biodiversity conservation.

Why use *Trichogramma* as a biocontrol agent on sugarcane?

*Trichogramma* spp. (*Hymenoptera: Chalcididae: Trichogrammatidae*) are extremely tiny egg parasitoids widely used on sugarcane and other crops in the world to control moth borers of economic importance. They are characterised by wings covered by hairs layered in radiant lines. Once mass-produced and released, the tiny parasites seek out and destroy eggs of caterpillar pests, such as sugarcane borers, codling moths, cotton bollworms, corn borers, spruce budworms and many others (Hassan, 1993; Li *et al*., 1994). The result is a living, biological ‘insecticide’ that strikes only the target pest with no risk to other natural enemies, human health or the environment.

The interest of these parasitoids in biocontrol is evident because they kill the pest at the most critical stage (the egg) before the damage occurs. In France, there is a good example of the efficacy of *Trichogramma brassicae*, which is currently used to control the European corn borer, *Ostrinia nubilalis*, on 20% of the maize crop area (more than 100 000 hectares) (Frandon and Kabiri, 1999). Futhermore, the low cost of production has encouraged the commercialisation of rearing *Trichogramma*.

10 years of research and continuous improvement of field releases

Results were accumulated during two critical periods: Period 1 (2000 to 2004) when preliminary inventory and experiments were conducted in the field and Period 2 (2005 to the present) which mainly focused on the improvement of the quality of production and *Trichogramma* releases. All research phases were supported by funding through the European Union and the Ministry of Agriculture in France.

The importance of identifying the best *Trichogramma* candidate for field releases

In 2000, a thorough inventory of egg parasitoids on the island showed that only one species was present in sugarcane fields: *Trichogramma chilonis* Ishii. Rather than introducing additional egg parasitoids, it was decided to use the local parasitoid which was probably introduced from Indonesia, as was its host. However, further observations concluded *C. sacchariphagus* egg batches were not sufficiently parasitised by the local species to be an effective control measure (Goebel, 1999; Rochat *et al*., 2001). It was then decided to use inundative releases to increase parasitism.

Before implementing such releases, the first step was to select the best candidate through laboratory experiments. To assess the potential of the parasitoid, the functional response of three *T. chilonis* strains (St. Benoît, St. Joseph, and St. Pierre, corresponding to three different climatic conditions, from humid to dry) was tested with *G. mellonella*, a facticious host, and one strain (St. Benoît) with *C. sacchariphagus* host eggs. The functional response is defined as the relationship between the number of prey consumed by a predator/parasitoid and prey density. The shape of the functional response (type II or III) based on logistic regression, attack coefficients and handling times (Th) led to the conclusion that the behaviour of all three strains with *G. mellonella* host eggs exhibited a type III response (Reay-Jones *et al*., 2006). The St. Benoît *T. chilonis* strain had a significantly shorter estimate of handling time than the St Pierre strain ($P < 0.05$).

In addition, the functional response with *C. sacchariphagus* host eggs was also a type II with the St. Benoît strain. Lastly, more *T. chilonis* wasps from this locality developed from the larger *C. sacchariphagus* host eggs (2.9 per egg) relative to *G. mellonella* (1.1 per egg). From these results, it was decided to use the St. Benoît strain for further evaluations.

*Trichogramma* releases: timing and application rates are essential

The rationale behind our biocontrol project conducted in Reunion was to set up inundative releases in sugarcane fields at the beginning of the crop cycle because it corresponds to the oviposition period of the borer which occurs on 1 to 4 months old cane (Tabone *et al*., 2002;
Tabone and Goebel, 2005). Field experiments started in 2001–02 in two locations, Sainte-Marie (SM: humid area/north east part of the island) and Savannah (SAV: dry area/west part of the island) and it was decided to apply 100 000 \( T. \ chilonis \) per hectare per week, during a 4 month-period.

Two-hundred release points/ha were also set up at this time to ensure a good distribution of the parasitoids. The results from these first experiments showed that releases totalling 16 releases significantly increased the cane yield from 15 to 20% depending on the location. In field releases set up later in 2003 (Table 1), the results showed a financial gain estimated from 600 to 1400 €/ha (Soula \textit{et al.}, 2003; Barreault \textit{et al.}, 2005).

SB = Stalks bored; INB = Internodes bored; CV = coefficient of variation; T80 = 80 000 Trichogramma per ha. Statistical results are from an ANOVA (SAS Institute). For each variable, the means followed by the same letters (a,b) are not significantly different (\( P > 0.05 \), Student-Newmans-Keuls test).

Between 2007 and 2009, two additional experiments confirmed and validated optimisation and simplification of release methods, particularly the reduction of release points per hectare from 200 to 100 (gain yield of 23%) (Marquier \textit{et al.}, 2008). Furthermore, the experiment in 2007 did not show any difference between 100 and 50 release points. This trial is being confirmed in a new experiment with the following treatments:

- Untreated control (UTC);
- Treatments ‘Reference’ (16 weekly releases of 100 000 \( T. \ chilonis \) per ha with 100 release points per ha for 4 months);
- Treatments ‘Period’ (12 weekly releases at the same rate for 3 months);
- Treatments ‘Optimisation’ (8 fortnightly releases of 200 000 \( T. \ chilonis \) per ha with the density of 50 release points per ha for 4 month).
The data are not fully collected yet, but the low level of infestation observed could hinder us from seeing a significant effect among the treatments. In future experiments, we will continue to reduce the number of releases (the ideal is 5 or 6) while ensuring that the efficacy of borer control will not be compromised.

**Predation by ants: how to manage it?**

On Reunion, the importance of predation of *C. sacchariphagus* eggs by ants (mainly *Pheidole megacephala*, the big-headed ant) has been reported as an essential component of the natural control of this pest (Goebel *et al.*, 1999), but ant predation is better known on other stemborer species (Teran, 1980; Bonhof *et al.*, 1997).

The biocontrol strategy which was successfully implemented for some years takes this predatory action into account which is particularly efficient in 6–12 month old cane fields. Unfortunately, our results tend to show ant predation can have a negative impact on the efficacy of *T. chilonis* releases. Because this predatory ant is small and very active, the parasitised eggs released are often predated, despite the different protection systems tested in the field.

To decrease this negative impact, new dispensers with tiny holes to prevent ants from penetrating and feeding on parasitised eggs are being tested. These dispensers are produced by our private partner, Biotop.

**Initial results on diapause and storage at cold temperature.**

To apply a biocontrol strategy on a wider scale, there is a critical need to decrease the costs of insect production and field releases. Delaying emergence of *Trichogramma* spp. is critical for commercial production, and cold storage has been widely studied and used for this purpose (Voegelé *et al.*, 1986; Pitcher *et al.*, 2002; Ventura-Garcia *et al.*, 2002; Özdö, 2004; Rundle *et al.*, 2004; Tezze and Botto, 2004), including its use on *T. chilonis* (Farid *et al.*, 2001; Shirazi, 2006). The technique has many advantages, including reducing overall costs, optimising the organisation and increasing production capacity. The storage capacity of *Trichogramma* will undoubtedly allow better management of staff and premises devoted to production. Finally, by reducing the number of progenies per year the risk of having a genetic drift is minimised. For the field, the possibility to cold store *Trichogramma* with delayed emergence will also facilitate delivery to farmers and reduce the number of releases.

At the end of 2008, a new research program began to determine optimal conditions (T°, RH, photoperiod, developmental stage) for arresting development by diapause or inducing quiescence of *T. chilonis*. Initial efforts allowed us to store the *T. chilonis* strain from Reunion for 2 months in a state of quiescence without affecting biological performance in the laboratory (Table 3 and Figure 1). The egg numbers per female were not different at 6 and 9 weeks (Student’s *t*-test, *p* > 0.05), but fecundity was significantly higher after 3 weeks of storage at 3°C than the control (Student’s *t*-test, *p* < 0.001) (Figure 1).

However, it is essential to determine if cold storage affects the efficacy of *Trichogramma* in the field, which will be an important step for our project in conjunction with our local partner FDGDON (Fédération Départementale de Défense contre les organismes nuisibles).

**Trichogramma production: How to optimise biocontrol and the supply?**

The production of T. chilonis has improved through the years by our main partner FDGDON on Réunion. From 2000 to 2004, a small production unit was first set up for experimental needs using the greater wax moth *Galleria mellonella* (Lepidoptera, Pyralidae) as host.

In 2008, FDGDON reached its capacity in production of *G. mellonella* with 8 million eggs and 2 million of *T. chilonis* produced per month. This production is very costly and time consuming and the parasitism level on *Galleria* eggs is often variable.

In 2009, *Galleria mellonella* (Gm) was replaced by the Mediterranean flour moth *Ephestia kuehniella* (Ek), a widely used host for commercial production of *Trichogramma* spp. Further laboratory tests comparing the quality of *T. chilonis* produced on these two factitious hosts concluded that *E. kuehniella* was superior in terms of fecundity per *T. chilonis* female (Ek: 31 parasitised eggs; Gm: 26) average parasitism (Ek: 70%; Gm: 30%) and emergence rate (Ek: 92%; Gm: 55%).

However, rather than starting a new production site locally with FDGDON, we began to produce *Trichogramma* in France via our industrial partner Biotop. In 2009, experiments were conducted from consignments (cool boxes) sent to FDGDON, in Réunion on a regular basis.

The *E. kuehniella* eggs were then conditioned in appropriate dispensers and released in the fields. Having a company specialised in biological control in the project has become a necessity to apply *Trichogramma* releases on a wider scale.

This will also guarantee the quality of production and field releases of beneficial insects at an affordable price to farmers.

Biotop, a company based in France and is a subsidiary of the InVivo group, plans to develop the appropriate technology for Réunion through our project. Biotop has been working many years on improving the use of *Trichogramma brassicae* to control the European corn borer, *Ostrinia nubilalis*.

After 20 years of experience, this strategy is used in France on 120 000 ha of maize (2008); good results have convinced many farmers to adopt biological control instead of chemical control.

Biotop has successfully developed a technology based on very efficient preparation and packaging plus delayed emergence of *Trichogramma* in the fields (Figure 2). The parasitised eggs are prepared in special dispensers, made with cardboard sheets, which protect eggs from predators and rain or irrigation during several weeks.

These preparations use different stages of *T. chilonis* larvae (basically 4 stages) in order to successively release waves of this parasitoid, providing a long duration of beneficial activity. It has been possible to reduce the number of applications in corn fields from three to only one, with the same efficacy. In addition, the dispensers are easily supported by the plants and it is possible to treat 5 ha in one hour walking in the fields.

![Figure 2](image-url) — An example of the ultra-delayed release waves in dispensers implemented by Biotop for the control of the European corn borer *O. nubilalis* in France

In France, the cost of a *Trichogramma* application approximates a chemical application, including the mechanisation, of about 35€/ha. For this project, the goal is to use the same release technology with an expectation of controlling the pest with six applications, at a cost to the farmer ≈ 200€/ha. Considering the financial gain due to biological control, this price is affordable for sugarcane farmers.

**Discussion: which biocontrol strategy for the sugarcane industry in the future?**

Based on the promising results obtained and the experience accumulated during this project, we are confident that biocontrol using *Trichogramma* spp. will be a success story and a realistic strategy for growers to reduce borer infestations. However, *Trichogramma* is just one of the components of biocontrol and certainly not a panacea. From our experience in Reunion, we have learned that a biocontrol program needs proper research following strict protocols and requires constant technical improvement. The failure of borer control using *Trichogramma* spp. in the 1960s and 1970s was partly due to lack of research on parasitoids themselves (species, bionomics and efficacy), but also lack of quality control of mass production (Goebel, 1999). During this period, biological programs often introduced exotic parasites and released them without evaluating (in some cases) their impact on pests (Goebel, 1999). All these facts have led to a negative image of biocontrol with *Trichogramma* spp. and other parasitoids and loss of interest for this strategy (Tabone et al., 2002). Nevertheless, many countries, such as Indonesia (Java) and India are using this parasitoid as the main component of their biocontrol strategy. Indonesia is still producing millions of *Trichogramma* in association with the sugar factories while India has seen small farmers taking over the production and release of *Trichogramma* wasps in their own fields.

Another example is Brazil which has succeeded in controlling *Diatraea saccharalis* using two parasitoids: *Cotesia flavipes* and *Trichogramma galloi* (Botelho et al., 1999). This example is noteworthy as it is an example where key parasitoids are used in concert. It demonstrates that it is preferred to have additional pressure on stemborer populations. It is an interesting option to
consider for Reunion. As we have seen, predation should also be considered as a component of the system.

Research and Development activities should continue to improve biocontrol in all its components: quality control, cost reduction, conditioning, packaging, efficacy and adoption by growers. We have started to understand the induction mechanisms of quiescence and/or diapause of *T. chilonis* in laboratory conditions. If successful, this research offers the possibility of storing the parasitoid for long periods without loss of viability.

In the era of GMOs and the concern of the environmental impacts of such technologies, biological control remains a credible alternative for ecologically, sound-based pest management.

MOTS-CLES: Canne à Sucre, Foreur des Tiges, Trichogramma chilonis, Production de Masse, Lâchers au Champ.

Résumé

Le contrôle biologique des foreurs de la canne à sucre utilisant les lâchers de \textit{Trichogramma} est une stratégie commune utilisée dans de nombreux pays et l’efficacité de tel lâcher a été prouvée dans la plupart des cas. À l’île de la Réunion, un ravageur-clé \textit{Chilo sacchariphagus} et son parasitoïdes d’œufs \textit{Trichogramma chilonis} ont été le sujet d’une recherche intensive depuis 10 ans. De l’identification d’un meilleur candidat pour le contrôle biologique à la production de masse en passant par les lâchers expérimentaux dans les champs de canne à sucre, des améliorations ont été constamment apportées au fil des années, avec succès. Dans cet article, nous présentons des avancées majeures de cette recherche, les problèmes rencontrés et les questions qui ont été soulevées au cours des expérimentations au champ (Réunion) et lors des activités d’élevage au laboratoire (Réunion et France métropolitaine). Derrière les résultats prometteurs d’une technologie qui préserve l’environnement et utilisée à travers le monde, l’un des débats actuels qui demeure est le coût d’un tel contrôle biologique pour les planteurs. Depuis 2008, un nouveau projet de recherche-développement est conduit pour optimiser la technologie des lâchers au champ et accroître l’efficacité de la production de masse et du stockage au froid. Pour répondre aux critères de rentabilité et de qualité avec mis en œuvre d’un nouveau process industriel pour la production de \textit{Trichogramma}, un partenariat a été créé avec la société française BIOTOP qui a une expérience large et reconnue sur la lutte biologique contre le foreur du maïs \textit{Ostrinia nubilalis} en France.

Palabras clave: Caña De Azúcar, Barrenadores, Trichogramma Chilonis, Producción Masiva, Liberaciones en Campo

Resumen
EL CONTROL biológico de barrenadores de la caña de azúcar usando liberaciones de Trichogramma es una estrategia común usada en muchos países, y la eficacia de estas liberaciones ha sido probada en la mayoría de los casos. En la Isla Reunión, el principal barrenador Chilo sacchariphagus y su parasitoide de huevos Trichogramma chilonis han sido objeto de investigación intensiva durante 10 años. Se han hecho mejoras constantemente a través de los años con resultados exitosos desde la identificación del mejor agente de control biológico, su producción masiva y experimentos de liberaciones en campo. En este trabajo, se informa sobre algunos de los resultados importantes, los problemas encontrados y las preguntas que surgen durante los experimentos de campo (Reunión) y las actividades de cría en laboratorio (Reunión y Francia). Detrás de los resultados prometedores de una tecnología eco-amiga que se utilice a nivel mundial, uno de los debates actuales que permanecen es el costo de estos controladores biológicos para los cultivadores. Desde 2008, una nueva investigación y proyecto de desarrollo se está conduciendo para optimizar la tecnología de liberaciones de campo así como para aumentar la eficacia de la producción masiva y almacenamiento en frío. Para tratar sobre la viabilidad económica y calidad, se está estableciendo un nuevo proceso industrial para la producción de Trichogramma, se ha formado una sociedad con una compañía francesa, BIOTOP, la cual tiene una larga experiencia en control biológico del barrenador del maíz Ostrinia nubilalis en Francia.
THE EFFECT OF BAGASSE FURNACE ASH APPLICATION ON SUGARCANE RESISTANCE TO TOP BORER SCIRPOPHAGA NIVELLA INTACTA SNELLEN (LEPIDOPTERA: PYRALIDAE)

By

SAEFUDIN SAEROJI, SUNARYO and HERU GUNITO

saefudin@risetgmp.com

KEYWORDS: Sugarcane, Bagasse Furnace Ash, Top Borer, Resistance, Silicon.

Abstract

SUGARCANE top borer, Scirpophaga nivella intacta Snellen, is a major pest of sugarcane at PT Gunung Madu Plantations, Lampung, Indonesia. Infestation on several commercial varieties is alarming despite an integrated control program. Many studies have been done in South Africa, Hawaii, Florida, India, and Taiwan on use of the element silicon to improve plant resistance to pest and disease. Bagasse furnace ash, plentiful at a cane sugar factory, is known as an important silicon source. A field trial was conducted in the plantation to study the effect of bagasse furnace ash application on sugarcane resistance to top borer infestation. A susceptible variety TC4 was used. Treatments comprised a control and 40, 80, and 120 t/ha of pre-plant broadcast application. In the 120 t/ha treatment, the number of top borer larvae successfully boring into the leaf spindle was 20.7% fewer than the control. Also 19.2% fewer larvae bored into the growing point and the internodes. Similarly, the length of boring tunnels (measured from the growing point) in this treatment was shorter than in the control. In addition, stalk population, height, and diameter increased with the rate of ash application. Application of 120 t/ha bagasse furnace ash of approximately 7.97 ± 0.58% silicon content increased the resistance of susceptible variety TC4 to top borer infestation and increased the cane yield by 39.89%.

Introduction

Sugarcane moth borers (Lepidoptera: Pyralidae) are predominant pests in Gunung Madu sugarcane plantation, Lampung, Indonesia. The borer complex consists of white top borer (Scirpophaga nivella intacta Snellen), and spotted- and glossy- stem borers (Chilo sacchariphagus Boj. and C. auricilius Dudg.). Borer population cycles overlap under the tropical conditions found here. Infestation pressure is exacerbated by the massive size of the plantation (> 25 000 ha) and uninterrupted mono-cropping practices applied therein (Sunaryo, 2005).

Stem borers have been acceptably controlled by augmented natural enemies reared in the laboratory such as egg parasitoid Trichogramma chilonis Ishii and larval parasitoids Cotesia flavipes Cam. and Sturmiopsis inferens Tns.

Top borers have been acceptably controlled by recolonisation and preservation of natural enemies in the field and soil application of granular insecticide on selective fields of young canes adjacent to heavily damaged mature canes. At the peaks of moth flight, a combination of light trappings and manual collection has been occasionally done to reduce moth populations. However, the overall infestation in the last decade reached 7.80% (3.04 – 13.52%) and was 9.61% (3.47 – 18.77%) on susceptible variety TC4. Other approaches are explored to improve the overall result.
Top borers lay eggs on the uppermost leaves; the hatched larvae then penetrate the leaf spindle through the midrib. They move to the growing point, kill it and bore further downward into the internodes. They feed and transform into pupae inside the internodes.

Field and greenhouse trials in Florida, Hawaii, and Mauritius indicated that the application of silicon fertiliser had a positive effect on sugarcane resistance to pests, diseases, and frost tolerance (Matichenkov and Calvert, 2002). This knowledge is potentially useful, as silicon is concentrated in bagasse ash (furnace- and fly-ash), which is abundantly available at most sugar mills. In India, sugarcane varieties which are resistant to shoot borer were found to contain higher silicon per leaf area unit, and a study in Taiwan showed that borer infestation on silicon-treated sugarcane was lower compared with untreated cane (Meyer and Keeping, 2005). Keeping and Meyer (2006) compared the efficacy of several silicon sources, including fly ash, on controlling boring by *Eldana*. Also from South Africa, Kvedaras *et al.* (2007) reported a comprehensive study on soil applied silicon, sugarcane cultivars, and borer feeding sites in the stalks.

The objective of the present study is to find out the effect of the application of bagasse furnace ash on sugarcane resistance to top borer *S. nivella intacta*. This material is abundantly available at most sugar mills. The use of bagasse to fuel mill boilers at Gunung Madu sugar mill (12 000 TCD) leaves up to 23 000 t bagasse furnace ash annually, and therefore it is potentially a good and practical silicon source for this purpose.

**Materials and method**

The present study was carried out at Gunung Madu sugarcane plantation, Lampung, Indonesia (approximately 4°42’ S/105°12’ E), from August 2005 to July 2006. The study used field plots 20 m long x 40 m (26 sugarcane rows) wide, with 5 m inter-plot spacing. In each plot, 16 rows were selected for pest observation and 10 other rows for agronomy observation.

The treatments consisted of one control (no-ash application) and 40, 80, and 120 t/ha-of bagasse ash application, each replicated three times in a complete randomised design. The bagasse ash, supplied from Gunung Madu sugar mill, was pre-plant broadcasted as in Keeping *et al.* (2004). Silicon content of the material, analysed at the Soil and Plant Analysis Laboratory of the plantation using a yellow silico-molybdic acid method, was 7.97 ± 0.58%. TC4 variety, which is highly productive but susceptible to top borer, was planted.

Resistance was assessed on artificially-infested plants. Three newly hatched top borer larvae were laid on top of leaf number –1 of each of 80 sugarcane stalks in each plot. This was done on 9 month old plants, the same plant age chosen by Kvedaras *et al.* (2005). These stalks were marked for spindle and internode observations. Observations were made 14 and 27 days after infestation with 40 infested plants for each observation (where at least one larva was already in the midrib). The first observation was to assess larval penetration and position in the leaf spindle while the second was to assess the extent of boring into internodes.

Infestation success rate in the spindle and internodes was used to describe plant resistance. An infestation was considered successful when the larva was still alive. The distance of larvae from the growing point when they were in the spindle (14 days after infestation) and when they were in the internodes (27 days after infestation) was measured to find out the movement and position of larvae.

The larval infestation success rate (%) within both spindle and internodes was calculated by the number of successful infestations relative to the total samples artificially infested. The infestation success rate (%) in the spindle was formulated as:

\[
\text{infestation success rate in the spindle} = \frac{s}{40} \times 100
\]

where \( s = \) number of successful infestations in the spindle,

40 = total samples infested.
As for larva success rate in the internodes, the following formula was used:

\[(i/40) \times 100\]

where \(i\) = number of successful infestations in internodes,

\(40\) = total samples infested.

Data on stalk population, height, and diameter of millable stalks from 10 through 12 month age (harvest time) were also recorded to give a general idea on the effect of bagasse ash application on cane agronomy. Samples for agronomic evaluations were collected from the specifically assigned 10 rows as described before, ignoring natural top borer infestation that might have occurred therein. In each plot, a row sample equal to 1/1000 ha was used for population counts, out of which 20 stalks were randomly selected for height and diameter measurement. Adequate size of sub-plots were sampled and weighed to estimate cane yield per hectare.

**Results and discussion**

**Larva penetration in leaf spindle (14th day after infestation)**

There was significantly lower initial success rate of infestation in the control compared to the treatment with 120 t/ha ash application, with a reduction (compared to control) of 20.7%. Treatments with 80 and 40 t/ha ash application reduced the success rate by 15.0 and 3.9% respectively (Table 1). The lower success rate of larval penetration into the spindle with higher rate of ash application may be attributed to the increased silicon supply to the plant. The same table shows that larvae were closest to the growing point in the controls and significantly further away in the 80 and 120 t/ha ash treatments. It suggests that the movement of larvae to the growing point was significantly hindered with 80 and 120 t/ha ash applications which presumably contributed to plant resistance.

* means within the same column followed by the same letter are not significantly different (P = 0.05, HSD- test).

**Larva boring in the internodes (27th day after infestation)**

The application of bagasse furnace ash decreased the infestation success rate into top internodes, similar to the increase of application rate. The 120 t/ha treatment gave the lowest success rate (58.0%) with a tunnel length (treatment average) of 4.1 cm. It means that only 58.0% larvae were found alive and arriving at the growing point or further through the internodes.

Some of the larvae were just at the growing point and 1st internodes (each 10.0%), the remainder have been further down in the lower internodes, but none at 4th internodes. In controls, the success rate was 77.2%, significantly higher by 19.2% compared to 120 t/ha treatment and all larvae have bored further down to 2nd and lower internodes with a total 83.3% at 3rd and 4th internodes (Table 2).

These findings suggest that ash application resulted in lower infestation success rate and may constitute plant resistance. With the increasing rate of ash application, the hindrance to larval movement was greater as indicated by the shorter tunnel length and larval position. It confirms the earlier observation taken on the 14th day.

Deposition of silicon in surface cell layers, and especially the epidermis, has a bearing as well on physical surface properties (Epstein, 1999). Pan et al. (1979), using similar bagasse furnace ash as silicon provider, also found that borer damage was lower when compared to no-ash application. The increased presence of silicon crystals in sugarcane plant tissues hinders the feeding of the larvae, which at their early instar has rather fragile mandibles (Meyer and Keeping 2005).

On a different crop, Ukwungwu and Odebiyi (1985) found that silicon increases hardness of plant tissue, interferes with insect larval boring and feeding activity, and constitutes a strong factor in resistance to rice striped borer.

The present results conform to those of Keeping et al. (2004), who assessed the effect on Eldana borer of fly-ash application containing 10% silicon. They reported a similar reduction of borer infestation from 45 per 100 stalks in control plots to 18 per 100 stalks in ash treated plots. Further, Keeping et al. (2008) stated that silicon is accumulated in the epidermis tissues of sugarcane internodes, root bands, and also contained in the internal tissues.

This silicon accumulation obstructs the penetration and larval feeding of Eldana borer, and adversely affects the feeding mechanism. As a result of their slower movement, there will be more time for larvae to be exposed to natural predators, weather stress, or pest control measures (Kvedaras et al., 2008).

The application of silicon fertilisers (based on various silicon sources) has been considered as worth including in the integrated pest management scheme as they do not leave unwanted residues in the sugarcane products and environment, and yet are compatible with any other pest control technique including biological control (Pan et al., 1979).

**Cane agronomy**

Bagasse furnace ash application gave a positive effect on sugarcane stalk population. Stalk population at 10-month age with 120 t/ha ash application was 97 000/ha as compared to 85 000/ha of no-ash application. Statistical analysis showed a significant difference between no-ash application with either 80 or 120 t/ha ash application treatment, where the latter two had higher stalk population (Table 3).

There was also a significant difference on the height of millable stalks between the control and the 120 t/ha ash application treatment, the latter being 13.7 cm longer at 10-month age. Similar effect was observed on stalk diameter, which was only 2.3 cm for no-ash but 3.0 cm for 120 t/ha ash application treatment.

Eventually, at harvest time (12-month age), the total sampled stalks weight was higher on all ash application treatments. The estimated yield with 120 t/ha ash application was 39.9% higher compared to no-ash treatment (Table 3).
Table 3—Population, height, stalk diameter and cane yield.

It appears that, in addition to the potential benefit of improved plant resistance and possible lower borer damage, the ash application under local soil condition, especially at higher rates, has increased stalk population, stalk length and diameter, and eventually the cane yield. This could be due to improved status of silicon in the plant. Elawad (1982), Alloerung (1989), and Matichenkov and Calvert (2002), using various silicon materials, reported a similar cane yield improvement.

Although no biochemical role for Si in the development of plants has been positively identified, it has been proposed that enzyme-Si complexes form in sugarcane that act as protectors or regulators of photosynthesis and enzyme activity. Si can suppress the activity of invertase in sugarcane, resulting in greater sucrose production. A reduction in phosphatase activity is believed to provide a greater supply of essential high-energy precursors needed for optimum cane growth and sugar production. Si additions have improved the growth of sugarcane in Florida, Hawaii, Mauritius, Puerto Rico, and Saipan (Tisdale et al., 1993).

Conclusion

Under the conditions of this trial, the application of bagasse furnace ash has resulted in improved resistance of a susceptible variety to top borer infestation. The ash application at 120 t/ha has significantly lowered the success rate of larval penetration into the leaf spindle and hindered further penetration into the growing point and top internodes. On top of the potential benefit of plant resistance and reducing borer damage, the ash application had the positive effect of improving stalk population, plant height (length), and stalk diameter, which resulted in 39.9% increase in cane yield.

Future studies need to include measurement of silicon content in plant tissues, probably in the midribs, spindle leaves, and the meristem tissues of growing points and top internodes. This is to know the extent of hindrance that silicon may be responsible for the penetration of the top borer. Growth observations, such as periodical plant height measurement, may be worthwhile to learn if there is any improved growth rate due to silicon application that may eventually be responsible for changes in top borer penetration. Also, measurement of larva and pupa weight will be useful to confirm the role of silicon in constituting plant resistance.

Acknowledgement

The authors acknowledge the generous opportunities and facilities given by Mr M. Jimmy Mahshun, General Manager of PT Gunung Madu Plantations, to do the study and present the report in this prestigious medium. They are also very grateful to Mr Koko Widyatmoko, the Head of Research & Development Department, for his continuous support in completing this paper.

Résumé

Le foreur apical de la canne à sucre, Scirpophaga nivella intacta Snellen, est un ravageur majeur de la canne à sucre au PT Gunung Madu Plantations, Lampung, Indonésie. L’infestation de plusieurs variétés industrielles est alarmante malgré un programme de lutte intégrée. Plusieurs études en Afrique du Sud, Hawaï, Floride, Inde et Taiwan ont démontré que l’utilisation de la silice peut améliorer la résistance de la plante contre les ravageurs et les maladies. La cendre de bagasse, produit en abondance aux sucreries, est connue pour être une source importante de silice. Un essai a été effectué à la propriété susmentionnée pour déterminer l’effet de la cendre de bagasse sur la résistance de la variété TC4, qui est sensible au foreur. L’essai comprenait un témoin non-traité ainsi que des traitements de 40, de 80, et de 120 t/ha, de cendre appliqués à la volée avant la plantation. Pour le traitement de 120 t/ha, le pourcentage de la feuille du fuseau attaqué était de 20.7% de moins que le témoin. De plus, 19.2% moins de larves ont pénétré le point de croissance et les entrenœuds. La longueur des tunnels forés (mesurée du point de croissance) était aussi réduite pour ce traitement que le témoin. De plus, il a été constaté que le nombre, la longueur et le diamètre des tiges étaient supérieurs en fonction de l’augmentation du taux d’application de cendre. Il a été conclu qu’une application de 120 t/ha de cendre de bagasse avec un taux approximatif de 7.97 ± 0.58% de silice augmente la résistance de la variété TC4 au foreur et occasionne un rendement de canne supérieur par 39.89%.
EL EFECTO DE LA APLICACIÓN DE CENIZAS DE BAGAZO EN LA RESISTENCIA DE LA CAÑA AL BARRENADOR DEL COGOLLO SCIRPOPHAGA NIVELA INTACTA SNELLEN (LEPIDOPTERA: PYRALIDAE)

PALABRAS CLAVE: Cenizas de Bagazo de Caña, Barrenador del Cogollo, Resistencia, Silicio.

Resumen

EL BARRENADOR del cogollo, Scirophaga nivella intacta Snellen, es una plaga importante de la caña de azúcar en las plantaciones de PT Gunung Madu, Lampung, Indonesia. La infestación en diferentes variedades comerciales es alarmante, pese a que se tiene un programa de control integral. Muchos estudios se han realizado en Sudáfrica, Hawái, Florida, la India y Taiwán sobre el uso del elemento silicio para mejorar la resistencia de las plantas a las plagas y enfermedades. Las cenizas de bagazo, abundante en las fábricas de azúcar, son conocidas como una fuente importante del silicio. Por tanto, se realizó un ensayo de campo en una plantación de caña de azúcar tendiente a estudiar el efecto de las cenizas de bagazo sobre la resistencia de la caña a la infestación por el barrenador del cogollo. La variedad TC4 susceptible fue utilizada. Los tratamientos comprendieron un control y aplicaciones en el campo de 40, 80 y 120 t/ha antes de la siembra. En el tratamiento de 120 t/ha, el número de larvas del barrenador del cogollo emergidas fue de 20.7% inferiores al control. También el número de larvas fue inferior al 19.2% entre el punto de crecimiento y los entrenudos. Del mismo modo, la longitud de los túneles del barrenador (medidos desde el punto de crecimiento) en este tratamiento fueron más cortos que en el control. Además, la población de tallos, altura y diámetros fueron mayor en este tratamiento. La aplicación de 120 t/ha cenizas de bagazo con aproximadamente 7.97 ± 0.58% de silicio aumentó la resistencia de la variedad susceptible TC4 a la infestación del barrenador del cogollo y el aumento de los rendimientos de caña en 39.89%.
UTILISATION OF THE GREEN MUSCARDINE, *METARHIZIUM ANISOPLIAE*, TO CONTROL THE SUGARCANE LONGHORN STEM BORER *DORYSTHENES BUQUETI GUERIN* (COLEOPTERA: CERAMBYCIDAE)

KEYWORDS: Biological Control, *Metarhizium anisopliae*, Entomopathogen, Sugarcane Longhorn Stem Borer.

Abstract

The green muscardine, *Metarhizium anisopliae* is used to control the sugarcane longhorn stem borer, *Dorysthenes buqueti*, in infested areas of sugarcane fields in Thailand. Fields are treated by dispersing a fresh culture of *M. anisopliae* colonising cooked rice \((2.7\times10^8\) spores/g). Single applications of *M. anisopliae* at the rate of 80 kg/ha were made in three locations at Suphanburi and Kanchanaburi Province in 2008. The effect of green muscardine on the larvae of longhorn borer as well as on sugarcane production was evaluated. The results revealed that, after applying the fungi, the green muscardine killed on average 35.09\(\pm\)8.68\% of the borer larvae in all treated plots and 4.49\(\pm\)1.64\% in all non-treated plots. The highest average percent of infested larvae was 41.67\(\pm\)36.03\% at Rang Sa Ri district, Kanchanaburi Province. The sugarcane production averaged 135.61\(\pm\)4.67 t/ha in treated plots while, in non-treated plots, yields averaged 72.11\(\pm\)10.51 t/ha. These findings indicate that the *M. anisopliae* was an effective biological control agent in controlling sugarcane longhorn stem borer in Thailand.

Introduction

The sugarcane longhorn stem borer, *Dorysthenes buqueti* (Coleoptera: Cerambycidae), is considered as one of the most serious insect pests of sugarcane in many areas of sugarcane production in Thailand (Charernsom and Suasaard, 1994). Infestations frequently cause economic losses. In 1998, in some areas of the North-Eastern and the Eastern region, 100\% of the sugarcane fields surveyed were infested by *D. buqueti*. Outbreaks have now spread to all sugarcane growing areas including the lower Northern and the Central regions of Thailand. Sommartya et al. (2007) reported that all entomopathogenic fungi infecting *D. buqueti* larvae collected from sugarcane fields throughout Thailand were identified as *Metarhizium anisopliae* var. *anisopliae*, Family Monilaceae, Order Moniliales, and Class Deuteromycetes. *M. anisopliae* is considered the most effective natural enemy to control *D. buqueti*. It infects all stages of *D. buqueti* killing 100\% of infected larvae in the laboratory 14 days after inoculation with a suspension of 1x10\(^7\) conidia per mL. In the greenhouse, 80–100\% of larvae were killed within 20 days after application. Attempts to utilise *M. anisopliae* as a biological control agent for controlling insect pests was first recorded in 1879 (Cloy, 1999) and is utilised in the field in many countries such as Trinidad, Grenada, Mexico, Guatemala and Canada (Cloy, 1999; Hernandez-Velazquez et al., 2003; Kabaluk and Ericsson, 2007).

The objective of this study was to evaluate the utilisation of *M. anisopliae* var. *anisopliae* as a biological control agent of sugarcane longhorn stem borer, *D. buqueti* under field conditions in Thailand.
Materials and methods

**Mass production of *M. anisopliae***

*D. buqueti* infected larvae were collected from sugarcane fields from several locations and the pathogen was isolated and identified. A pure culture of *M. anisopliae* was used for initial stock culture. Mass production of *M. anisopliae* was carried out by colonisation of cooked rice at the National Biological Control Research Center (NBCRC) Central Regional Center, Kamphaeng Saen, Nakhon Pathom.

About 3000 kg of fresh culture on cooked rice were produced monthly for application and evaluation in the fields.

**Field application and assessment**

Three test sites each were established in the Rang Ngoen, Pho Ngoen, Suphanburi Province and Rang Sa Ri Districts of Kanchanaburi Province in the central region of Thailand. *D. buqueti* is a serious pest in these areas.

At each site, 2 plots (ca.10 ha) were selected for treated and non-treated (control) *M. anisopliae* plots. Approximately 80 kg of fresh culture of *M. anisopliae* mixed with 1000 kg of biofertiliser (filter cake) was applied per hectare by spreading into the row at planting (Figure 1). Water was applied as furrow irrigation in every plot.

Field assessments were made at two week intervals beginning one month after planting and until harvest of sugarcane. The total number of *D. buqueti* larvae, the number of infected larvae, and the number of infested stalks in one stool were counted and recorded as one sample. Fifty samples were done in each plot.

The yield of sugarcane in each plot was evaluated. These data were used for evaluating the success of *M. anisopliae* to control *D. buqueti*.

**Results and discussion**

**Field assessment of utilization of *M. anisopliae***

Comparisons between percent infested larvae of *D. buqueti* by *M. anisopliae*, percent infested sugarcane stalks by *D. buqueti* and yield of sugarcane in treated and non-treated plots were indexed to evaluate the success in utilizing *M. anisopliae*.

The efficacy of *M. anisopliae* in controlling *D. buqueti* was obvious when the population of *D. buqueti* was evaluated. The population dynamics of *D. buqueti* in treated plots were of a similar pattern at every location.

Populations decreased one month after application of *M. anisopliae* especially in Rang Ngoen and Rang Sa Ri while the population in non-treated plots increased. It was apparent that the population of *D. buqueti* in treated plots was lower than those in nontreated plots at every location as shown in Figure 2.
Fig. 2—Population of sugarcane longhorn stem borer, *Dorysthenes buqueti* in the treated and non-treated plots of the green muscardine, *Metarhizium anisopliae* plots at Rang Ngoen, Pho Ngoen and Rang Sa Ri districts in 2008.

The percent infected larvae of *D. buqueti* in treated and non-treated plots at every location were evaluated and results are illustrated in Figure 3.

The figure shows that the percent of infected larvae in treated plots was clearly higher than those in non-treated plots during the investigation period March to September 2008 at every location. Infected larvae of *D. buqueti* in treated plots increased after application of *M. anisopliae*, while the infested larvae in non-treated plots did not increase. The highest percent infested larvae was 100% in treated plots at Rang Sa Ri district, Kanchanaburi Province.
Fig. 3—Percent infected larvae of sugarcane longhorn stem borer, *Dorysthenes buqueti* by the green mascardine, *Metarhizium anisopliae* in treated and non-treated plots at Rang Ngoen, Pho Ngoen and Rang Sa Ri districts in 2008.

The average percent infested larvae of *D. buqueti* in treated/non-treated plots at Rang Ngoen and Pho Ngoen, Suphanburi Province were 38.63/6.13 and 25.25/2.86.

In Rang Sa Ri, Kanchanaburi Province these values were 41.67 and 4.49 for treated and non-treated plots respectively.

The average percent infested larvae in treated plots was significantly different from those in non-treated plots at every location as shown in Table 1 and Figure 4. *M. anisopliae* killed on average 35.09±8.68% of the larvae of *D. buqueti* in all treated plots and 4.49±1.64% in all non-treated plots.
Table 1—Average percent infected larvae of sugarcane longhorn stem borer, *Dorysthenes buqueti* by the green mascaline, *Metarhizium anisopliae* in treated and non-treated plots at Rang Ngoen, Pho Ngoen and Rang Sa Ri districts in 2008.

Means followed by different letter were significantly different at the 95% probability level.

Yield evaluation from treated and non-treated plots confirms the success of *M. anisopliae* in controlling *D. buqueti*. The yields of sugarcane in treated and non-treated plots from all locations are shown in Table 2. It clear that the yield in treated plots was higher than those in non-treated plots and that these differences were significant at every location. The average yield in all treated plots was 135.6 t/ha while, in all non treated plots, was 72.1 t/ha. The highest yield was 146.3 t/ha at Pho Ngoen district, Suphanburi Province as illustrated in Figure 5. Although the average yields in all treated plots were higher than in non-treated plots, these were still lower than the average yield in the areas not damaged by *D. buqueti*. These findings suggest that further studies in the development of formulations and application of *M. anisopliae*, including identifying important environmental factors affecting the system, are necessary.

**Fig. 5**—Yield of sugarcane in treated and non-treated plots at Rang Ngoen, Pho Ngoen and Rang Sa Ri districts and average yield in all treated and all non-treated plots in every location in 2008.

**Conclusions**

The application of 80 kg fresh culture of the green muscardine, *M. anisopliae*, mixed with 1000 kg of biofertiliser per hectare during planting of sugarcane will provide effective control of the sugarcane longhorn stem borer, *D. buqueti*. The high numbers of infected larvae of *D. buqueti* and the higher yields of sugarcane in treated plots than in non-treated plots show the efficiency of *M. anisopliae* in controlling *D. buqueti* in Thailand sugarcane fields.

Résumé

La muscardine verte, *Metarhizium anisopliae* est utilisée dans la lutte contre le longicorne foreur de tige, *Dorysthenes buqueti*, dans les zones de canne à sucre infestées en Thaïlande. Les champs ont été traités en dispersant une culture de *M. anisopliae* (2.7 × 10^8 spores/g) nouvellement préparée sur le riz cuit. Une seule application de *M. anisopliae* au taux de 80 kg/ha a été faite sur trois sites à Suphanburi et dans la province de Kanchanaburi en 2008. L’effet de la muscardine verte sur les larves du longicorne foreur de tige et sur le rendement de canne a été évalué. Les résultats ont montré que l’application du champignon tuait en moyenne 35.09±8.68% des larves du foreur dans toutes les parcelles traitées et 4.49±1.64% dans toutes les parcelles non-traitées. La moyenne la plus élevée de larves infestées était de 41.67±36.03% au district de Rang Sa Ri, dans la province de Kanchanaburi. Le rendement de canne était en moyenne de 135.61±4.67 t/ha dans les parcelles traitées, alors que celui des parcelles non-traitées était en moyenne de 72.11±10.51 t/ha. Cette étude démontre que *M. anisopliae* est un agent efficace de lutte biologique contre le longicorne foreur de tige en Thaïlande.

Palabras clave: Control Biológico, *Metarhizium anisopliae*, Hongos Entomopatógenos, Barrenador del Tallo de Antenas Largas de la Caña de Azúcar.

Resumen

La muscardina verde, *Metarhizium anisopliae* se utiliza en el control del barrenador de antenas largas del tallo, *Dorysthenes buqueti*, en áreas infestadas de cultivos de caña de azúcar en Tailandia. Los campos se trataron asperjando cultivos frescos de *M. anisopliae* cultivado en un sustrato de arroz cocido (2.7 × 10⁸ esporas/g). Una sola aplicación de *M. anisopliae* en la dosis de 80 kg/ha se hizo en tres localidades en las Provincias de Suphanburi y Kanchanaburi en 2008. Se evaluó el efecto del hongo sobre las larvas del barrenador, así como la producción de caña de azúcar. Los resultados mostraron que, después de la aplicación del hongo, este mató en promedio 35.09±8.68% de las larvas del barrenador en todas las parcelas tratadas, observándose una mortalidad de 4.49±1.64% en las parcelas no tratadas. El porcentaje más alto de infestación por las larvas fue de 41.67±36.03%, en el distrito de Rang a Ri, de la Provincia Kanchanaburi. El promedio de producción de la caña de azúcar fue de 135.61±4.67 t/ha en las parcelas tratadas, mientras que en las parcelas no tratadas, la producción promedia fue 72.11±10.51 t/ha. Estos resultados indican que *M. anisopliae* fue un controlador biológico efectivo en el control de este barrenador de la caña de azúcar en Tailandia.
POTENTIAL IMPACT OF MEXICAN RICE BORER NON-CROP HOSTS ON SUGARCANE IPM

KEYWORDS: Eoreuma loftini (Dyar), Integrated Pest Management, Alternate Hosts.

Abstract

The Mexican rice borer, Eoreuma loftini (Dyar) (Lepidoptera: Crambidae), was detected in Louisiana in 2008, having first spread from Mexico into Texas. E. loftini is a severe pest of sugarcane, but it also feeds on rice and a wide range of other grasses. Research on E. loftini management has focused on studying the pest in its main crop host plants, with the role of non-crop grasses only recently studied. Two four-replication sentinel plant studies were conducted in 2006 and 2007 to assess naturally occurring E. loftini infestations in five selected weed species: Leptochloa panicoides, Sorghum halepense, Paspalum urvillei, Urochloa platyphylla and Echinochloa crus-galli. Results showed that L. panicoides, a common weed in Louisiana rice fields, was a highly suitable host, harbouring the highest E. loftini infestations with as many as 78% of the plants infested with at least one larva. In addition, S. halepense and P. urvillei, two ubiquitous perennial grasses, also supported complete larval development of E. loftini. On the other hand, both U. platyphylla and E. crus-galli, which are two common weeds in and near rice fields in Louisiana, proved to be poor E. loftini host plants. Continuous pheromone trapping in the southeast Texas rice area showed that adult moths are active throughout the year. Our studies showed that non-crop hosts could play a key role in E. loftini population build-up, thus warranting a better characterisation of E. loftini source-sink interactions in Louisiana sugarcane producing areas. The manipulation of E. loftini non-crop sources has the potential to decrease a significant proportion of area-wide populations, minimising damaging infestations in sugarcane fields.

Introduction

The Mexican rice borer, Eoreuma loftini (Dyar) (Lepidoptera: Crambidae), is indigenous to Mexico and was first reported in 1980 in south Texas (Johnson, 1984). This borer quickly became the most damaging insect pest of sugarcane (Saccharum spp. hybrids) in the Lower Rio Grande Valley of Texas, where it represents more than 95% of stem borer infestations (Legaspi et al., 1997). After expanding its range in a northeast direction along the Gulf Coast (Reay-Jones et al., 2007b), E. loftini has also become an increasing problem for rice (Oryza sativa) production in southeast Texas. E. loftini was detected in Louisiana for the first time in December 2008 (Hummel et al., 2008), representing a serious threat to the state’s sugarcane and rice industries. The imminent establishment of E. loftini in Louisiana sugarcane producing areas encouraged proactive studies that integrate cultivar resistance, biorational insecticides, and irrigation-based population suppression to develop an effective management program (Reay-Jones et al., 2005). Insecticides and cultivar
resistance have also been studied in rice, which is also grown in sugarcane areas of Louisiana. In addition to crop hosts, Van Zwalunwenburg (1926) stated that *E. loftini* ‘attacks practically all the grasses large enough to afford it shelter within the stalk’. Non-crop grasses may therefore play a role in the overwintering and build-up of *E. loftini* populations, and should be integrated into the development of new cultural practices for an improved pest management program. This paper reports on initial studies with *E. loftini* non-crop hosts and discusses their possible importance in future sugarcane integrated pest management (IPM) for Louisiana.

**Material and methods**

**Sentinel plant experiments**

Two sentinel plant experiments were designed to compare *E. loftini* infestation development on selected non-crop grass species under natural infestations. Experiments were conducted in southeast Texas during 2006 and 2007 near Ganado (N 29.0267°, W 96.4394°) and Hankamer (N 29.8554°, W 94.5451°), respectively, where *E. loftini* populations naturally occur at high densities.

Five weed species that are abundant in or near sugarcane and rice fields and have the potential to host *E. loftini* populations were studied (Table 1). Rice (cultivar Cocodrie) served as a control. Seeds were obtained from Azlin Seed Service (Leland, MS), except for *Paspalum urvillei* seeds that were collected in Lafayette Parish, LA. Plants were grown in a greenhouse in 7.57 L pots, each containing eight (2006) or six (2007) evenly spaced plants. In mid-August, after growing for two months under greenhouse conditions, the potted plants were placed in a rice field near a levee. For each plant species, six pots constituted a plot, and plots were arranged in a randomised complete block design with four blocks (1 replication per block). Plots were separated by 75 cm (2006) or 2 m (2007) spaces. Plants remained in the pots, but pot bottoms were removed to facilitate better equalisation with field moisture conditions.

In 2006, ten plants from each plot were randomly selected and cut at the base both four and nine weeks after transplanting. In 2007, 12 plants were sampled both four and seven weeks after transplanting. Each tiller was measured and the number of leaves counted. Plants were observed for borer feeding signs and dissected for the presence of larvae and pupae.

Statistical analyses were performed using Proc GLIMMIX (SAS Institute, 2008). Generalised linear mixed models (GLMMs) with an over-dispersion parameter were used to analyse the proportion of plants infested with *E. loftini* (binomial distribution) and *E. loftini* abundance as affected by plant species (Poisson distribution). Because sugarcane borers, *Diatraea saccharalis* (F.), also infested sentinel plants in 2006, a GLMM with a binomial distribution was used to compare borer species composition as affected by the plant species. The Kenward-Roger adjustment for denominator degrees of freedom was used in all models to correct for inexact *F* distributions.

**Adult pheromone trapping**

Male *E. loftini* moths were continuously monitored to determine seasonal patterns of flight activity. From April 2007 to April 2009, monitoring was conducted at three sites in southeast Texas. Two standard universal pheromone traps were used at each site according to the method of Reay-Jones *et al.* (2007b). Traps were located near the Texas AgriLIFE Research Center at Beaumont (N 30.0672°, W 94.2932°), and near Hankamer and Ganado where the two sentinel plant experiments were conducted. Traps were checked for *E. loftini* moths every two-to-three weeks, and trap catches were estimated on a daily basis for each sampling period (Reay-Jones *et al.*, 2007b).

**Results**

**Sentinel plant experiments**

The five grass weed species used as sentinel plants presented a diverse range of height, number of tillers, and leaf availability (Table 1). In 2006, four weeks after transplanting to the field, rice, *S. halepense*, *E. crus-galli*, and *U. platyphylla* were either heading or showing maturing
flowerheads, whereas \textit{L. panicoides} was senescent. \textit{P. urvillei}, which had a slow germination rate, was still in a vegetative stage. Nine weeks after transplanting, \textit{L. panicoides}, \textit{E. crus-galli}, and \textit{U. platyphylla}, all three annual grasses, had completed their life cycles and had died. Rice was senescent whereas \textit{S. halepense} and \textit{P. urvillei}, two perennial grasses, showed a mixture of senescent and maturing leaf and stem tissues.

\hline
\textbf{} & \textbf{Oryza sativa} & \textbf{Sorghum halepense} & \textbf{Paspalum urvillei} & \textbf{Leptochloa panicoides} & \textbf{Echinochloa crus-galli} & \textbf{Urochloa platyphylla} \\
\hline
\textbf{Height (cm)} & 63.4 & 38.5 & 97.4 & 75.0 & 27.3 & 37.2 & 53.8 & – & 85.9 & – & 54.3 & – \\
\hline
\textbf{No. tillers / plant} & 1.8 & 3.2 & 1.7 & 1.3 & 2.6 & 5.5 & 1.5 & – & 1.9 & – & 3.3 & – \\
\hline
\textbf{No. total leaves / plant} & 9.9 & 10.2 & 10.3 & 3.4 & 10.2 & 18.3 & 9.5 & – & 12.7 & – & 22.2 & – \\
\hline
\textbf{No. green leaves / plant} & 5.1 & 6.4 & 5.4 & 2.6 & 9.0 & 12.9 & 1.9 & – & 4.9 & – & 7.4 & – \\
\hline
\end{tabular}
\end{table}

Each grass species harboured at least some stage of \textit{E. loftini} larvae. In addition, the grasses also harboured \textit{D. saccharalis} larvae. Depending on the grass species, \textit{E. loftini} represented 48% to 73% and 74% to 93% of the recovered borers after four and nine weeks, respectively. However, the proportion of \textit{E. loftini} versus \textit{D. saccharalis} was not affected by the grass species ($F= 0.37; df= 5, 12.25; P= 0.857$ after 4 weeks and $F= 0.66; df= 2, 4.615; P= 0.558$ after 9 weeks). After four weeks under natural infestations, there were differences in the proportion of plants infested with \textit{E. loftini} ($F= 3.94; df= 5, 15; P= 0.018$) and the number of \textit{E. loftini} per plant ($F= 3.45; df= 5, 18; P= 0.023$) as affected by the plant species. \textit{L. panicoides} was numerically the most infested species (Figures 1 and 2). \textit{E. loftini} fourth and larger instars represented 61.5% (LS mean) of the recovered immatures. \textit{E. loftini} pupae and pupal casings, indicating completion of life cycle, represented 19.8% (LS mean) of the fourth instars and larger immatures, hereafter referred to as late instars. Infestations in rice and \textit{S. halepense} were not different from \textit{L. panicoides} although numerically trending lower. \textit{E. loftini} late instars represented 19.4% and 5.6% (LS means) of the immatures recovered in rice and \textit{S. halepense}, respectively, with no pupae observed. \textit{U. platyphylla} harboured less infestation compared to \textit{L. panicoides}, but was not different from the other grasses. \textit{E. loftini} late instars represented 25% (LS mean) of the immatures recovered from \textit{U. platyphylla}, with one pupa observed. However, this pupa was in a folded flag leaf, suggesting that the original larvae possibly came from another plant. \textit{E. crus-galli} and \textit{P. urvillei} harboured the lowest \textit{E. loftini} infestations (Figures 1 and 2). Pupae were not found in \textit{E. crus-galli}, however; 12.5% (LS mean) of the recovered immatures were late instars. No late instars were recovered from \textit{P. urvillei}. Five weeks later, there were trends ($F= 2.62; df= 2, 9; P= 0.127$) for a greater proportion of \textit{E. loftini} infested rice plants, in comparison to \textit{S. halepense} and \textit{P. urvillei} plants (Figure 1). When considering the overall number of \textit{E. loftini} per plant, rice also showed a strong trend ($F= 5.00; df= 2, 5.711; P= 0.056$) for greater borer densities (Figure 2). In rice, \textit{S. halepense}, and \textit{P. urvillei} pupae
and pupal casings represented respectively 60.4%, 22.5%, and 12.5% (LS means) of the recovered *E. loftini*, indicating completion of the life cycle.

In 2007, four weeks after transplanting to the field, all plants were either heading or had maturing flowerheads. Seven weeks after transplanting, all plants exhibited maturing flowerheads, except *L. panicoides*, which was senescent. Almost exclusively, *E. loftini* infested the sentinel plants. However, three *D. saccharalis* larvae were recovered from *L. panicoides* plants collected from the same plot. All grasses except *U. platyphylla* were infested with *E. loftini* (Figures 1 and 2). The proportion of plants infested after four weeks (*F* = 10.40; df = 5, 15.06; *P* < 0.001) and seven weeks (*F* = 8.83; df = 5, 18; *P* < 0.001) changed with the plant species, as well as the number of *E. loftini* per plant (*F* = 2.061; df = 5, 14.82; *P* = 0.001 after 4 weeks and *F* = 15.02; df = 5, 18; *P* < 0.001 after 7 weeks). *L. panicoides* harboured the highest *E. loftini* infestations (Figure 1 and 2).

Late instars were found only in *L. panicoides*, representing 25% (LS mean) of the larvae collected. No pupae were recovered after four weeks in the field. Three weeks later, the late instars observed in *L. panicoides*, rice, *E. crus-galli*, and *P. urvillei* represented 59.1%, 31.3%, 10% and
6.3% (LS means) of the recovered *E. loftini*. Only *L. panicoides* and rice had allowed completion of *E. loftini* life cycle, with five and one pupae or pupal casings recovered, respectively representing 13.8% and 8.3% of the *E. loftini* late instars found in each grass.

**Adult pheromone trapping**

Pheromone trapping showed that moth flight activity reached its peak between September and November while it was at a minimum between December and February (Figure 3). The highest *E. loftini* moth numbers were caught from the Hankamer site with 72.9 moths/trap/day for the November 2, 2008 sampling period.

---

**Fig. 3**—Male *E. loftini* pheromone trap catches estimated on a daily basis near Beaumont (a), Hankamer (b), and Ganado (c), Texas, April 2007–April 2009.
An early spring flight activity peak was recorded at the three trapping sites in March 2009. For the March 16 sampling period, 25.8 moths/trap/day were collected near Beaumont. For the Hankamer and Ganado sites, trap catches were 27.2 moths/trap/day for the March 22 period and 23.6 moths/trap/day for the March 7 period, respectively.

At the Beaumont site, *E. loftini* moths were not caught over more than two subsequent samplings from December 23, 2007 to March 10, 2008. At the Hankamer site, *E. loftini* moths were not caught over more than two subsequent samplings from January 21, 2008 to February 11, 2008. During the winter from 2008 to 2009, there were no two subsequent dates with zero catches at the Beaumont and Hankamer sites. Further south near Ganado, although trap catches were reduced somewhat in December and January, *E. loftini* moths were active all year long with no two subsequent dates of zero catches.

**Discussion**

The impacts on arthropod population dynamics of non-crop plants occurring in an agroecosystem are complex and far from following a general principle (Norris and Kogan, 2005). Non-crop plants may offer shelter for predators, and both shelter and food for their prey, increasing natural enemy density and subsequently decreasing pest populations (Letourneau, 1987; Russell, 1989). Conversely, non-crop plants may also serve as hosts and emit host-finding stimuli for crop pests, increasing pest populations (Karban, 1997, Tindall *et al.*, 2004). Our sentinel plant experiments showed that non-crop grasses could host *E. loftini*. Additional sampling of non-crop habitats near southeast Texas rice fields in February yielded *E. loftini* densities attaining as many as four immatures per m² (JMB, data not shown).

A plant is a host if both herbivore feeding and completion of the herbivore life cycle occur. *L. panicoides*, a weed in Louisiana rice fields, is a highly suitable host. Because *D. saccharalis* injury to rice is higher in plots surrounded by *L. panicoides* (Tindall, 2004), this grass may also enhance *E. loftini* infestations in surrounding areas. With no strong evidence of *E. loftini* completing its life cycle in *U. platyphylla* and *E. crus-galli*, two common weeds in and near rice fields, the contribution of these grasses to *E. loftini* population pressure seems small. Plant morphological (e.g., pubescence, stem hardness and diameter, abundance of dry leaves) and biochemical (e.g., primary metabolites, allelochemicals) factors affect stem borer oviposition preference and larval performance (Martin *et al.*, 1975, Sosa, 1990, Meagher *et al.*, 1996, Reay-Jones *et al.*, 2007a). Among other factors, the relatively smaller stem diameter of *U. platyphylla* and *E. crus-galli* likely contributes to the lack of suitability as a host for *E. loftini*.

Plant availability over time also plays a major role in the use of non-crop grasses as hosts by *E. loftini*. *S. halepense*, a ubiquitous grass in weedy areas and sugarcane fields, was infested with *E. loftini* in both sentinel plant experiments and winter samplings of non-crop habitats (JMB, data not shown). With all borer life stages recovered and infestations not differing from those in rice in the sentinel plant experiments, *S. halepense* is certainly a primary non-crop host. Bynum *et al.* (1938) concluded that if not mowed often, *S. halepense* could provide overwintering shelter for *D. saccharalis* and would be a source for spring infestations in Louisiana sugarcane. Another common perennial grass in weedy areas, *P. urvillei*, was heavily infested in samplings of non-crop habitats during the winter (JMB, data not shown), whereas not particularly infested in the sentinel plant experiments. From these observations, *P. urvillei* may not be a preferred host although suitable. *P. urvillei* plants grow large over the years and offer green material during the winter when other grasses are dry or too small (e.g., *S. halepense*). Despite reduced numbers during the winter, *E. loftini* adults fly during any season. The difference in plant availability may therefore explain *E. loftini* aggregation in *P. urvillei* plants during the winter; hence, *P. urvillei* is certainly a primary non-crop host.

Our studies were conducted in southeast Texas agroecosystems where rice is a dominant crop. Results suggest that non-crop hosts could play a role in *E. loftini* population dynamics. Weeds
differ in their life cycles (annual vs. perennial), timing of seasonal development, and habitat (crop fields vs. crop field margins, roadsides, ditches, or canal banks). Thus, the relative importance of each non-crop host species may change with time of the year, geographical area, and the dominant crop. The manipulation of *E. loftini* non-crop sources may decrease a significant proportion of area-wide populations, decreasing infestations in sugarcane fields. Thus, our studies warrant a better characterisation of the influence of non-crop hosts as *E. loftini* sources in Louisiana sugarcane. Ongoing research includes periodical non-crop habitat sampling and *E. loftini* oviposition preference and larval performance studies. Our ultimate goal is to incorporate findings from studies reported in this paper and ongoing research into a model that will simulate different weed management strategies (e.g., mowing, biorational insecticide applications) and predict their impact on *E. loftini* area-wide populations, thereby improving the overall sugarcane area IPM.

Résumé

APRÈS avoir envahi le Texas à partir du Mexique, le foreur des tiges Eoreuma loftini (Dyar) a été détecté en Louisiane en 2008. *E. loftini* est un sérieux ravageur de la canne à sucre, mais il attaque aussi de nombreuses autres graminées. La recherche pour lutter contre ce ravageur s’est concentrée sur les insectes attaquant les plantes cultivées, le rôle des infestations dans les mauvaises herbes n’ayant été que récemment étudié. Une étude de deux ans a déterminé les infestations d’*E. loftini* sur cinq graminées non cultivées: *Leptochloa panicoides*, *Sorghum halepense*, *Paspalum urvillei*, *Urochloa platyphylla* et *Echinochloa crus-galli*. *L. panicoides*, une mauvaise herbe dans les rizières en Louisiane, est une plante hôte très adéquate, abritant les infestations les plus élevées avec jusqu’à 78% des plantes infestées avec au moins une larve. Avec *L. panicoides*, *S. halepense* et *P. urvillei*, deux herbes pérennes, étaient les seules à permettre la complétion du cycle biologique de l’insecte. *U. platyphylla* et *E. crus-galli*, deux mauvaises herbes communes dans les rizières et leurs alentours, étaient des hôtes peu adéquats. Le piégeage à l’aide de phéromones a montré que les adultes volent tout au long des saisons. Ces études menées au sud-est du Texas ont montré que les graminées non cultivées pourraient jouer un rôle dans la croissance des populations d’*E. loftini*, justifiant une meilleure caractérisation de ce rôle dans les zones cannières de Louisiane. La manipulation des hôtes non cultivés a le potentiel de diminuer les populations du foreur, minimisant les infestations qui endommagent les champs de canne à sucre.
IMPACTO POTENCIAL DEL BARRENADOR MEXICANO DEL ARROZ EN HOSPEDANTES ALTERNOS EN UN MIP DE CAÑA DE AZUCAR

PALABRAS CLAVE: \textit{Eoreuma loftini} (Dyar), Manejo Integrado de Plagas, Hospedantes Alternos.

Resumen

El barrenador mexicano del arroz, \textit{Eoreuma loftini} (Dyar) (Lepidoptera: Crambidae), se detectó en Luisiana en 2008, siendo la primera vez que se dispersa de México a Texas. \textit{E. loftini} es una plaga muy seria de la caña de azúcar, pero también se alimenta de arroz y otra serie de gramíneas. La investigación sobre el manejo de \textit{E. loftini} se ha concentrado en el estudio de la plaga en su principal hospedante y solo recientemente se ha puesto interés en el papel que juegan los pastos no cultivados. Dos estudios con plantas centinelas con cuatro repeticiones se condujeron en 2006 y 2007 para evaluar la ocurrencia natural de infestaciones de \textit{E. loftini} en cinco especies de malezas, \textit{Leptochloa panicoides}, \textit{Sorghum halepense}, \textit{Paspalum urvillei}, \textit{Urochloa platyphylla} y \textit{Echinochloa crus-galli}. Los resultados mostraron que \textit{L. panicoides}, una maleza común en campos de arroz de Luisiana, fue un hospedante muy apropiado, albergando las infestaciones más altas de \textit{E. loftini}, llegando hasta un 78\% de las plantas con al menos una larva. Además, \textit{S. halepense} y \textit{P. urvillei}, dos gramíneas perennes muy ubicuotas, también soportaron el desarrollo completo larval de \textit{E. loftini}. Por otra parte, tanto \textit{U. platyphylla} como \textit{E. crus-galli}, que son malezas comunes en y cerca de campos de arroz en Luisiana, probaron ser muy pobres como plantas hospedantes de \textit{E. loftini}. Un trampeo continuo con feromonas en el sureste del área arrocera de Texas mostró que las polillas adultas se mantienen activas a través del año. Nuestros estudios mostraron que plantas no cultivadas pueden jugar un papel muy importante en el incremento de las poblaciones de \textit{E. loftini}, proporcionando así un mejor conocimiento sobre la fuente de \textit{E. loftini} en las interacciones con las áreas productoras de caña de azúcar en Luisiana. La manipulación de las plantas no cultivadas que albergan poblaciones de \textit{E. loftini} tiene un potencial para disminuir en proporción significativa las poblaciones, minimizando así las infestaciones que dañen los campos de caña de azúcar.

KEYWORDS: Sugarcane Borer, Spittlebug, Insect-Plant Relationship, Yield.

Abstract

The sugarcane borer (*Diatraea saccharalis*) and spittlebug (*Mahanarva fimbriolata*) are considered important sugarcane pests in South America. Damage caused by these pests has already been studied for each species separately; however, knowledge of sugarcane’s response to attack by these two pests combined as well as the effect on sugarcane yield has not. The aim of this work was to evaluate the plant response to infestations of these two biotic stressors. Treatments comprised high and low sugarcane borer infestations, spittlebug infestation, both sugarcane borer and spittlebug infestations combined, and controls (uninfested plants). Plots comprised 2 m² caged and uncaged sugarcane stalks. Damage attributed to spittlebug nymph attack alone, or in combination with borer attack, decreased the diameter of the stalks. When compared to the control (caged stalks), such damage resulted in a significant reduction in yield: (17.6%) from stalks that were attacked by spittlebug nymphs alone; (15.5%) from spittlebug nymphs + sugarcane borer combined and (6.9%) from sugarcane borer alone. There was no significant difference among the treatments in levels of soluble solids and apparent sucrose. However, when evaluating the sucrose yield per unit area, spittlebugs did affect sugar production (individually and in combination with the borer). Therefore, infestation by these pests does lead to yield reduction in the sugarcane crop.

Introduction

The sugarcane borer, *Diatraea saccharalis* (Fabricius, 1794) (Lepidoptera: Crambidae), is a key pest of sugarcane and occurs in several countries of the Americas, including Brazil where it is distributed in all producing regions (Gagliumi, 1973; White et al., 2008). Also, due to the increase of mechanical harvest (green cane) and decrease of traditional system (burned cane), the trash layer that is kept on the soil surface has brought changes in environmental characteristics within the sugarcane habitat. These changes have favoured an increase in populations of the spittlebug *Mahanarva fimbriolata* (Stål, 1854) (Hemiptera: Cercopidae), a native pest which is now also considered a key pest of sugarcane in Brazil (Dinardo-Miranda et al., 2001; Mendonça et al., 1996).

In spite of the importance of the two sugarcane pests and their simultaneous occurrence, mainly during the rainy season, there is no information on how sugarcane responds to these pests combined (biotic stress). Current information on plant-insect response aiming at implementing
economic thresholds is usually from infestations where only one pest was present or where one pest was kept under control (White et al., 2008; Madaleno et al., 2008).

According to Peterson and Higley (2001), stress interactions represent the potential relationships among different agents that produce stress in a plant. Thus, the knowledge of infested plant response by two pests combined (e.g.: spittlebug and sugarcane borer) can be an important tool for decision making. Therefore, the aim of this work was to evaluate the sugarcane plant response where both biotic stressors were present.

**Material and methods**

The experiment was carried out in the São Martinho Sugar Mill, located in São Paulo State, Brazil, (21º19’S and 48º06’W), from December 2007 to October 2008. The variety selected was SP80-3280 (4th ratoon), which is susceptible to spittlebug and sugarcane borer (Dinardo-Miranda, 2003).

The trial was a randomised complete block design with six treatments and four replications. Each plot comprised a 2 m row of sugarcane. Plots were individually protected using a cage structure surrounded by voile fabric to prevent insect movement, except the unprotected control (check). However, when the cages were placed over the plants (72 days after harvest), stalks already bored by sugarcane borer were noticed. Thus, plants were naturally infested. Pests were monitored on every stalk at 2 to 3-day intervals.

Treatments comprised single or combined infestations of spittlebug and sugarcane borer at different levels of Infestation Intensity (I.I.) as follows: high sugarcane borer infestation (I.I.: 15.80%), low sugarcane borer infestation (I.I.: 2.75%), spittlebug nymph infestation (3.07 nymphs/m), both sugarcane borer and spittlebug nymph infestation (I.I.: 13.63% and 2.95 nymphs/m), caged control (I.I.: 0.12% and 0.60 nymphs/m) and unprotected control (check). In spite of an effort to have no spittlebug infestation on sugarcane borer only infested plots, a very low infestation was observed (0.64 nymphs/m). This was attributed to the resident soil population of this pest. Similarly, plots that should have only spittlebug infestations, were also infested by sugarcane borer before cage placement. However, infestation levels were also very low (II: 3.07%).

The stalks were manually harvested around three hundred days after ratoon emergence (nine months after the infestation started). All stalks (n=25) were taken from each plot and their weight, length, and diameter recorded. Stalks were then shredded and juice extracted using a hydraulic press, as suggested by Tanimoto (1964). Immediately after the extraction, the level of soluble solids (Brix) and the apparent sucrose (Pol) were determined according to Scheneider (1979). The sucrose yield per area was estimated using the sucrose content (Pol) and the stalk yield.

Data were analysed (Anova) and means compared using LSD (P = 0.05).

**Results and discussion**

Spittlebug injury negatively affected (F=3.27, P=0.034) the diameter of stalks (Table 1). The stalks infested by spittlebugs, either individually or in combination with the sugarcane borer, were significantly shorter and thinner than non-infested stalks. Feeding by spittlebug nymphs results in plant dehydration, lower nutrition, and possibly plant death (Dinardo-Miranda, 2003).

As the spittlebug affected stalk characteristics, yield was significantly lower (F=3.45, P=0.0284) than yield from non-infested stalks. This was also noted for stalks infested by spittlebugs alone or infested by both spittlebugs and sugarcane borer. On the other hand, stalks infested only by sugarcane borer did not show a significant reduction in stalk yield, compared to the controls (protected and unprotected stalks). The stalk yield losses due to borer infestation is 1.14% per each 1% of infestation intensity (CTC, 2007).

In spite of different pest infestations, all caged plants had similar levels of Brix; however, uncaged plants had significantly higher Brix than caged plants (F=10.64, P=0.0002). However, the
apparent sucrose content (Pol) varied among treatments (F=14.66, P<0.0001). The lowest Pol level was observed in stalks infested by both pests and was 8.37% lower than the level noted in non-infested uncaged stalks.

Means within a column indicated by different letters are significantly different (LSD test, P<0.05).

Pol was not significantly different between stalks infested by either pest separately. Stalks infested by spittlebug, either individually or combined with the sugarcane borer, resulted in a lower sucrose yield per unit area than stalks without any pest infestation (F = 4.86, P = 0.0077). Spittlebug infestation caused a 15.14% to 16.65% reduction in sucrose yield per hectare.

Overall, plants infested by spittlebug, either associated with or without the sugarcane borer, were severely damaged. On the other hand, the sugarcane borer did not seem to affect the yield. However, the sucrose yield was affected and may be related to the influence of fungi (*Colletotrichum* and *Fusarium* spp.) associated with the sugarcane borer and different infestation levels. Severe infestations of the sugarcane borer result in longer galleries in the stalk, and a greater likelihood of fungal occurrence. These fungi are responsible for sucrose inversion and production of metabolite inhibitors (McGuire *et al.*, 1965; Stupiello & Moraes, 1974; Blumer, 1992) which can lead to even greater yield reductions. Technological parameters such as sugar production and quality should also be evaluated. This information will be very important to enhance the current threshold levels adopted to control these pests in Brazil.

**MOTS CLÉS: Foreur de la Canne, Cicadelle Ecumeuse, Relation Plante-Insecte, Rendement.**

**Résumé**

Le foreur de la tige (*Diatraea saccharalis*) et la cicadelle écumeuse (*Mahanarva fimbriolata*) sont considérés comme les ravageurs majeurs de la canne à sucre en Amérique du Sud. Les dégâts causés ont déjà été étudiés séparément pour les deux espèces. Toutefois, nos connaissances sur la réaction de la canne à sucre à l’infestation simultanée par ces deux ravageurs et leur effet sur le rendement ne sont pas connues. L’objectif de cette étude a été d’évaluer la réponse de la canne à l’infestation de ces deux bioagresseurs. Les traitements comprenaient les niveaux faibles et élevés d’infestation du foreur, l’infestation par la cicadelle écumeuse, une combinaison des infestations de ces deux bioagresseurs, et un témoin (plantes non-infestées). Les parcelles comportaient des tiges...
de canne sur 2 m², encagées et non-encagées. Les dégâts attribués uniquement aux nymphes de la cicadelle écumeuse ou en combinaison avec une attaque du foreur, ont occasionné une réduction du diamètre de la tige. Par rapport au témoin (tiges encagées), ces dégâts ont eu un effet significatif sur le rendement avec les résultats suivants: tiges attaquées par les nymphes de la cicadelle écumeuse : 17.6%, effets combinés des nymphes de la cicadelle écumeuse + foreur de la tige: 15.5% et foreur de la tige seulement: 6.9%. Aucune différence parmi les traitements n’a été observée au niveau des sucres solubles et du saccharose apparent. Toutefois, la cicadelle écumeuse a significativement affecté le rendement en sucre par unité de surface (seul ou en combinaison avec le foreur). Par conséquent, l’infestation due à ces deux ravageurs peut affecter le rendement de la canne à sucre.

LA RESPUESTA DE LA CAÑA DE AZÚCAR A DOS FACTORES DE ESTRÉS BIÓTICO: DIATRAEA SACCHARALIS Y MAHANARVA FIMBRIOLATA

Resumen

El barrenador de la caña de azúcar (Diatraea saccharalis) y salivazo (Mahanarva fimbriolata) son considerados plagas importantes de la caña de azúcar en América del Sur. Los daños causados por estas plagas ya ha sido estudiado para cada especie por separado, sin embargo, el conocimiento de la respuesta a los ataques de estas dos plagas en forma combinada, así como el efecto sobre la producción en la caña de azúcar no se tienen resultados. El objetivo de este trabajo fue evaluar la respuesta de la planta a las infestaciones de estos dos factores de estrés biótico. Los tratamientos comprendieron altas y bajas infestaciones del barrenador de la caña de azúcar y del salivazo, solos y como combinados y los controles (plantas no infestadas). Las parcelas comprendieron tallos en jaulas de 2 m² y tallos sin enjaular. El daño atribuido al ataque de las ninfas de salivazo, solo o en combinación con el ataque del barrenador, disminuyó el diámetro de los tallos. Cuando se compararon estos resultados con el control (tallos en jaulas), los daños ocasionaron disminuciones significativas de la producción: (17.6%), cuando los tallos fueron atacados únicamente por las ninfas del salivazo; (15.5%) cuando las ninfas de salivazo y barrenador de la caña de azúcar en combinado y (6.9%) cuando fue solo el barrenador de la caña de azúcar. No hubo diferencias significativas entre los tratamientos en los niveles de sólidos solubles y sacarosa aparente. Sin embargo, al evaluar la producción de sacarosa por unidad de área, se encontró que el salivazo afectó la producción de azúcar (individualmente y en combinación con el barrenador). Por tanto, la infestación por estas plagas se traduce en la reducción de productividad en el cultivo de caña de azúcar.
A NUTRITIONAL PERSPECTIVE OF SUGARCANE RESISTANCE TO STALK BORERS AND SAP FEEDERS

KEYWORDS: Eoreuma loftini, Melanaphis sacchari, Saccharum spp., Free Amino Acids, Cultivar Resistance.

Abstract

TWO RELATIVELY new key species in Louisiana that conform to the plant stress hypothesis are the Mexican rice borer, Eoreuma loftini (Dyar) and the sugarcane aphid, Melanaphis sacchari (Zehntner). High performance liquid chromatography differentiated insect resistant and susceptible sugarcane cultivars based on nutritional profiles involving free amino acids (FAAs). For E. loftini susceptible cultivar LCP 85-384, concentrations of essential and nonessential FAAs in whole leaf tissue samples were more than twice as high as in the resistant cultivar HoCP 85-845. Similarly, M. sacchari susceptible L 97-128 exhibited more than three fold higher concentrations of essential FAAs in the phloem sap compared to the resistant cultivar, HoCP 91-555. Two essential FAAs, histidine and arginine, were detected only in the sap of L 97-128. A novel approach to evaluate insect resistant and susceptible cultivars is proposed.

Introduction

The Mexican rice borer, Eoreuma loftini (Dyar) (Lepidoptera: Crambidae) and sugarcane aphid, Melanaphis sacchari (Zehntner) (Hemiptera: Aphididae) conform in their herbivore-plant interactions to the plant stress hypothesis (White, 1969). In this relationship, host plants stressed from lack of water, increased salt, reduced soil fertility, or excessive damage are more suitable hosts enhancing one or more aspects of herbivore bionomics (Reay-Jones et al., 2003, 2005b, 2007a). M. sacchari and E. loftini are relatively new pests to Louisiana sugarcane (White et al., 2001, Hummel et al., 2008). In contrast, the more established invasive species, the sugarcane borer, Diatraea saccharalis (F.) conforms to the plant vigour hypothesis where the biology is enhanced by an association with vigorously growing plants (Price, 1991).

Introduced from Mexico into the Lower Rio Grande Valley of Texas in 1980 (Johnson, 1985), E. loftini is the major insect pest of sugarcane representing more than 95% of stalk borer populations in that area (Reay-Jones et al., 2005a). The insect spread northward and north-eastward into Louisiana at a rate of 16.5–23 km/year (Reay-Jones et al., 2007b). E. loftini has been cited as having a potential economic impact on the Louisiana sugarcane industry of up to $220 million/annum (Reay-Jones et al., 2008). Cryptic oviposition sites on dried sugarcane leaves, larval mining of midribs and leaf sheaths, boring into stalks within 3–7 days after egg hatch, and pupation in frass-packed tunnels render E. loftini inaccessible to control by biological and chemical agents (Reay-Jones et al., 2005a).

M. sacchari is the most abundant aphid species in Louisiana sugarcane. It vectors sugarcane yellow leaf virus (SCYLV). SCYLV was discovered in Louisiana in 1999, and in 2002, 48% of
fields were infected throughout the industry (McAllister et al., 2008). Disease management of SCYLV is facilitated using a seed cane certification program conducted by the Louisiana Department of Agriculture and Forestry (McAllister et al., 2008). Spread and incidence of SCYLV depends mainly on the spring migration of *M. sacchari* into the field (McAllister et al., 2005). This indicates potential for using resistant cultivars to prevent disease spread, since these cultivars will presumably attract fewer aphids and/or negatively affect their biology.

The *M. sacchari*-resistant cultivar (HoCP 91-555) and experimental lines with *E. loftini* resistance similar to the commercial resistant HoCP 85-845 demonstrate potential for managing these two invasive pests based on host plant resistance. This paper highlights some of the biochemical relationships involving free amino acids (FAAs) associated with *Saccharum* spp. plant resistance to *E. loftini* and *M. sacchari*.

**Eoreuma loftini**

Screening and finding genetic sources of resistance to *E. loftini* is an important component of the variety development program of the Louisiana State University AgCenter. Commercial and experimental cultivars are evaluated yearly in replicated trials under natural infestations with heavy *E. loftini* pressure at Ganado in Jackson County, TX. Initial studies at this location conducted in 2002 helped identify *E. loftini* susceptible (LCP 85-384) and resistant (HoCP 85-845) cultivars that are used as standards (Table 1). Even though the older cultivar CP 70-321 demonstrated significantly better resistance than HoCP 85-845 under heavy pressure, studies at Weslaco in Hidalgo County with lighter *E. loftini* infestations, showed that HoCP 85-845 would make a better standard (Reay-Jones et al., 2003). Assessing resistance to *E. loftini* requires determination of percentage of bored internodes and per hectare moth production based on frequency of adult (moth) emergence holes (Table 1).

**Table 1**—Injury (+ SEM) by *E. loftini* to six sugarcane cultivars, resultant survival (+ SEM) of older larvae inside the stalks, and moth production (+ SEM) at Ganado, Jackson County, TX, 2002 (Reay-Jones et al., 2003).

^aTotal of selected ‘essential free amino acids,’ as a necessary component in insect diet, critical for growth and development (Chapman, 1998).

^bNonessential amino acids are not critical for growth but are needed for optimal growth of insect (Chapman, 1998).

These studies also showed a strong ovipositional preference for cultivars and plant conditions which had higher amounts of essential FAAs. Methionine, an essential amino acid was only detected in the leaves of the susceptible LCP 85-384. Ovipositional preference of *E. loftini* indicated positive associations between egg masses per plant and both essential FAAs (arginine, phenylalanine, and threonine) and dry leaves, and between eggs per plant and both essential FAAs (methionine and threonine) and dry leaves (Reay-Jones et al., 2007a). It is also pointed out that this increased nutritional quality is not necessarily limited to just FAAs.

*Melanaphis sacchari*

Greenhouse studies on biotic potential of *M. sacchari* on commonly grown commercial sugarcane cultivars in Louisiana have shown significant cultivar effects on aphid reproductive rates. The cultivar with the least biotic potential (0.06) was HoCP 91-555 compared to the maximum (0.16) on L 97-128, showing greater than 2.6-fold differences in the number of offspring per female per day (Fig. 1).

![Fig. 1—*Melanaphis sacchari* biotic potential on Louisiana sugarcane.](image)

FAAs in the phloem sap indicated that free histidine and arginine were present only in susceptible cultivar L 97-128 (Table 3). The total amount as well as the percentage of essential FAAs in the phloem sap of L 97-128 was also higher when compared to that in the sap of the resistant cultivar HoCP 91-555. In contrast, the phloem sap of HoCP 91-555 was dominated by nonessential FAAs. On-going analyses of honeydew from aphids feeding on both cultivars is
revealing that certain FAAs are detected only in the honeydew of the susceptible cultivar L 97-128 suggesting that the aphid is able to synthesise these FAAs while feeding on this cultivar.

**Discussion**

Population growth and in turn the pest population on many host plants relates to the plant’s nutritional status, and often the availability of plant FAAs (McNeil and Southwood, 1978; Showler, 2004) in susceptible versus resistant cultivars. Resistant and susceptible cultivars to E. loftini and M. sacchari are showing association with the presence of certain amino acids (Table 3), consistent with the concept that their absence can prevent insect growth (Chapman, 1998). We are finding that some essential amino acids can be synthesised by the sugarcane aphid, and this can help increase their biotic potential on some cultivars lacking those FAAs.

Moths utilise contact chemoreceptors on their antennae, proboscis, tarsi, and ovipositor to assist in completing the behavioural responses essential to accepting or rejecting a host plant (Kogan, 1994). Assuming that E. loftini can detect host plant FAA levels and that such levels influence oviposition preference, levels of essential FAAs may help explain variability in oviposition. E. loftini oviposition was associated with arginine (egg masses per plant) and aspartic acid (eggs laid per plant), which accumulated under water deficit stress (Reay-Jones et al., 2007a). Thus, host plant foliar FAAs likely affected the oviposition preference of E. loftini, a devastating insect pest of sugarcane.

Aphids feed on phloem sap that largely consists of sugars and is limited in nitrogenous compounds. Essential amino acids in the phloem sap are generally less than 25% of the total amino acid concentration with some less than 0.2% (Chapman, 1998). A close association exists between host plant nutritional status including nutrient ratios and development of aphids (Dixon, 1985, Febvay et al., 1988). Our study suggests that the differences in biotic potential on L 97-128 and
HoCP 91-555 are associated with differences in composition and concentration of FAAs detected in the sap.

The preferred feeding site of *M. sacchari* is the lower senescing leaves of sugarcane plants, and one reason for this may be the higher levels of FAAs in these leaves (Reay-Jones *et al.*, 2005b). *E. loftini* prefers to oviposit on senescing leaves of sugarcane that are associated with higher FAAs levels. Therefore, reducing sugarcane drought-stress with irrigation is cited as a way of decreasing *E. loftini* oviposition and possibly *M. sacchari* build up by decreasing both the nutritional value of the crop for these insects and the number of ovipositional sites (i.e., dry leaves) for *E. loftini*. The practical value of these fundamental studies is the potential use of a non-bioassay approach to evaluate resistance and susceptibility of sugarcane cultivars to stalk borers and sap feeders. This would allow screening and selection of insect resistant cultivars in the absence of invasive species, a technique of value in proactive research when the pest has not yet invaded.

Résumé
Parmi les principaux insectes ravageurs attaquant la canne à sucre en Louisiane, le foreur des tiges Eoreuma loftini (Dyar) et le puceron Melanaphis sacchari (Zehntner) se comportent similairement dans leurs interactions avec leur plante hôte. Ces deux insectes suivent la « plant stress hypothesis », hypothèse selon laquelle un herbivore préférerait une plante stressée. La technique de chromatographie liquide à haute performance a été utilisée pour différencier les cultivars résistants et sensibles à ces insectes en se basant sur les profils des acides aminés libres (AAL) présents. Dans le cultivar sensible a E. loftini, LCP 85-384, les concentrations en AAL essentiels et non-essentiels étaient plus du double de celles mesurées dans le cultivar résistant, HoCP 85-384. De même, L 97-128, un cultivar sensible a M. sacchari, avait des concentrations en AAL essentiels plus de trois fois supérieures a celles mesurées dans la sève élaborée du cultivar résistant HoCP 91-555. Deux AAL essentiels, l’histidine et l’arginine, n’ont été détectés que dans la sève de L 97-128. A partir de ces résultats, la possibilité d’une approche évaluant la résistance des cultivars de canne à sucre à certains ravageurs sans recourir à des infestations d’insectes est discutée.
UNA PERSPECTIVA NUTRICIONAL DE LA RESISTENCIA DE LA CAÑA DE AZUCAR A BARRENADORES DEL TALLO Y CHUPADORES

Resumen

DOS PLAGAS relativamente nuevas, el barrenador mexicano del arroz, Eoreuma loftini (Dyar) y el áfido gris de la caña de azúcar, Melanaphis sacchari (Zehntner), son claves en Luisiana para probar la hipótesis del estresamiento de la planta. A través de la técnica de la cromatografía líquida de alta eficacia, se pudo diferenciar cultivares de caña de azúcar resistentes y susceptibles al ataque de insectos, basados en perfiles nutricionales que involucran amino ácidos libres (FAAs). Para el cultivar LCP 85-384 susceptible a E. loftini, las concentraciones de los FAAs esenciales y no esenciales en las muestras de todo el tejido de la hoja fueron superiores en más de dos veces que las encontradas en el cultivar resistente HoCP 85-845. Similarmente, L 97-128 susceptible a M. sacchari presentó concentraciones tres veces más altas de FAAs en la savia del floema al compararlo con el cultivar resistente, HoCP 91-555. Dos FAAs esenciales, histidina y arginina, se detectaron solo en la savia de L 97-128. Se propone este enfoque novedoso para evaluar cultivares resistentes y susceptibles.
VECTOR-VIRUS RELATIONSHIP FOR MELANAPHIS SACCHARI (ZEHNT.) (HEMIPTERA: APHIDIDAE) TRANSMITTING SUGARCANE YELLOW LEAF LUTEOVIRUS IN MAURITIUS

KEYWORDS: Melanaphis sacchari, Acquisition, Transmission, Yellow Leaf.

Abstract

SUGARCANE yellow leaf virus (ScYLV) was reported in Mauritius in 1995. It spreads by vegetative propagation and is transmitted to healthy plants by the aphid, Melanaphis sacchari (Zehnt.) that prevails at a very low density in commercial plantations. The relationships pertaining to the vector and the luteovirus were investigated under laboratory conditions, as an understanding of the acquisition and transmission of the virus by the vector is a prerequisite for further studies on the epidemiology, economic importance and management of the disease at field level. An appropriate aphid rearing technique was developed so as to establish cultures of infected and healthy aphids for the relevant studies. To determine the acquisition time of the virus by aphids, infected plants of the sugarcane variety M 695/69 were infested with non-viruliferous aphids which were sampled daily over 4 consecutive days and tested by RT-PCR. M. sacchari acquired the virus within 24 h and more precise tests in the insectary, whereby aphids were sampled every 30 min over 6 h, indicated that the virus was acquired after 4.5 h of feeding on infected plants. The time taken for the viruliferous aphids to transmit the virus to disease-free tissue cultured plantlets was determined by allowing infected aphids from the breeding cages to feed on the plantlets for periods of 2, 8, 17 and 28 days. The virus was transmitted to healthy plants within 2 days. This is the first record of M. sacchari being a vector of ScYLV in Mauritius and the present laboratory data provide basic information for future field experimentation and research work on vector-virus interactions.

Introduction

Yellow leaf (previously referred to as yellow leaf syndrome) was first reported in Hawaii in 1988. The disease, which is now widespread across the world, is caused by Sugarcane yellow leaf virus (ScYLV), a Polerovirus of the Luteoviridae family (D’Arcy and Domier, 2005) which also contains barley dwarf virus, soybean dwarf virus, potato leaf roll virus and pea mosaic virus (Comstock and Gilbert, 2008). ScYLV is limited to the phloem tissue and is spread mainly by vegetative propagation through infected cuttings and transmitted to healthy plants by aphids (Rassaby et al., 2004; Comstock and Gilbert, 2008). The aphid species proven to transmit the virus are the sugarcane aphid, Melanaphis sacchari (Zehntner), the corn leaf aphid Rhopalosiphum maidis (Fitch) and the rice root aphid, R. rufiabdominalis (Sasaki). The former species is a vector of three persistent viruses, namely millet red leaf, sugarcane yellow leaf and sugarcane mosaic viruses (Singh et al., 2004). Not all aphid species infesting sugarcane are vectors of ScYLV (Schenck and Lehrer, 2000).

The disease was reported in Mauritius in 1994 but its epidemiology and the effect on yield were not clear. Symptoms were subsequently observed in several commercial varieties (Saumtally and Moutia, 1997), although the aphid population in commercial plantations is low. This paper
describes the incidence of the vector in the fields and studies in the insectary relating to the establishment of cultures of healthy and infected aphids, the determination of the acquisition time of the virus by aphids and the transmission of the disease to healthy plants. These studies will give a better understanding of the relationships pertaining to the vector and the virus. Data from these investigations may help to implement appropriate measures for timely provision of infected aphids for future studies on yield assessments of different varieties and the rate of transmission and ScYLV dissemination in the field with respect to the different genotypes detected locally.

**Materials and methods**

**Incidence of aphids**

To assess the potential of early infection in the epidemiology of the disease, surveys were initially conducted in transplanted seedling plantations set on four experimental stations located in the subhumid, humid and superhumid zones of Mauritius. Potted seedlings in the shadehouses at Réduit (humid region) were also surveyed.

Field surveys were then conducted to identify the aphid species, their distribution and their incidence in the various agroclimatic zones of the island. Surveys were carried out in commercial plantations and varietal preference was recorded. Leaf samples and aphids, if any, were collected at 25 points selected at random in each field. All aphids were kept in 70% alcohol and tested for whether they were viruliferous according to the method of Rassaby *et al.* (2004). To allow correlations to be made between the virus incidence and the vector population, the leaf samples were tested by tissue blot immunoassays (TBIA) using a cross-absorbed polyclonal antibody and the technique developed by Schenck *et al.* (1997). Confirmatory tests were effected with the leaf samples by reverse transcription polymerase chain reaction (RT-PCR) (Joomun and Dookun-Sauntally, 2008; Khoodoo *et al.*, 2008; MSIRI, 2008b).

**Insect rearing**

An investigation was carried out in the insectary to determine the most appropriate rearing method for *M. sacchari*. Young potted maize plants, potted sugarcane plants, cut leaves and cut shoots in water were infested with aphids in wooden cages (45 cm x 45 cm x 118 cm) and observations on insect development were recorded weekly over at least two generations.

**Acquisition tests**

Acquisition tests were conducted to determine whether *M. sacchari* is a potential vector of the ScYLV under controlled conditions in the insectary. Virus-free aphids, which were collected from healthy seedlings, were reared in three wooden insect cages (30 aphids/cage) each containing two cut shoots of infected plants of cane variety M 695/69 in water. After about two weeks, a random sample of five aphids was collected from each of these cages and tested for the presence of the ScYLV in single aphids by RT-PCR (MSIRI, 2008b). Positive results on the potential of *M. sacchari* as a vector of ScYLV then led to the establishment of additional tests to determine the time taken for the vector to acquire and transmit the virus.

About thirty virus-free aphids were collected from seedlings at Réduit and placed in contact with infected shoots of M 695/69 in wooden cages as described above. In addition to the three replicate cages with infected shoots, a control batch was also set with disease-free plantlets of variety R 570. Five aphids were removed from each of the four cages after 24, 48, 72 and 96 hours and kept in 70% alcohol for the detection of the virus.

Further tests were conducted to determine more precisely the acquisition time within 24 hours. One infected shoot of M 695/69 was placed in a conical flask containing water and was artificially infested with about eighty virus-free aphids collected from the seedlings. Three replicate flasks were set up and a control using disease-free plantlets of variety R 570 was also established. Five aphids were removed from each replicate flask every 30 minutes from 10 am for 5 ½ hours and kept in alcohol for virus detection.
Transmission tests

To determine whether infected aphids would transmit the virus to healthy plants, infected aphids from the breeding cages were placed in contact with three disease-free plantlets of R 570 in each wooden cage for different time periods of 2, 8, 17 and 28 days. All aphids from each of the cages were killed after the respective time periods by foliar application and soil drenching with thiamethoxam (Actara 25 WG) at 0.0625 g a.i./L. Samples of five aphids were taken at random from each plant in each cage to ascertain their infective nature. All the plants were subsequently transferred to insect-proof cages; after 45 days, leaves were sampled randomly from all the cages for the detection of the ScYLV by TBIA.

Results

Incidence of aphids

Results from the field surveys showed that the population of aphids in transplanted seedlings on three of the experimental stations was much lower than that at Réduit situated in the humid region. Surveys in the seed beds at Réduit indicated a high infestation and several colonies of about twenty aphids per leaf were sometimes encountered on the small plants despite the weekly cutting back prior to their transplantation to the commercial plantations. No ScYLV infection was detected in the leaves or aphids at the seedling stage on the four experimental stations.

Surveys in the commercial plantations showed that the only recorded aphid species was *M. sacchari* while the other potential vector, *R. maidis*, was not recorded. The population of *M. sacchari* was low island-wide, being prevalent in about 10% of the fields which were visited, except in one field at Savannah where hundreds of aphids comprising all stages were recorded on a few leaves in association with the soft scale, *Pulvinaria iceryi* Sign.

Insect rearing

*M. sacchari* could be successfully reared for 2–3 generations on young cut shoots of M 695/69 kept in water and this breeding method was adopted throughout the studies. Both apterous and alate forms of *M. sacchari* developed in large numbers (approximately 100–200 aphids per shoot) in the breeding cages. Young maize plants, cut sugarcane leaves and young potted plants were not appropriate for breeding aphids for several generations in the insectary.

Acquisition and transmission tests

Healthy aphids collected from seedlings multiplied rapidly on the infected leaves of cane variety M 695/69 in the insectary. After about four days, leaves showed pronounced yellowing and in about three weeks, a very high population of alate and apterous aphids was observed in all three cages. These aphids were found to be infected with ScYLV while aphids from the control cage tested negative. Laboratory tests clearly demonstrated that *M. sacchari* is a potential vector of ScYLV. Acquisition tests showed that the vector could acquire the virus within 24 hours as reported in the literature and more precise laboratory tests indicated that the virus was acquired after 4.5 hours in two replicate flasks (MSIRI, 2008a).

Tests on the aphids prior to the transmission studies confirmed their infective nature. Investigations on the transmission of the virus in the insectary at Réduit showed that the virus could be transmitted by viruliferous aphids to healthy plantlets of cane variety R 570 within two days (MSIRI, 2008a). All the leaf samples, except those sampled from plants that were exposed for a period of eight days, were found to be infected.

Discussions and conclusions

Field surveys in Mauritius have provided useful information on the epidemiology of ScYLV for the subsequent implementation of appropriate measures for its management and for future studies. The only aphid species that was found to be associated with the disease was *M. sacchari*. Similar investigation of infestation and transmission efficiency reported in the literature showed that *M. sacchari* was the only vector important for the field spread of the disease in Hawaii (Lehrer *et*
of $M. \text{sacchari}$ was limited and its population in the commercial plantations was low as colonies were detected in very few localities.

This contrasts with the situation in Guadeloupe where $M. \text{sacchari}$ is widespread in all areas and ScYLV appears to be spread by aphid vectors and infected cuttings (Edon-Jock et al., 2007). However, in Louisiana, the incidence and rate of disease increase remained low despite the widespread occurrence of the potential vectors (McAllister et al., 2008) which have a low rate of dispersal (Lehrer et al., 2007). In Mauritius, the widespread and high incidence of the virus in commercial varieties, the absence of infected aphids in transplanted seedlings and the low vector population in commercial fields indicate that the main source of infection is through the vegetative propagation of infected cane settts as reported by Khoodoo et al. (2008). This is despite the fact that our studies highlighted the short time needed for the vector to acquire and transmit the virus.

In this present study, the aphids were killed in alcohol right after removing them from the infected plants. The acquisition time might have been shorter if the aphids were left on healthy plants for some time to allow the virus to multiply in the aphids.

These observations in Mauritius correlate well with previous studies carried out by Edon-Jock et al. (2007) in Guadeloupe, where virus incidence was consistently high in R 579 even though colonisation by aphids was low. Similarly, no indication of long-distance transfer via aphids could be seen in Hawaii, indicating that it may be possible to produce and use virus-free seed cane for planting of high-yielding but susceptible cultivars (Lehrer et al., 2007).

Aphid control using insecticides as proposed in the literature should be adopted judiciously. In Mauritius, this practice is not warranted due to the low vector population and because established biological control of major sugarcane pests through a complex of predators and parasitoids may be disrupted by insecticide use.

In countries where control of the vector population is necessary, biological control of the main vector species, $M. \text{sacchari}$, integrated within a varietal development program may be attempted as revealed by the high potential of the coccinellid predator, $Diomus \text{terminatus}$ Say, in adult voracity tests in Louisiana (Akbar et al., 2009; Akbar and Reagan, 2006).

The present study highlighted the fact that initial contamination occurs in the field probably by aphid vectors and subsequently settts issuing from infected fields help in the transmission of the disease. The short acquisition and transmission time by the vector is definitely of concern, especially as four different genotypes have been detected so far as revealed by genetic diversity studies (Joomun and Dookun-Saumtally, 2008; MSIRI, 2008b).

As genotypes vary in their virulence, future studies can be carried out to determine whether there is a differential pattern in the transmission and acquisition of the different biotypes of the virus by $M. \text{sacchari}$. Additionally, the information obtained on transmission and acquisition will be useful to obtain infected plants for field experimentation, using $\text{in vitro}$ plantlets as initial starting material.

Résumé

La maladie de la feuille jaune de la canne à sucre a été répertoriée à Maurice en 1995. Le virus (*Sugarcane yellow leaf virus* – ScYLV) est propagé par boutures infectées et est transmis par le puceron *Melanaphis sacchari* (Zehnt.) présent à faible densité dans les plantations commerciales. Des études ont été effectuées au laboratoire sur la relation virus-vecteur, car des données sur l’acquisition et la transmission du virus sont nécessaires pour déterminer l’épidémiologie, l’impact économique et la gestion de la maladie. Une méthode fut établie pour l’élevage en masse de pucerons infectés et sains. L’acquisition du virus fut déterminée en exposant les pucerons sains à des plantes infectées de la variété M 695/69. Des échantillons de pucerons ont été prélevés chaque jour sur une période de quatre jours et analysés par RT-PCR. Les résultats démontrent que le virus est acquis dans les 24 heures et des essais plus précis, en prélevant des pucerons chaque trente minutes sur une période de six heures indiquent que le vecteur peut acquérir le virus après avoir été exposé pendant 4.5 heures aux plantes infectées. Le temps requis pour la transmission du virus par le vecteur à été évalué en exposant les pucerons infectés aux plantules *in vitro* pour une période de 2, 8, 17 et 28 jours. Le virus était transmis aux plantules en 2 jours. L’étude démontre que *M. sacchari* est un vecteur du ScYLV et les données préliminaires obtenues seront importantes pour des études plus approfondies au champ.

Resumen
El virus de la hoja amarilla de la caña de azúcar (ScYLV) se registró en Mauricio en 1995. El virus se dispersa por propagación vegetativa y se transmite a plantas sanas por el áfido, Melanaphis sacchari (Zehnt.) que prevalece en poblaciones muy bajas en plantaciones comerciales. Las relaciones que tienen que ver con el vector y el luteovirus se investigaron bajo condiciones de laboratorio, ya que entender el proceso de adquisición y transmisión del virus por el vector, es un prerrequisito para posteriores estudios sobre la epidemiología, importancia económica y manejo de la enfermedad a nivel del campo. Se desarrolló una metodología apropiada de cría del áfido para establecer cultivos de áfidos infectados y sanos para los estudios pertinentes. Para determinar el tiempo de adquisición del virus por los áfidos, se infestaron con áfidos no virulentos, plantas infectadas con el virus de la variedad de caña de azúcar M 695/69. Los áfidos se muestearon diariamente durante 4 días consecutivos y se probaron por RT-PCR. M. sacchari adquirió el virus en 24 h y ensayos más precisos en el insectario, donde los áfidos se muestrearon cada 30 min durante 6 h, indicaron que el virus se adquirió después de 4.5 h de alimentarse en plantas infectadas. El tiempo que toma a los áfidos virulíferos para transmitir el virus en tejido libre de virus de plántulas se determinó permitiendo a los áfidos infectados de las jaulas de cría alimentarse de las plántulas por periodos de 2, 8, 17 y 28 días. El virus se transmitió a plantas sanas en 2 días. Este es el primer registro de M. sacchari como vector de ScYLV in Mauritio y los datos de laboratorio de este estudio proveen información básica para futuras investigaciones de campo y trabajos sobre interacciones entre vector y virus.
EFFECTS OF FIPRONIL BAIT ON SUGARCANE YIELD IN OKINAWA, JAPAN

KEYWORDS: Fipronil Bait, Phytostimulatory, Sorghum, Sugarcane Yield, Wireworm.

Abstract
FIPRONIL bait (Prince® Bait, BASF Agro), newly registered as a sugarcane insecticide in 2006 in Japan, has been shown to reduce sugarcane wireworm, Melanotus sakishimensis and M. okinawawesis (Coleoptera: Elateridae), damage and increase sugarcane yield. In January 2008, a high sugarcane growth rate was observed in fipronil bait-treated areas in Minami-daitou Island. To confirm this high growth rate, we investigated sugarcane growth and yield in two fields on Minami-daitou Island from March to December 2008. Moreover, as we suspected that fipronil has a phytostimulatory effect that promotes sugarcane growth, we conducted a simple test using sorghum, also a gramineous C4 crop and a species with a high degree of collinearity with sugarcane. Research on Minami-daitou Island showed that sugarcane growth in the fipronil bait-treated area was significantly higher than the areas treated with ethylthiodemeton granule insecticide (TD®, Sankyou Agro) or isoxathion granule insecticide (TD® Ace, Sankyou Agro). Further, cane yield in the fipronil bait-treated area was also significantly increased as compared with that in the ethylthiodemeton granule and isoxathion granule insecticide-treated areas. Sorghum tests showed that the coleoptile length of sorghum seeds increased when treated with 0 to 10 ppm of fipronil, and then decreased for concentrations over 10 ppm. It was concluded that fipronil bait treatment in sugarcane fields can significantly increase both the growth and yield of sugarcane. Moreover, it was suggested that fipronil at low concentrations may have a phytostimulatory effect on sorghum seedlings.

Introduction
Fipronil (5-amino-1-[2,6-dichloro-4-(trifluoromethyl) phenyl]-4-[(trifluoromethyl)sulfinyl]-1H-pyrazole-3-carbonitrile) is a phenylpyrazole insecticide that interferes with GABA (γ-aminobutyric acid)-gated ion channels (Figure 1).

It blocks chloride ions influx by acting on GABA-gated chloride ion channels, and causes excessive neural excitation, paralysis, and eventual death (Gunasekara et al., 2007). Since registration in 1996, fipronil has been widely used in many cropping systems around the world, including Japan, particularly in rice production.

In 2006, fipronil bait insecticide (0.5% active ingredient, Prince® Bait, BASF Agro) for sugarcane was registered in Japan. The formulation consists of only 0.5% fipronil and approximately 99.5% grain-based material, and differs from conventional sugarcane insecticides in its mode of action.

This insecticide attracts insects with the grain-based material, which leads to the uptake of fipronil by the insect. In addition, fipronil has systemic activity and can control insects such as boll weevils, rootworm and wireworm (Clive, 2006). Sugarcane wireworm, Melanotus sakishimensis and M. okinawawesis (Coleoptera: Elateridae), is a serious economic pest in Japan (Nagamine and Kinjo, 1979).
Tarora et al. (2007) demonstrated that Prince® Bait has an attractant effect and causes high wireworm mortality in laboratory tests. Moreover, the number of ratoon shoots was significantly higher in bait-treated fields than in fields treated with carbosulfan granule insecticide, a conventional insecticide used against wireworm in Japan, on Miyako Island.

However, their research differs from our research in terms of location, insecticide standard and planting season. They studied wireworm damage in three crops: summer planting, spring planting and ratooning, but the yield research was performed only at spring planting.

As no fipronil insecticides for sugarcane were available in Japan before 2006, there are few reports on the effects of fipronil bait insecticide on sugarcane yield.

The present study was aimed at demonstrating the effects of this bait insecticide on sugarcane yield on Minami-daitou Island, its impact on pest insects, as well as its phytostimulatory effects.

\[ \text{Chemical structure of fipronil.} \]

**Materials and methods**

**Research on Minami-daitou Island**

The research was conducted in two fields, A (1.3 ha) and B (1.6 ha), planted with *Saccharum* spp. cv. Ni26 on Minami-daitou Island in Okinawa.

Fields A and B were treated with fipronil bait, while the control areas in each field were treated with ethylthiodemeton granule insecticide (3.0% a.i., TD®, Sankyou Agro) and isoxathion granule insecticide (2.0% a.i., TD® Ace, Sankyou Agro), respectively.

Ethylthiodemeton insecticide and isoxathion granule insecticide are both conventional insecticides used against wireworms in Okinawa. Field studies were conducted on March 21–22, April 12–13, July 12–13, October 8–9, and December 20–21, 2008.

From March 21–22 to October 8–9, growth analysis was conducted. Briefly, 3 blocks were selected in each insecticide-treated area, and the sub-stem length of the main stem, number of tillers and number of dead heart stalks per block were measured. In addition, the number of stalks was determined for an area of 7.0 × 1.5 m. Sub-stem length was defined as the length to the dewlap of the first leaf.

Data on the number of tillers, stalks and dead heart stalks were not recorded on October 8–9 in field A due to severe lodging. Yield sampling was conducted on December 20–21. A 2.2 × 1.5 m plot was cut in each insecticide-treated area, and the diameter of each stem, sub-stem length, and number of stalks per plot was measured.

The crown above the dewlap of the 5th leaf was pruned off, and the length and weight of each stem was measured. Sugarcane yield per 10 a was calculated from the number of stalks per 2.2 × 1.5 m plot and stem weight data. To evaluate sugarcane quality, sucrose content was analysed from 5 juice samples per plot using an HPLC system (LC-10A, Shimadzu). The data for each field were analysed using Student’s t-test, with a value <0.05 considered as significantly different.
Phytostimulatory effect

Sorghum seeds (Sorghum bicolor cv. FS501) were used to assess potential phytostimulatory effects because sorghum has the same photosynthetic process as sugarcane and a high degree of collinearity exists between the two crops. Adjustment of the fipronil concentration was difficult as it has low water solubility. A suspension concentrate (SC) (5.0% a.i., Prince® Flowers, BASF Agro) was therefore used for the laboratory experiments. A 5.0% (50 000 ppm) fipronil SC was diluted to produce 10 concentrations (0, 1, 2.5, 5, 7.5, 10, 25, 50, 75, 100 ppm) in distilled water. A total of 10 seeds per treatment were placed in a vial (50 mL), and 50 mL of each fipronil concentration was added. All vials were capped and left to incubate for 2 h.

Seed samples (one seed per tube) and solutions (4 mL per tube) were then transferred to a liquid-filter paper culture medium in glass tubes. All tubes were covered by parafilm and maintained in the dark for 4 days at 30°C. Germination rate, rooting rate, coleoptile length and root length were measured.

Germination and rooting were considered to have occurred if the coleoptile and root were more than 1 mm in length. The experiment was replicated three times and means compared by Scheffe’s test at p<0.05.

Results

Research on Minami-daitou Island

Figures 2 and 3 show sugarcane growth from March to October, 2008, and Figures 4 and 5 are photos taken in March, 2008. In field A, sub-stem length in the fipronil-bait treated area was significantly longer than that in the ethylthiodemeton insecticide-treated area in March and April. In field B, sub-stem length in the fipronil-bait treated area was also significantly longer than that in the isoxathion-treated area in March, April and October.

The number of stalks peaked in March in all areas, except in the isoxathion-treated plots where it peaked in April, and decreased thereafter. This decrease was due to the death of non-productive tillers through competition.

Although the number of tillers peaked in April and thereafter decreased in all plots, no significant differences were detected between the fipronil bait- and conventional insecticide-treated plots.

The number of dead heart stalks in the fipronil bait-treated plots was lower than in the conventional insecticide-treated plots in March, April and October, but this difference was not apparent in July.

Table 1 shows the yield sampling results for December 2008. In the fipronil bait-treated plots, stem length and sub-stem length in field A, and stem length, diameter and weight in field-B were significantly higher than the values obtained in the conventional insecticide-treated plots.

*p<0.05.

There were no significant differences in sucrose content between fipronil treatments. These results show that fipronil bait treatment improved sugarcane growth and yield without reducing cane juice quality.
Fig. 2—Effects of fipronil bait treatments on the number of stalks and sub-stem length. Bar and line graphs show sub-stem length and number of stalks per 10 a, respectively. *P<0.05, **P<0.01.

Phytostimulatory effect

Figures 6 and 7 show the effects of fipronil on coleoptile (upper) and root (lower) length in sorghum, respectively, and Table 2 shows the results of germination and rooting rates.

From these results, no significant differences were observed between treatment concentrations.

However, there was a tendency for coleoptile length to gradually increase from 0 to 10 ppm, and then to decrease again over 10 ppm. Germination and rooting rates were 85 to 100% regardless of concentration.

These results show that fipronil, at a low concentration of 10 ppm, enhanced sorghum growth.
Fig. 6—Effects of fipronil on sorghum coleoptile and root length. The thin lines in the figures show coleoptile (thin red line) and root (thin blue line) length at 0 ppm.

Discussion

The sugarcane wireworm has caused substantial damage for a number of years to sugarcane production in Okinawa. Wireworms damage sugarcane shoots, stems and roots, and shoots are especially damaged as compared with other plant parts. Therefore, non-germination, dead heart, non-ratooning are caused, and sugarcane yield decreases in damaged field (Oshiro et al., 2006). In the 1960s, the incidence of wireworm decreased due to the use of organic chlorine insecticides; however, the subsequent ban of this type of insecticide led to an increase in wireworm numbers after 1971 (Azuma, 1977). Sugarcane production, therefore, decreased as wireworms damage ratoon shoots, and the ratoon crops do not grow as well in damaged fields. At
the same time, labour costs increased, leading to lower profitability. Therefore, a strong demand existed for a new insecticide to prevent wireworm damage in ratoon fields.

In the present study, research was conducted on Minami-daitou Island, one of the areas of large-scale sugarcane production in Okinawa. Sugarcane growth and yield were found to be significantly increased in the fipronil bait-treated areas compared with the control area in each field studied. Early growth (6 months after planting) was increased substantially by the use of fipronil. Nagamine and Kinjo (1979) showed that wireworm damage was confirmed in the early growth stages until three months after planting, especially within the first month (personal communication). In our study, we did not detect any wireworm damage up to 6 months after planting. Future research will focus on sampling for damage earlier in the season.

Although ethylthiodemeton insecticide has been used for a long time to control wireworms in Minami-daitou Island, it was found to be not as effective in controlling wireworms as the fipronil bait. The results suggest that wireworms may have developed resistance to this insecticide on Minami-daitou Island. Future research will also focus on this resistance of wireworm.

From the present study, we speculate that the increase in growth and yield in the fipronil-treated sugarcane was caused by factors other than the reduction in wireworm-related damage. It is already known that 3-cyano-1-phenylpyrazoles, such as fipronil, regulate and promote plant growth. Therefore, we hypothesised that fipronil has a phytostimulatory effect that promoted sugarcane growth, and developed a simple test using sorghum, which has the same type of photosynthetic process as sugarcane. Although there were no significant differences, 10 ppm of fipronil led to a slight increase in the length of the coleoptile of sorghum seedlings. Stevens et al. (1999) showed that 2000 mg/L fipronil inhibited the early growth of rice. Though they examined higher fipronil concentrations (250–4000 mg/L), Garcia del Pino and Jove (2005) also showed that the optimum field rate for fipronil was 12–60 ppm, and suggested that the same concentration of fipronil should be used in sugarcane fields. These results show that fipronil at low concentrations of about 10 ppm can increase plant growth, whereas high concentrations of about 2000 ppm can inhibit plant growth. Moreover, Clive (2006) indicated that the application of fipronil as an incorporated soil treatment to cotton, maize, sugar beet or sunflower leads to limited uptake of fipronil into plants. However, it is not known about penetration of fipronil into sugarcane. Further study is required to clarify the uptake of fipronil into sugarcane and the phytostimulatory effect of fipronil on sugarcane.

The present study showed that fipronil bait treatment increases sugarcane growth and yield as compared with conventional insecticides on Minami-daitou Island; therefore, fipronil bait can be regarded as a promising insecticide for use in sugarcane production. However, further research is necessary to better quantify the systemic activity of fipronil in sugarcane as well as its phytostimulatory effect on growth.

MOTSCLÉS: Appât au Fipronil, Phytostimulateurs, Sorgho, Rendement De Canne, Taupin.

Résumé

Un appât à base de fipronil (Prince®, Bait, BASF Agro), nouvellement homologué comme insecticide pour la culture de la canne à sucre en 2006 au Japon, a réduit efficacement les dégâts du taupin, Melanotus sakishimensis et M. okinawawesis (Coleoptera: Elateridae), tout en augmentant le rendement. En janvier 2008, une croissance élevée de la canne à sucre a été observée dans les régions traitées à l’appât sur l’île Minami-daitou. Afin de confirmer cette forte croissance, nous avons étudié la pousse de la canne et le rendement dans deux champs sur l’île de mars à décembre 2008. De même, comme nous soupçonnions que le fipronil avait des propriétés phytostimulatrices permettant de promouvoir la croissance de la canne à sucre, nous avons effectué un test simple en utilisant le sorgho, une graminée à fort degré de parenté avec la canne à sucre et une plante C₄. La recherche sur l’île Minami-daitou a démontré que la croissance était significativement plus élevée dans les régions traitées à l’appât au fipronil comparée aux régions traitées à l’insecticide éthylthiodémeton (TD®, Sankyou Agro) ou isoxathion (TD® Ace, Sankyou Agro) en formulation granulée. De plus, le rendement en canne dans les régions traitées au fipronil était significativement supérieur comparé aux traitements d’éthylthiodémeton et d’isoxathion. La longueur du coléoptile des graines de sorgho était supérieure avec un traitement de 0 à 10 ppm de fipronil par rapport à des concentrations de plus de 10 ppm où une diminution a été constatée. Il est conclu que l’appât à base de fipronil pourrait accroître le rendement ainsi que la croissance de la canne de manière significative. De plus, il semblerait qu’une faible concentration de fipronil ait un effet phytostimulateur sur les plantules de sorgho.
EFECTOS DEL CEBO FIPRONIL EN LA PRODUCCIÓN DE CAÑA DE AZÚCAR EN OKINAWA, JAPÓN

PALABRAS CLAVE: Cebo Fipronil, Fitoestimulatorio, Sorgo, Rendimiento Caña de Azúcar, Gusano Alambre.

Resumen

EL CEBO Fipronil (Prince Bait, BASF Agro), recientemente registrado en 2006 como un insecticida para la caña de azúcar en Japón, se encontró que reduce el daño causado por los gusanos alambres Melanotus sakishimensis y M. okinawawesis (Coleoptera: Elateridae) y a su vez puede aumentar la producción de la caña de azúcar. En enero de 2008, se observó una alta tasa de crecimiento de las cañas tratadas con cebo Fipronil en la isla de Minami-daitou. La confirmación del aumento en la tasa de crecimiento y su producción, se investigó en dos campos en la isla de Minami-diatou entre marzo y diciembre de 2008. Más aún, debido a que se sospechaba que el Fipronil, tiene un efecto fitoestimulador al promover el crecimiento de la caña de azúcar, se condujo una prueba sencilla usando sorgo, también un cultivo de una especie de graminea C₄, especie que tiene un alto grado de colinearidad con la caña de azúcar. La investigación se realizó en la isla de Minami-daitou y demostró que el crecimiento de la caña de azúcar en las áreas tratadas con el cebo Fipronil fue significativamente más alto que en las áreas tratadas con el insecticida granulado etiltiodemeton (TD, Sankyou Agro) o el insecticida granulado isofoxation (TD Ace, Sankyou Agro). Además, la producción de caña de las áreas tratadas con el cebo Fipronil también fue significativamente superior al de las áreas tratadas con los insecticidas granulados etiltiodemeton e isofoxation. Las pruebas con sorgo mostraron que la longitud del coleóptilo de las semillas de sorgo aumentó cuando se trataron con 0 a 10 ppm de Fipronil y luego disminuyeron en las concentraciones superiores a 10 ppm. Se concluye que el tratamiento con el cebo Fipronil en campos de caña de azúcar pueden aumentar significativamente tanto el crecimiento como la producción de caña de azúcar. Más aún, se sugiere que el Fipronil a bajas concentraciones puede tener un efecto fitoestimulador en plántulas de sorgo.
COMBATING SUGARCANE PESTS IN SOUTH AFRICA: FROM RESEARCHING BIOTIC INTERACTIONS TO BIO-INTENSIVE INTEGRATED PEST MANAGEMENT IN THE FIELD

Abstract

THE MOST common definition of conventional Integrated Pest Management (IPM) is ‘a decision-making process using multiple pest management tactics to prevent economically damaging out-breaks while reducing risks to human health and the environment’. Low–level IPM is the most often employed form, consisting of the most basic of IPM practices—scouting and insecticide applications according to economic thresholds. Some growers have progressed to medium–level IPM, the adoption of a few additional preventive measures, e.g. cultural controls and plant resistance, coupled with efforts to cut back on broad spectrum pesticide use in order to protect beneficial organisms. These IPM strategies are mainly targeted towards single pest species and do not consider all of the pests in a specific agro-ecosystem. High–level, or Bio-intensive IPM, is where multiple interventions are integrated in a bio-intensive approach targeting multiple pests. Bio-intensive IPM is based on holistic agro-ecosystem interactions, in which knowledge about insects, their symbionts, pathogens, natural enemies, plants, endophytes and interactions between all of these are combined to develop IPM in an area-wide, environmentally friendly manner. Reviewed here are advances in knowledge of, and of biotic interactions between direct, indirect and induced plant resistance, plant nutrition, habitat management, chemical ecology, natural enemies, soil-health, micro-organisms such as endophytic fungi and Wolbachia and phylogenetics and phylogeography. All of these are potential building blocks of a bio-intensive IPM system under-construction at SASRI. Also discussed are opportunities and challenges in these areas of research, taking into account bio-security threats to the South African sugar industry and possible limitations in current sugarcane plant breeding material.

Introduction

SASRI has been working to improve control of the African sugarcane stalk borer Eldana saccharina Walker (Lepidoptera: Pyralidae) since the early 1970s (Carnegie, 1974). A few cultural control measures (Carnegie, 1981; Carnegie and Smaill, 1982) and several less susceptible varieties have been developed against it (Keeping, 2006).

However, it still remains a pest throughout the sugar industry (Webster et al. 2005, 2009).

In order to build resilience into the sugarcane agro-ecosystem, a refocusing of control efforts into a bio-intensive area-wide integrated pest management approach is necessary (Klassen, 2005). Such an approach marries conventional control options with ecologically based new technologies.
such as delineation of within species populations, chemical ecology, stimulo-deterrent diversion (push-pull) and enhancement of natural enemies through habitat management and good soil health practices, to produce sustainable IPM strategies applicable across large areas involving multiple stakeholders (Conlong and Rutherford, 2009).

There is also a need to refocus bio-security to again build resilience to invasion into agro-ecosystems, rather than building walls around them (Waage and Mumford, 2008). One such regional threat is the spotted sugarcane stem-borer, *Chilo sacchariphagus* (Bojer) (Lepidoptera: Crambidae).

This pest originates in South-East Asia and is largely restricted to *Saccharum* as host plants (Bleszynski, 1970). *C. sacchariphagus* is now present in Mozambique and is an imminent bio-security threat to the South African, Malawian, Tanzanian and Swazi sugar industries (Way and Turner, 1999).

**IPM–From the bottom up**

Plant resistance to pests and diseases can be linked to optimal physical, chemical and, biological properties of soil (Altieri and Nicholls 2003; Zehnder et al., 2007). ‘Healthy’ soil is described as having sufficient organic matter to support a high diversity of animal (arthropods, nematodes etc.) and microbial life. Soils can act as important reservoirs for a diversity of entomopathogenic fungi and nematodes, as well as predaceous arthropods, which can contribute significantly to the regulation of pest populations (Keller and Zimmerman, 1989).

Ninety percent of insect pest species spend at least part of their life cycle in soil (Villani and Wright, 1990; Kaya and Gaugler, 1993). In addition, pests that occasionally come into contact with soil can be attacked by predators or become infected by entomopathogens (Klingen et al., 2002). After the harvest of heavily infested sugarcane, the residual *E. saccharina* population from which infestation of the following ratoon crop can be expected is found in the sugarcane stubble at soil level and in the stool below ground.

By minimising compaction and tillage, and by mulching and increasing organic matter, soils can support increased populations of entomopathogenic fungi, entomopathogenic nematodes and predaceous arthropods such that these natural enemies of insects can be included in the suppression of pests in a conservation biological control strategy (Landis et al., 2000; Meyling and Eilenberg, 2007).

**Direct and indirect host-plant resistance**

Insect resistance in grasses is the result of many defence mechanisms that act in parallel to limit the damage of herbivore attacks. Many of these defence mechanisms are based on plant secondary metabolites, or defensive proteins that directly affect the herbivore due to their toxic, deterring or anti-nutritional properties.

Structural resistance also occurs. Keeping and Meyer (2002) have shown that resistance to *E. saccharina* can be enhanced using soil-applied silicon, which becomes incorporated into the plant alongside lignin and fibre increasing resistance to penetration. These authors emphasise a relationship between nitrogen and silicon nutrition whereby the ratio of these elements determined in leaf analyses can be used as an indicator of *E. saccharina* infestation risk. Keeping and Rutherford (2004) have reviewed mechanisms of direct resistance to *E. saccharina*.

Two decades ago, a new type of defence mechanism, termed indirect defence, was first described in maize (Turlings et al., 1990). Central to this type of defence is the release of a volatile plant SOS signal, a mixture of volatile secondary metabolites.

Plant volatiles are derived from complex biochemical processes and include fatty-acid-derived products [methyl-jasmonate, cis-jasmonate, and green leaf volatiles (GLV) like hexenal and hexenyl-acetate], monoterpenes, sesquiterpenes, and shikimic acid-derived products [e.g. methyl-
salicylate and indole] (Turlings et al., 1998; Ferry et al., 2004). These can serve as signals, not only to attract predators and parasites of attacking herbivores, but they can also repel the herbivore itself, and they can elicit responses in neighbouring undamaged plants (Bruin et al., 1995; De Moraes et al., 2001). The use of elicitors to directly activate or prime resistance shows much promise as an IPM tool (Zehnder et al., 2007).

**Habitat management**

Therefore, it is very important to understand the role of plants in managing insect populations. An example comes from our experience in trying to control E. saccharina with indigenous and new association biological control agents.

Conlong et al. (2007) found that female E. saccharina moths will accept Cyperus papyrus and Cyperus dives as host plants in preference to the indigenous grass Pennisetum purpureum, with sugarcane being least preferred.

A preference was again demonstrated by Keeping et al. (2007), who showed that, if given the choice between older sugarcane and maize, E. saccharina would oviposit on the maize, even if it were Bt maize.

Keeping et al. (2007) further showed that larval survival on this Bt maize was zero. A hierarchical oviposition preference (Thompson and Pellmyr, 1991) is suggested in Southern African E. saccharina females, with most oviposition found on or close to its indigenous sedge hosts, followed by indigenous grasses, and then sugarcane.

However, a large proportion of these eggs were not laid directly on the plants, but in cryptic oviposition sites in the vicinity of potential host plants (Kasl, 2004; Barker, 2008).

Thompson and Pellmyr (1991) suggest that egg dumping is behaviour of highly polyphagous species (E. saccharina attacks species of the Cyperaceae, Typhaceae, Juncaceae and Graminaceae (Atkinson, 1980; Conlong, 2001; Mazodze and Conlong, 2003)), or in species associated with superabundant host plants.

These are both possibilities with E. saccharina in sugarcane and its cyperaceous hosts, as both hosts occur in large essentially mono-specific stands. Adult females therefore may not be particularly attracted by host or ‘pull’ plants in an IPM system and conversely they may be more strongly repelled by non-host or ‘push’ plants, since the presence of these could indicate that the insect had reached the edge of the preferred mono-specific host plant stand.

Nevertheless, E. saccharina seems to have a hierarchical preference in choosing a host plant habitat to oviposit in, i.e. Cyperaceae and maize, both of which have E. saccharina population controls in place; natural enemies in the Cyperaceae (Conlong, 1990, 1997, 2000) and genetically engineered Bt toxin in maize (Keeping et al., 2007).

Further evidence to promote habitat management as a control option was provided by Khan et al. (1997a, 2001) who demonstrated the repellent ‘push’ properties of the indigenous grass Melinis minutiflora Beauv. to cereal stemborers, and also its attractant properties to their parasitoids (Khan et al., 1997b). M. minutiflora produces volatiles similar to damaged maize, even in the absence of pest damage to itself (Gohole et al., 2003).

Stimulo-deterrent diversion using M. minutiflora has been successfully deployed against the spotted stemborer, Chilo partellus (Swinhoe) (Lepidoptera: Crambidae), in Central African maize (Cook et al., 2007; Khan et al., 1997a,b).

In a glasshouse experiment at SASRI, Xanthopimpla stemmator (Thunberg) (Hymenoptera: Ichneumonidae) parasitised more E. saccharina pupae in sugarcane in close proximity to this grass, than in sugarcane only (Figure 1) (Kasl, 2004). This suggests that the searching behaviour of the parasitoid was increased by Melinis volatiles.
The next phase in developing this habitat management approach for *E. saccharina* was to set up field trials using rows of *M. minutiflora* along either in irrigation or contour breaks as a repellent or ‘push’ plant. *E. saccharina* populations and damage were halved in field plots planted next to strips of *M. minutiflora* compared to control plots, suggesting that the pest was repelled by *Melinis* volatiles (Figure 2) (Barker *et al*., 2006). Planting *Cyperus papyrus* as a trap, or ‘pull’ plant along drainage lines of selected sugarcane fields resulted in significantly reduced damage in the cane associated with it (Figure 3) (Kasl, 2004).

Fig. 1—Total *Eldana saccharina* pupae parasitised by *Xanthopimpla stemmator* when offered on companion plants (unshaded bars) and on sugarcane (shaded bars). Total number of parasitised pupae, from 100 pupae offered per experiment, indicated by circular points. Plants were tested in two groups. (K–Kenyan; S–South African; A–Australian) (from Kasl, 2004).

Fig. 2—Mean percent internodes damaged and *E. saccharina* numbers in cane planted with (at 20 row intervals) and without *Melinis minutiflora* (differences significant at *p* < 0.001 within each measure) (from Barker *et al*., 2006).
Fig. 3—Monthly damage levels in sugarcane (var. NCo376) adjacent to Cyperus papyrus stands (shaded bars), and in control sugarcane not associated with C. papyrus (unshaded bars). * Means (+1 SD) significantly higher in paired tests at $\mu = 0.05$ (from Kasl, 2004).

Based on the success of these trials, a farm based habitat management plan has been devised, incorporating indigenous host plants and Bt maize as ‘pull’ plants for *E. saccharina* and *M. minutiflora* as the ‘push’ component. This bio-intensive approach has been expanded into a Bio-intensive-IPM plan, incorporating plant nutrition, soil health and the use of less susceptible sugarcane varieties (Figures 4 and 5).

An added aspect to the plan is to plant buckwheat at the time of sugarcane planting. This is to attract adult parasitoids and predators into the sugarcane environment by providing a pollen and nectar source for their survival during periods of low host availability, much the same as advocated
by Wäckers et al. (2005) and Zehnder et al. (2007) in their conservation biological control approach to enhance the activity of indigenous natural enemies.

**Does sugarcane emit SOS volatiles when attacked by *E. saccharina***?

In contrast to the situation in the natural hosts of *E. saccharina*, negligible parasitism has been recorded in sugarcane, even when this crop was planted adjacent to infested indigenous host plants with abundant parasitoids present (Conlong and Hastings, 1984). Many introduced parasitoids have also failed to colonise the sugarcane habitat (Conlong, 1997).

Using gas chromatography, Smith et al. (2006) showed different volatile emission patterns between *Cyperus papyrus* infested by *E. saccharina* and uninfested *C. papyrus*. Infested sugarcane was neither qualitatively or quantitatively different from uninfested sugarcane and both were different from *C. papyrus* (Figure 6). In addition, these authors showed that the parasitoid *Goniozus indicus* (Ashmead) (Hymenoptera: Bethylidae) was attracted to frass from *E. saccharina* that had...
fed on *C. papyrus*, and was not attracted to frass from *E. saccharina* that had fed on sugarcane. Adding this to the lack of parasitism recorded in sugarcane, even in the vicinity of natural host plants harbouring parasitoids, suggests that modern sugarcane genotypes may not attract natural enemies through the release of herbivore induced SOS volatiles, or that they may differ in the ability to do so.

![Fig. 6—Gas chromatograms of volatiles released by (a) uninfested *C. papyrus*, (b) infested *C. papyrus*, (c) uninfested sugarcane variety N11 and (d) infested sugarcane variety N11 (Ψ= compounds showing major differences–volatiles were not identified) (from Smith et al., 2006).](image)

**Genotypic differences in plant volatile emission**

The ability to mount indirect defence against *E. saccharina* may have been lost in sugarcane as a result of inadvertently concentrating on direct resistance in a monoculture oriented plant breeding selection program. Besides this possibility, the release of plant volatiles is characterised by a large degree of genotypic variation within plant species, for example, maize genotypes and their closest wild relatives, *Zea mays* ssp. *parviglumis* and *mexicana* (collectively known as teosinte), show significant differences in emissions when attacked (Gouinguene et al., 2001; Degen et al., 2004).

An example of loss of indirect defence has been found below ground in maize. In response to feeding by the western corn rootworm, *Diabrotica virgifera virgifera* (LeConte) (Coleoptera: Chrysomelidae), maize roots release (E)-b-caryophyllene that attracts the entomopathogenic nematode *Heterorhabditis megidis* (Rasmann et al., 2005). Most North American maize lines do not release (E)-b-caryophyllene in response to rootworm attack, whereas many European lines and teosinte accessions do (Kollner et al., 2008).

The existence of genotypic differences in the emission pattern of volatile compounds for Kenyan *M. minutiflora* cultivars has also been demonstrated (Gohole et al., 2003). The lack of response by *X. stemmator* in the presence of Australian *M. minutiflora* again points to variability within this species (Figure 1). Australian *M. minutiflora* is extensively used for cattle fodder. The strong odour of the plant can be carried through to milk and, because of this, there has been an
extensive program to breed a less volatile variety with similar nutritional quality. The volatile(s) that the parasitoid responded to in the African variety could have been bred out of the Australian variety, as explained by Pickett and Woodcock (1993).

**Breeding for artificially primed and induced resistance**

The loss of the ability to produce an SOS volatile and the observed genotypic variability in their production by maize points towards the exploitation of the phenomenon in sugarcane, by breeding varieties for enhanced attractiveness to natural enemies (Bottrell et al., 1998). This could be achieved through the application of an artificial elicitor followed by selection for enhanced direct and indirect resistance in a system that includes natural enemies.

Experimental application of elicitors is fairly simple and it is worth trying to make selections among plant breeding lines grown under the influence of plant defence elicitors, aiming for new cultivars optimised for artificially inducible resistance traits without significant yield penalty (Agrawal et al., 2002; Ahman, 2006). Historically, induced resistance research has mostly concentrated on direct activation where resistance is expressed in advance of challenge by the pest. The possibility of priming as a mechanism of protection has often been overlooked because it only becomes apparent in challenged plants. Priming equates to a ‘heightened state of readiness’, in that in the event of damage to a primed plant, resistance responses are faster and more intense (Conrath et al., 2006).

Direct activation of resistance might best be employed where the target pest is widespread and has predictable outbreaks. An example is the sugarcane thrips, Fulmekiola serrata (Kobus) (Thysanoptera: Thripidae) that affects more than two thirds of sugarcane plants in a particular field at the same time. Outbreaks occur in summer with numbers peaking every January since the pest was first discovered on the African continent in 2004 (Way et al., 2006). Primed resistance would, however, be more suitable for E. saccharina, since a much lower proportion of plants is attacked and infestations tend to be patchy.

**Ecology and phylogeography**

The basic building block of IPM is still regarded as ecology (Gurr et al., 2003). In a study of E. saccharina, Conlong (2001) found behavioural, host plant and natural enemy differences in populations occurring between South, Central and West Africa, with them seemingly coming together in Uganda.

These confusing factors between different populations of what is otherwise a morphologically similar species made it an ideal candidate for molecular systematic analyses. Assefa et al. (2006), using the cytochrome oxidase subunit 1 (CO1) region of the mitochondrial genome, separated E. saccharina into three distinct groups (west, south and Ethiopian). Two of these groups (west and south) were found in Uganda.

The CO1 genetic diversity between these groups was larger than that between recognised species within the genus Ostrinia (Lepidoptera: Crambidae) (Coates et al., 2005). In other insects, unexpected mtDNA CO1 patterns have led to the discovery of cryptic species (Hebert et al., 2004; Smith et al., 2007). Such diversity should encourage us to confirm covarying genetic, behavioural and ecological characteristics which would lend support to the notion that cryptic species exist within the E. saccharina complex.

In IPM programs which use classical biocontrol as one of their management options, or translocation of natural enemies (Schulthess et al., 1997), these aspects can be enhanced by using such techniques to identify cryptic species, or populations of species most closely related to each other, so that more informed decisions can be made regarding natural enemy selection for use against pests. This applies not only to pest species, but also to parasitoids (Dittrich et al., 2006; Muirhead et al., 2006; Ngi-Song et al., 1998).
Since 1992, surveys for indigenous parasitoids of *E. saccharina* in a variety of African habitats have been completed. Thirty species of larval parasitoids have been found in eight countries (Conlong, 2000). Several of these have failed to parasite *E. saccharina* from South Africa due to incompatibility. For example, from West Africa, *Descampsina sesamiae* (Diptera: Tachinidae) larvae are encapsulated by *E. saccharina* (Conlong, 1997). *Cotesia sesamiae* (Cameron) (Hymenoptera: Braconidae) from South Africa is also unsuccessful as eggs are encapsulated (Potting *et al*., 1999). Further collections of parasitoids from Central Africa, where southern and western populations of *E. saccharina* co-exist, could reveal biotypes of parasitoids that could be effective against this pest (Muirhead *et al*., 2006; Ngi-Song *et al*., 1998).

**Wolbachia**

These obligate intracellular bacteria (Phylum α-Proteobacteria: Family Rickettsaceae) are commonly found in diverse insect taxa and can profoundly alter their host’s reproduction. They are maternally inherited, residing mostly in the reproductive tissues of their hosts and it has been suggested that they may infect over 70% of arthropod species worldwide (Jeyaprakash and Hoy, 2000).

In their reviews on the biology of *Wolbachia*, Werren (1997), Floate *et al.* (2007) and Bourtzis (2007) all regard the symptoms of infection such as feminisation of genetic males, male embryo killing and cytoplasmic incompatibility (CI) as potentially useful characters for insect population regulation. Attempts have been made to exploit CI as a method to suppress natural populations of pests in a way analogous to the sterile insect technique through the release of incompatible infected male insects (Brower, 1980). Alternatively *Wolbachia* could be introduced into South African *E. saccharina* (populations of which are currently free of infection) using hybrid introgression and field release.* Wolbachia* have potential as a new type of biological control agent by altering the reproductive success of their hosts and probably also that of parasitoids (Fytrou *et al*., 2006).

Recent results (Rutherford, unpublished) have confirmed the presence of *Wolbachia* in *E. saccharina* from Kenya, Uganda and Tanzania, all close to the probable centre of origin for *E. saccharina*, while it is absent from *E. saccharina* populations in western and southern Africa. This now opens up the potential use of *Wolbachia* in our IPM strategy.

**The interaction between *E. saccharina* and *Fusarium***

When *E. saccharina* bores in sugarcane, the tissue surrounding the boring becomes reddish discoloured often affecting a whole internode. Following on from this, and work of Schulthess *et al.* (2002), McFarlane *et al.* (2009) cultured numerous *Fusarium* spp. isolates, from the red tissue surrounding *E. saccharina* borings, as well as from undamaged stalks as endophytes. Most of the isolates from borings were beneficial to *E. saccharina* in artificial diet in terms of larval survival and growth rate, and were attractive to neonates in olfactory choice assays. A few of the endophytic isolates were antagonistic, with *E. saccharina* neonates repelled and growth retarded. Moths may also be attracted or repelled depending upon isolate. Ako *et al.* (2003) showed that West African *E. saccharina* females laid on average 32 eggs on maize stalks with *F. verticillioides* present as an endophyte, versus nine on stalks grown from fungicide or hot water treated seeds.

In an integrated control approach against *E. saccharina*, seedcane hot water treatment and/or treatment with fungicides could reduce endophytic colonisation by *Fusarium* isolates beneficial to *E. saccharina*, thereby reducing the chance of infestation. Alternatively, the facilitation of endophytic colonisation of sugarcane by *Fusarium* isolates antagonistic to *E. saccharina* could afford more sustainable and environmentally friendly protection from this stalk borer. Another approach could be to exploit the differences in volatiles between repellent and attractive isolates in the development of repellents and lures of use in the field.
Concluding remarks

Khan et al. (1997a) described a ‘push–pull’ system effective against cereal stem borers in maize. This system includes the indigenous parasitoid Cotesia sesamiae as well as C. flavipes which was introduced against the exotic Chilo partellus (Overholt et al., 1997). C. sacchariphagus, now present in Mozambique, is being parasitised by both C. flavipes and X. stemmator on larvae and pupae respectively in sugarcane (Conlong, pers.comm). Ngumbi et al. (2005) showed that C. flavipes females respond to terpenoids and the green leaf volatiles which are released by maize plants damaged by C. partellus. This suggests that sugarcane may produce SOS volatiles in response to C. sacchariphagus.

There are alternative hypotheses to that of loss of ability to produce SOS volatiles. By boring the tops of stalks and leaf spindles in young cane, volatile emission could be elicited by C. sacchariphagus, whereas E. saccharina may avoid eliciting volatile emission by boring the bottoms of stalks in older cane. Another hypothesis is that the Fusarium associated with E. saccharina could interfere with the elicitation of volatile emission or change the composition of emitted volatiles. These possibilities are worthy of further investigation.

Nevertheless, a bio-intensive IPM strategy could be made more effective if the crop itself is capable of releasing appropriate SOS volatiles when attacked. Breeding varieties for enhanced attractiveness to natural enemies has potential if natural enemies are already present in the habitat management system. Goniozus indicus parasitises E. saccharina in C. papyrus. It is also known to parasitise C. partellus (Keiji and Overholt, 1996) and has been found doing so in Sorghum arundinaceum growing in proximity to C. papyrus (Conlong, 1994; 1997). It is therefore possible that G. indicus could parasitise both C. sacchariphagus and E. saccharina in sugarcane. The same applies to the pupal parasite X. stemmator.

Conlong et al. (2004) showed that some of the varieties with the highest direct resistance to E. saccharina were the most susceptible to C. sacchariphagus and vice-versa. This has implications for variety choice in an IPM system designed to target both pests simultaneously, should C. sacchariphagus invade the South African sugar industry. Given increasing adoption of the ‘push-pull’ habitat management concept even in the absence of parasitoid activity against E. saccharina in sugarcane, and its success against C. partellus in maize, we are confident that ‘push-pull’ habitat management will also be effective against C. sacchariphagus.

The development of IPM strategies depends on a sound understanding of the chemical ecology of pest interactions with sugarcane, natural enemies and the habitat. Modern IPM is not only about insect/plant interactions, it is about holistic agro-ecosystem interactions, in which increased knowledge about the environment, soils, plants, pathogens, endophytes, symbionts and insects are all combined to provide effective crop protection in an environmentally friendly manner.

As knowledge about, and interactions between, induced plant resistance, chemical ecology, micro-organisms such as endophytic fungi and Wolbachia, and phylogenetics and phylogeography of arthropods becomes more easily available, it is hypothesised that these will become important components of bio-intensive AW-IPM, thereby minimising the impacts of synthetic pesticides even more (Conlong and Rutherford, 2009).

Résumé

LA DEFINITION la plus courante de la lutte intégrée contre les ravageurs (IPM) est « le processus décisionnel de gestion des ravageurs sur la base de stratégies multiples afin de prévenir les attaques avec des conséquences économiques, tout en réduisant les risques à la santé humaine et à l’environnement ». L’IPM de faible niveau est la forme la plus couramment utilisée, comprenant les pratiques de base de l’IPM – prospections et applications des insecticides en conformité avec les seuils économiques. Certains planteurs ont progressé jusqu’au niveau intermédiaire de L’IPM en adoptant quelques pratiques préventives additionnelles, comme les pratiques culturales et les variétés résistantes, en plus des efforts visant à diminuer les applications de pesticides à large spectre dans le but de protéger les organismes bénéfiques. Ces stratégies de l’IPM se focalisent principalement à une espèce de ravageur et ne considèrent pas l’ensemble des ravageurs d’un agro-écosystème spécifique. Par contre, l’IPM de haut niveau ou bio-intensif comprend des interventions multiples qui sont intégrées dans une approche ciblant plusieurs ravageurs. L’IPM bio-intensif est basé sur les interactions holistique de l’agro-écosystème, dans lequel la connaissance des insectes, leurs symbiontes, les pathogènes, les ennemis naturels, les plantes, les endophytes ainsi que leurs interactions, sont combinés pour développer un IPM adéquat tout en étant respectueux de l’environnement. Les avancées de nos connaissances sur les interactions biotiques directes et indirectes, l’induction de la résistance, la nutrition de la plante, la gestion de l’habitat, l’écologie chimique, les ennemis naturels, la qualité biologique du sol, les microorganismes comme les champignons endophytes, la bactérie Wolbachia, la phylogénétique et la phylogéographie sont passés en revue ici. Tous ces thèmes sont des composantes potentielles d’un système IPM bio-intensif en développement au SASRI. Les opportunités et défis dans ces thématiques de recherche sont aussi élaborées, en tenant compte des menaces de biosécurité à l’industrie sucrière d’Afrique du Sud et les limitations possibles du matériel génétique pour l’amélioration de la canne à sucre.

Resumen
LA DEFINICIÓN convencional más común de Manejo Integral de Plagas (MIP) es ‘un proceso de
toma de decisiones usando tácticas de manejo múltiples para prevenir brotes de insectos que causen
daño económico mientras se reducen los riesgos a la salud humana y al ambiente’. El MIP de bajo
nivel es la forma más común empleada, y consiste en el uso de las practicas básicas de monitoreo y
aplicaciones de insecticidas de acuerdo con umbrales económicos. Algunos cultivadores han
progresado a un nivel medio de MIP, la adopción de unas pocas medidas preventivas adicionales,
p. e., control cultural y resistencia de plantas, acopladas con esfuerzos de reducir el uso de
plaguicidas de amplio espectro con el fin de proteger organismos benéficos. Estas estrategias de
MIP son principalmente dirigidas hacia una sola especie de insecto y sin considerar todas las plagas
de un agro ecosistema en particular. Alto – nivel o MIP Bio – intensivo, en donde muchas
intervenciones se integran en un enfoque Bio- intensivo enfocándose a muchas plagas. MIP Bio –
intensivo se basa en interacciones holísticas del agro ecosistema, en las cuales el conocimiento de
los insectos, sus simbiontes, patógenos, enemigos naturales, plantas, endofíticos e interacciones
entre todos estos enfoques se combinan para desarrollar el MIP en un área amplia, de una manera
amigable con el ambiente. Por tanto, aquí se revisan los avances en el conocimiento de y de las
interacciones bióticas entre directas, indirectas y resistencia inducida en plantas, nutrición de las
plantas, manejo del hábitat, ecología química, enemigos naturales, sanidad del suelo,
microorganismos tales como hongos endofíticos, Wolbachia, la filogenia y filogeografía. Todos
estos son componentes potenciales para construir un sistema de MIP Bio – intensivo en SASRI.
También se discuten las oportunidades y desafíos en estas áreas de investigación, tomando en
consideración amenazas de bio seguridad a la industria azucarera de Sur África y las posibles
limitaciones a los actuales materiales de mejoramiento de plantas de caña de azúcar.
IMPACT OF GLOBALISATION ON SUGARCANE PESTS,
BIODIVERSITY AND THE ENVIRONMENT:
A REVIEW OF THE 2009 ENTOMOLOGY WORKSHOP

KEYWORDS: Biological Control, Pest Management,
Insect-Plant Interactions, Yield Losses, Biological Studies.

Abstract

The 7th International Society of Sugar Cane Technologists (ISSCT) Entomology Workshop was held from 20 to 24 April 2009 in San Miguel de Tucumán, Argentina under the theme: ‘Impact of Globalisation on Sugar Cane Pests, Biodiversity and the Environment’. Technical sessions held over three days were grouped into five subject headings: biological control of sugarcane pests; pest management; insect-plant interactions; losses due to sugarcane pests; and biological studies of sugarcane pests. Following the technical sessions, field trips allowed delegates to view important insect pests of the Argentine sugarcane industry in the field and visit the Estación Experimental Agroindustrial Obispo Colombres, as well as cultural sites in the region surrounding San Miguel de Tucumán. The Entomology section concluded that globalisation will most likely continue to impact on the world’s sugarcane industries. The ISSCT Entomology Workshops will therefore become increasingly important as a venue for entomologists to stay abreast of impending insect threats to their industries and to keep current with new technologies that will be vital for managing potential new invaders as well as maintaining sustainability.

Introduction

The 7th ISSCT Entomology Workshop was held from 20 to 24 April 2009 in San Miguel de Tucumán, Argentina. The Estación Experimental Agroindustrial Obispo Colombres hosted the workshop that enabled entomologists from 11 countries to share research findings under the theme: ‘Impact of Globalisation on Sugar Cane Pests, Biodiversity and the Environment’. Seventeen technical presentations were made during the first three days of the workshop. The presentations covered the topics of biological control of sugarcane pests, pest management, insect-plant interactions, losses due to sugarcane pests, and biological studies of sugarcane pests. As always, an active discussion period was held at the end of each session.

A series of field trips was provided to complement the technical sessions. One day was set aside to visit selected field sites. One stop highlighted the clean seed program that provided micro-propagated seed to participating growers. At other sites, delegates were able to view damage caused by the stem borer Elasmopalpus lignosellus and, at another, the stem borer Diatraea saccharalis.
The final stop was at a commercial field where delegates were able to view damage by the weevil *Acrotomopus actropunctellus*. Lunch was provided by a local mill. The mill manager spoke to the group about processing and also enlightened the group about a consortium of mills planning to venture into the area of ethanol production. The following day the delegates were given a tour of Estación Experimental Agroindustrial Obispo Colombres. This experiment station is one of the oldest in the world and coincidently is celebrating its centenary year in 2009. During the field tours, the delegates visited the region around San Miguel de Tucumán that included a visit to an archaeological site once inhabited by the indigenous people of this region of Argentina.

**Opening**

Dr Daniel L. Ploper, Head of the Estación Experimental Agroindustrial Obispo Colombres, opened the meeting by stressing the importance of the ISSCT workshops as venues for scientific exchange and the establishment of scientific contacts. Eng. Carlos Mirande, ISSCT Councillor from Argentina [Sociedad Argentina de Tecnico de la Caña de Azucar (S.A.T.C.A.)] and Mr Juan José Budeguer, president of the Board of Estación Experimental Agroindustrial Obispo Colombres also welcomed the attendees to the workshop and expressed their desire for a successful meeting. Dr Silverio Flores Cáceres, Honorary President of the 2010 ISSCT Congress, also welcomed delegates and encouraged all to come to Veracruz, Mexico in 2010. Dr William White, Entomology Section Committee Chairman, presented a historical review of the Entomology Workshops beginning with the first workshop held in 1991. He encouraged everyone to actively participate in the discussions as all could contribute to the workshop and their participation was important to group synergy.

**Biological control of sugarcane pests**

Biological control continues to be an important component of pest management by the world’s sugarcane industries. Even an industry like Louisiana that relies heavily on insecticides to control its key insect, *Diatraea saccharalis*, has found that the use of green chemistry can have a profound positive impact on beneficial insects inhabiting sugarcane fields. Researchers in Louisiana found that, following the labelling and wide-spread use of the insect growth regulator (IGR) tebufenozide, the carabid beetle *Leptotrachelus dorsalis* is now able to successfully exploit sugarcane fields once denied it by broad spectrum contact insecticides. This beneficial insect appears to be a good candidate for future research in biological control in Louisiana.

While the impact of biological control in the field is often reported, the socio-economic impact of biological control is often under-publicised. In one documented case in Thailand, total benefits of US$224-473 per hectare were realised with cost:benefit ratios of 0.12 and 0.33. The additional benefits to the environment and human health have not yet been taken into account.

*Cotesia flavipes* remains an important biological control agent of stem borers around the world. However, advances in mass rearing are needed to reduce the time and financial investment required to produce this parasitoid. Researchers in Argentina have found that production of cocoons was 8% higher following one inoculation rather than two. They also found that stinging 18 and 19 day-old larvae produce the most adults and female moths, while the ratio of males:females decreased from larvae 17 days old to 21 days.

Thailand has five important species of lepidopterous stem borers: *Chilo tumidicostalis, C. infuscatusellus, C. sacchariphagus, Sesamia inferens,* and *Scripophaga excerptalis*, as well as a longhorn beetle stem borer, *Dorysthenes buqueti*. Fortunately, a number of beneficial insects are present for biological control. These beneficial insects plus the stage of growth and nutritional condition of the cane plants play an important role in determining the level of damage incurred by Thai cane growers.

French researchers from INRA, FDGDON and CIRAD have developed an effective program for controlling the stem borer *C. sacchariphagus* on Réunion Island with the egg parasitoid, *Trichogramma chilonis*. However, they too are searching for ways to improve efficiency
of mass propagation of the parasitoid so that overall costs associated with the program can be lowered. Their approach is to develop cold-storage technology. Initial results have already defined biotic and abiotic parameters required for successful storage for up to two months.

**Pest management**

The main sugarcane pests in Mauritius are the stem borer *Chilo sacchariphagus*, the armoured scale *Aulacaspis tegalensis*, the soft scale *Pulvinaria iceryi*, the white grub *Heteronychus lica*, and armyworms *Mythimna* spp. Mauritius has a long history of successful biological control of these pests. However, with increased mechanisation of field operations to reduce production costs, major changes are occurring in the sugarcane landscape, causing a shift from a diverse habitat to one where sugarcane monoculture predominates. Researchers are investigating ways of creating conservation areas and undisturbed areas that would enhance the natural enemy populations and thus control incipient outbreaks of the pests.

The sugarcane leafhopper *Perkinsiella saccharicida* continues to be an important pest in Ecuador. While researchers continue to look for new and more effective biological control agents, an integrated pest management (IPM) approach that includes use of insecticides appears to be the approach most likely to succeed. However, insecticide application must be done in such a way as to minimise the risks to natural enemies.

Entomologists in South Africa are also focusing on an IPM approach with combinations of varietal resistance, cultural (planting date manipulation) and insecticide options to manage sugarcane thrips, *Fulmekiola serrata*. Research continues to be conducted to determine just how much yield loss is associated with thrips feeding.

White grubs continue to be the most important pests of sugarcane in Australia. Many growers in Australia are adopting new farming practices, i.e. legume rotations, controlled traffic and minimum tillage for economic and agronomic reasons and this may have positive or negative effects on white grub populations and damage. Existing insecticide recommendations may also be affected. Results of field trials are being included in guidelines for growers to manage white grubs in these systems.

**Insect-plant interactions**

Sugarcane is attacked by a complex of insect pests including stalk borers and leaf-sucking insects. In the U.S., two of these insect pests, the Mexican stem borer *Eoreuma loftini* and the sugarcane aphid *Melanaphis sacchari*, conform in their herbivore-plant interactions to the plant stress hypothesis.

The plant stress hypothesis predicts that environmental stresses on plants decrease plant resistance to insect herbivory by altering biochemical source–sink relationships and foliar chemistry, leading to more palatable food.

High-performance liquid chromatography analysis of whole leaf tissues indicates that several essential free amino acids increased in sugarcane leaves under drought stress. This increase was also associated with enhanced Mexican rice borer oviposition and injury.

Analysis of phloem sap composition of susceptible and resistant varieties revealed that two essential free amino acids (histidine and arginine) were missing in the phloem sap of an aphid-resistant variety. This change in amino acid content may also be associated with plant stress.

While *E. loftini* is a pest of stressed sugarcane, the stem borer *Diatraea saccharalis* is a pest of vigorously growing cane. Work in Argentina was conducted to investigate if fertilisation rates were associated with *Diatraea saccharalis* infestations.

When plots were fertilised with half of the standard rate, no differences were found between treated and control plots with respect to infestation levels. The researchers concluded that the gains in yield from proper fertilisation are greater than any increase in damage by the sugarcane borer.
Losses due to sugarcane pests

Assessing the losses due to insect feeding is a critical component in pest research. Dispersion of scarce research funds, as well as establishing action thresholds and other IPM management decisions, all depend on evaluations of pest losses. The sugarcane borer, *Diatraea saccharalis*, is the most important insect pest in Tucumán. Researchers there evaluated three varieties and determined field and factory losses due to this stem borer. Losses of 0.42% in stalk weight and 0.20% in pol of sugarcane were observed for each 1% increase in bored internodes.

In general, foliar feeding by insects is not considered to cause economic losses. However, in Argentina, the grassworm looper, *Mocis latipes*, appears to be an exception to this rule, with results from two separate studies being reported at the workshop. One study measured reductions in stalk weight of 11.3 to 41.2%, height of 1.7 to 20.7%, sugar content of 0.8 to 4.2%, and sugar yields of 13.9 to 42.9% while, in the second study, the average reduction in sugar yield was 58.3%. These studies indicate that the grassworm looper is capable of producing significant losses in sugar production. The differences in yield losses can be explained by cane variety and age of cane at attack.

Biological studies of sugarcane pests

Ecology processes take place within a spatial context, and the distribution of habitat may strongly impact the distribution, dynamics and evolution of natural populations. Today, the effective management of major insect pests requires an understanding of ecological processes involved in agroecosystem-insect pest interactions including the surrounding landscapes. With the growing use of remote sensing and electronic- and computer-based technologies in pest management, there is a real opportunity to understand the temporal and spatial movements of the insect populations as never-before possible. In Australia, a joint project is underway between CIRAD and BSES using new tools such as radiotelemetry, GIS and simulation models to unravel the spatial ecology of the white grub *Dermolepida albohirtum*.

Three species of leafhoppers, *Tomaspis nonozulia, T. australis* and *Tapajosa rubromarginata*, infest sugarcane fields in the Province of Jujuy, Argentina. These insects appear to have become important as pests with the adoption of green harvest and drip irrigation systems. Research has shown that the environmental factor that has the greatest adverse effect on population development is low precipitation during December.

When new pests are discovered attacking the sugarcane crop, rapid identification of the species and elucidation of basic pest biology are important early considerations. In 2003, while monitoring infestations of *Diatraea saccharalis* in Tucumán, a coleopteran larva was found in stalks causing damage similar to that produced by the *D. saccharalis*. Specimens were sent to the Museo de Ciencias Naturales in La Plata, Buenos Aires for identification. Dr Analía Lanteri identified the beetle as *Acrotomopus actropuntellus* (Coleoptera: Curculionidae). This weevil was previously cited by Jaynes in 1929 as occurring in sugarcane fields in Tucumán and Jujuy. The larvae feed on basal internodes, building wide and tortuous galleries, and also weaken the rootstocks where they hibernate. The insects colonise new fields mainly by the movement of seed-cane. Research continues on this emerging pest as its damage is frequently confused with that of the sugarcane borer and has likely been underestimated.

Conclusions

Globalisation is the integration of economic, political, and cultural systems around the world. It can be a force for economic growth but can also have an adverse impact on local agriculture by facilitating the introduction of insect pests and reducing biodiversity, thus increasing the frequency of pest outbreaks. Sugarcane industries will require their entomologists to react to the negative effects of globalisation by maintaining sustainability of their home industries. The ISSCT Entomology Workshops continue to be ideal forums to obtain knowledge on the most recent control
strategies, emerging pest developments and threats, and new technologies useful in unravelling difficult pest, host, and environmental inter-relationships. The 7th ISSCT Entomology Workshop was successful in meeting its obligations to those delegates investing the time and money to attend. Maintaining a high level of knowledge transfer remains an important challenge for organisers of future workshops as travel budgets diminish. Organisers must work hard to attract entomologists from developing and emerging countries, as well as provide services to sugarcane entomologists beyond the workshops, e.g. updating pest compendiums and forming consortiums to provide services unattainable to research institutions working alone.

Acknowledgments

The 7th ISSCT Entomology Workshop was hosted by the Estación Experimental Agroindustrial Obispo Colombres and its representatives Dr L. Daniel Ploper (Director Technico) and Mr Juan José Budeguer (President of the Board of Directors). The workshop was conducted under the auspices of the International Society of Sugar Cane Technologists and the Sociedad Argentina de Tecnicos de la Caña de Azucar (S.A.T.C.A.). The members of the local organising committee were L. Daniel Ploper, Eduardo Willink, Jorge Scandaliaris and Analía Salvatore, with Maria Teresa Vera serving as local coordinator. Support was also provided by Syngenta SA, Instituto de Desarrollo Productivo (IDEP), and Universidad San Pablo Tucumán. These individuals and entities are gratefully acknowledged by the participants, for without them the workshop would not have occurred nor have been so successful.

L’IMPACT DE LA GLOBALISATION SUR LES RAVAGEURS DE LA CANNE À SUCRE, LA BIODIVERSITÉ ET L’ENVIRONNEMENT : UNE REVUE DE L’ATELIER D’ENTOMOLOGIE EN 2009

Résumé

Le 7ème Atelier de Travail d’Entomologie de l’International Society of Sugar Cane Technologists (ISSCT) a eu lieu du 20 au 24 avril 2009 à San Miguel de Tucumán, en Argentine, ayant pour thème: «L’impact de la Globalisation sur les Ravageurs de la Canne à Sucre, la Biodiversité et l’Environnement». Les sessions techniques se sont déroulées pendant trois jours et étaient regroupées sous les thèmes suivants: la lutte biologique contre les ravageurs de la canne à sucre; la gestion des ravageurs; les interactions insecte-plante; les pertes occasionnées par les ravageurs; et les études biologiques des ravageurs de la canne. Après les sessions techniques, des visites aux champs ont permis aux délégués d’observer les ravageurs principaux de l’industrie sucrière d’Argentine et de visiter l’Estación Experimental Agroindustrial Obispo Colombres, aussi bien que
les sites culturels de la région de San Miguel de Tucumán. La Section d’Entomologie de l’ISSCT est arrivée à la conclusion que très probablement, la globalisation continuera à affecter l’industrie cannière dans le monde. Les ateliers d’Entomologie seront donc encore plus pertinents comme lieu de rencontre pour que les entomologistes puissent prendre connaissance des derniers développements, en particulier les menaces immédiates des ravageurs sur leurs industries. De plus, ils leur permettront de se familiariser avec de nouvelles technologies, essentielles pour gérer les envahisseurs potentiels et maintenir une lutte durable contre les ravageurs.

Resumen

El 7th Taller Internacional de Entomología de la Sociedad de Técnicos de la Caña de Azúcar se llevó a cabo entre el 20 y 24 de abril de 2009 en San Miguel de Tucumán, Argentina bajo el lema: “Impacto de la globalización sobre las plagas de la caña de azúcar, biodiversidad y ambiente”. Se desarrollaron sesiones técnicas durante tres días agrupadas en cinco temáticas tituladas: control biológico de las plagas de la caña de azúcar, manejo de plagas, interacciones de insectos y plantas, pérdidas debidas a plagas de la caña de azúcar, y estudios biológicos de plagas de la caña de azúcar. A continuación de las sesiones técnicas, se programaron viajes de campo para permitir a los delegados ver insectos plagas importantes de la industria de la caña de azúcar de Argentina y visitar la Estación Experimental Agroindustrial Obispo Colombres, así como sitios culturales en la región cercana a San Miguel de Tucumán. La sección de Entomología concluyó que la globalización muy probablemente continuará impactando las industrias en el mundo de la caña de azúcar. El taller de ISSCT en Entomología seguirá incrementando su importancia como una herramienta para que los entomólogos se mantengan alertas e impidan las amenazas de los insectos a sus industrias y para mantenerse actualizado sobre nuevas tecnologías que serán vitales para manejar nuevos invasores potenciales así como para mantener la sostenibilidad.
SUGAR LOSSES CAUSED BY THE SUGARCANE BORER
(DIATRAEA SACCHARALIS) IN TUCUMÁN, ARGENTINA

KEYWORDS: Sugarcane, Diatraea saccharalis, Losses.

Abstract

The sugarcane borer, Diatraea saccharalis is the most damaging pest of the sugarcane in Tucumán Province. Galleries produced in the stalk by the larvae are gateways to pathogens. Their effect generates losses in stalk weight, and reduces the quality and amount of sucrose and juice extraction in factories. The objective of this study was to evaluate the losses caused by Diatraea saccharalis on three sugarcane varieties and on cane under storage. During the 2005 harvest seasons, observations with three commercial varieties, LCP 85-384, TUCCP 77-42, and CP 65-357, detected significant losses on field and factory yield. Reductions of 0.42% in the stalk weight and 0.20% in pol were observed for each 1% attack, producing a 0.22% loss for each point of infestation loss on the factory yield, with a 620 to 650 g/t of cane loss of sugar, depending on the variety. In addition, the variety LCP 85-384 was assayed at three different dates: June, August and October, during the 2006 harvesting season, to evaluate the effect of storage on losses following D. saccharalis attack. Sugar losses were much greater after 4 days post harvest storage. This difference was higher as the harvest season progressed.

Introduction

The sugarcane borer, Diatraea saccharalis (F.), is the most damaging sugarcane pest in Tucumán province. Adult moths oviposit on sugarcane leaves. Eggs may be laid singly or in masses, and early instar larvae feed cryptically on leaves, whorls, or other succulent plant tissue. Young shoots die, since D. saccharalis bores into primary shoots killing the apical meristem, which reduces the number of millable stalks per unit area (McGuire et al., 1965). Older larvae, generally third instar and older, feed almost exclusively within tunnels in stalks; there, they are protected, making it difficult to control the insect with contact insecticides.

Pupation occurs within chambers constructed by mature larvae, often leaving an emergence hole, covered with a thin layer of plant tissue that can be pushed open to allow the adult moth to emerge from the stem. D. saccharalis causes damage throughout the year, from sugarcane germination to harvesting time. In addition to killing shoots, the galleries in stems open the way for several pathogenic microorganisms which destroy the sugar stored in stalks (Smith et al., 1993).

In the Lower Rio Grande Valley of Texas, the Crambine stalkborers Eoreuma loftini (Dyar) and D. saccharalis damage 20% of sugarcane internodes annually (Legaspi et al., 1999). These authors also quantified the relationships between stalkborer damage and sugar yield and quality to estimate the monetary loss incurred at these levels of damage, with sugar losses of 108 g/kg cane.
In Cuba, losses attributed to *D. saccharalis* were estimated at 20% of sugar production (Gallo *et al.*, 1988). In Cuba, Barreto (1954) found a reduction of 0.02329% sucrose per 1% increase in bored internodes. In Mexico, Ruiz *et al.* (1968) estimated a loss of 1.68 lbs sucrose/ton sugarcane per 1% of increase in bored stalks.

In Argentina, one key factor that can decrease yields is sugarcane storage after harvest and before crushing in the mills (Romero *et al.*, 1990). This practice is common due to the diversity in the harvest and transport systems used and the dynamics of reception of the raw material at the mill. Cane harvested with traditional methods (not under green cane harvesting conditions) can be stored in Tucumán from 3 to 7 days, with weight losses up to 1.46% per storage day being reported, although this varied along the harvest season (Romero *et al.*, 1993). No data exist on the impact of sugarcane storage at different infestation levels of *D. saccharalis*.

The objective of this study was to evaluate the losses caused by *Diatraea saccharalis* on three sugarcane varieties throughout the harvesting season and the impact of sugarcane storage before crushing on yields.

**Materials and methods**

To assess losses, three major varieties at various infestation levels were analysed throughout the harvest season. Considering storage, one variety was sampled at various infestation levels during three periods of the harvest season, and sugar production measured at 1 day and 4 days after sampling.

Sugarcane samples were collected from Fronterita (Famailla Departament, Tucumán) sugar factory fields. Samples were weighed, juice was extracted and analysed and sugarcane pol %, brix and fibre were determined. All sucrose parameters were determined at the chemistry laboratories of Estación Experimental Agroindustrial Obispo Colombres.

During the 2005 harvest season, samples of three of the most important commercial varieties in the province: LCP 85-384 (65.2% of sugarcane planted area), TUCCP 77-42 (17.2%) and CP 65-357 (5.8%), were assayed. Sampling of each variety occurred in May, July, August and October at 45 days intervals. At each sampling date, six hundred stalks per variety were collected from the field and taken to the experimental mill.

The individual stalks were grouped by infestation level in order to obtain 5 infestation categories: unattacked cane, cane with 1–10%, 11–20%, 21–30%, and >40% of bored internodes. Then, for each category, three samples of 10 stalks each were taken to the laboratory to perform the corresponding quality analysis. To avoid excessive variability, the same plot was sampled at each sampling date.

In addition, three samplings were performed in June, August and October during the 2006 harvesting season, to evaluate the interaction of storage on losses to LCP 85-384 from *D. saccharalis* attack. Sampling dates were set every 45 days, as previously described. Each time, the same methodology as described above was followed in creating the different infestation level categories. However, in this case, six groups of 10 stalks each were made and arranged in two sets of 3 samples each. One set of samples was analysed the day after harvest, and the other, 4 days later.

The regression lines were estimated for sugar losses for each evaluated variety, LCP 85-384, TUCCP 77-42 and CP 65-357, in relation to the infestation level in cane. Differences among varieties were evaluated by means of ANOVA followed with Duncan’s multiple comparisons test. In addition, to evaluate regression slopes for LCP 85-384 cane with and without storage, R program (R development core team, 2009) lineal model was used.

**Results and discussion**

Figure 1 shows the observed sugar losses for the three varieties, combining all the harvest periods. Figures 2, 3 and 4 show sugar loss values, combining all harvest periods, for each variety.
Fig. 1—Sugar losses in relation to infestation percentage combining the three varieties analysed.

Fig. 2—Sugar loss in LCP 85-384.
Fig. 3—Sugar loss in TUCP 77-42.

Fig. 4—Sugar loss in CP 65-357.
Calculated sugar losses for all varieties and the four harvest dates of sugarcane are shown in Table 1. Reductions of 0.42% in stalk weight and 0.20% in pol of sugarcane for each 1% of attack were estimated, producing a 0.22% loss in factory yield for each % point of infestation, with a 620 to 650 g/t loss of sugar, depending on the variety.

Figures 5, 6, and 7 illustrate sugar losses in LCP 85-384 cane, in relation to infestation percentage and to storage after harvesting for 1 or 4 days before processing, considering three harvesting dates.
In Table 3, the relationship that exists between sugar loss (kg per tonne of cane) and infestation levels is shown. It is quite evident that storage has a very large incidence, increasing the losses, and also that those losses increase along the harvest season.

In June, sugar losses per tonne of cane and per percent of infestation amounted to 676 g when cane was stored. By contrast, cane without storage led to lower sugar losses: 626 g/t of cane and per percent of infestation. In August, sugar losses reached 723 g/t of cane and per percent of
infestation in the case of cane with storage, and 805 g in the case of cane without storage. Although sugar loss rates in cane with storage are lower than those in cane without storage, the total sugar loss in cane with storage is significantly higher as losses for cane without damage with 4 days storage begins with more than 50% losses. In October, losses were even greater with cane storage, reaching levels higher than 1.3–1.84 kg of sugar per tonne of cane and per percent of infestation. In the case of cane without storage, losses amounted to 1.2–1.7 kg of sugar per tonne of cane and percent of infestation. In this last case, there is a point at which losses do not increase, even though infestation goes on increasing.

| Table 3—Sugar losses (kg per tonne of cane) in relation to infestation percentages in cane, 1 or 4 days after harvest, considering different harvesting dates. |
|-----------------|----------------|----------------|----------------|----------------|
| Infestation (%) | 1 d storage | 4 d storage | 1 d storage | 4 d storage | 1 d storage | 4 d storage |
| 0               | 0.00        | 32.00        | 0.00         | 45.00        | 0.00         | 46.00        |
| 1–10            | 6.26        | 38.76        | 8.13         | 53.65        | 14.46        | 61.53        |
| 11–20           | 12.52       | 45.52        | 16.26        | 62.30        | 27.45        | 75.40        |
| 21–30           | 18.78       | 52.28        | 24.39        | 70.95        | 49.00        | 98.20        |
| 31–40           | 25.04       | 59.04        | 32.52        | 79.60        | 64.65        | 114.40       |
| 41–50           | 31.30       | 65.80        | 40.65        | 88.25        | 74.40        | 124.00       |

The analysis to compare the linear models obtained revealed that there were no significant differences between sugar loss regression slopes for cane with and without storage as they are parallel lines (P > 0.05, data not shown). By contrast, there were significant differences in the intercepts from the two categories (with and without storage).

In 2006, 11,451,000 t of cane were milled in the province, with an average of 7.61% *D. saccharalis* infestation (Salvatore et al., 2008). If we consider the lowest sugar loss, 620 g/t of cane, the estimated losses reached a total of 54,506 t sugar.

Data of losses of sugar per infestation percent obtained in this research are used by sugarcane growers to decide on harvesting dates. When harvested late, during warmer months, higher temperatures increase deterioration and thus sugar losses.

**Conclusions**

As *D. saccharalis* infestation percentage rises, sugar losses become higher. Sugar losses were much greater after 4 days post-harvest storage than after 1 day; this difference increased as harvest time advanced.

MOTS CLÉS: Canne à Sucre, Diatraea saccharalis, Pertes.

Résumé
Le ravageur le plus dévastateur de la canne à sucre dans la Province de Tucumán est le foreur Diatraea saccharalis. Les galeries formées dans la tige sont des points d’entrées pour les pathogènes. Ces dégâts entraînent des pertes de poids de la tige, réduisent la qualité et la quantité de saccharose, et rendent difficile l’extraction du jus à l’usinage. Une étude a été entreprise afin de déterminer les pertes causées par le D saccharalis sur trois variétés de canne à sucre et sur la canne stockée avant l’usinage. Pendant la récolte de 2005, les observations faites sur les variétés industrielles, LCP 85-384, TUCCP 77-42 et CP 65-357 ont montré des pertes significatives au champ et à l’usine. Pour chaque 1% d’entremœufs attaqués, des réductions de 0,42% en poids de canne et 0,20% en pol ont été observées, causant des pertes de 0,22% à l’usinage. Dépendant de la variété, une chute en saccharose de 620 à 650 g/t de canne a été observée. En sus, la variété LCP 85-384 infestée par D. saccharalis a été échantillonnée en juin, août et octobre, pendant la récolte de 2006 pour évaluer l’effet du stockage. Une diminution en saccharose plus élevée après 4 jours de stockage post-récolte était constatée. La différence était plus marquée à mesure que la récolte progressait.
PERDIDAS DE AZÚCAR CAUSADAS POR EL GUSANO PERFORADOS DE LA CAÑA DE AZÚCAR (*DIATRAEA SACCHARALIS*) EN TUCUMÁN, ARGENTINA

PALABRAS CLAVE: Caña de Azúcar, *Diatraea saccharalis*, Pérdidas.

**Resumen**

El gusano perforador de la caña de azúcar, *Diatraea saccharalis*, es la principal plaga del cultivo de caña de azúcar en la Provincia de Tucumán. Las galerías producidas por las larvas son puerta de entrada a patógenos. Su efecto, genera pérdidas de peso en los tallos, reduce la calidad y el contenido de sacarosa y disminuye la extracción de jugo en la fábrica. El objetivo de este trabajo fue evaluar las pérdidas causadas por *Diatraea saccharalis* en tres variedades de caña de azúcar con y sin estacionamiento. Durante la zafra 2005, se realizaron ensayos en 3 variedades comerciales: LCP 85-384, TUCCP 77-42 y CP 65-357 y se determinó que el ataque provoca importantes pérdidas en el rendimiento cultural y fabril. Se encontraron reducciones por cada 1% de ataque de 0,42% en el peso de los tallos y de 0,20% en pol % caña, lo que produce pérdidas en el rendimiento fabril de 0,22% por punto de infestación, con una pérdida de azúcar de 620 a 650 g/t de caña, dependiendo de la variedad. Además, se realizaron ensayos con la variedad LCP 85-384 en tres diferentes fechas: Junio, Agosto y Octubre, durante la zafra 2006, se evaluó el efecto de las pérdidas por estacionamiento al ataque de *D. saccharalis*. Las pérdidas de azúcar fueron altas luego de 4 días de estacionamiento. Estas diferencias fueron mayores a medida que avanzaba la temporada de zafra.
EFFECTS OF INSECTICIDES ON MIGDOLUS FRYANUS WESTWOOD (COLEOPTERA: CERAMBYCIDAЕ) INFESTATIONS AND SUGARCANE YIELDS

KEYWORDS: Saccharum, Insect Pests, Chemical Control.

Abstract
THE DESTRUCTION of root system by Migdolus fryanus Westwood (Coleoptera: Cerambycidaе) larvae reduces the yield and the longevity of sugarcane crops. Because of this damage, this insect is one of the most important pests of sugarcane in São Paulo State, Brazil. The present study was conducted to evaluate insecticide efficacy, when applied: a) at a depth of 40 cm, using ploughshares, during the land preparation prior to planting; b) in the furrows, at planting; and c) both at 40 cm and in the furrows. The experiment was carried out at the Santa Rita Sugar Mill, São Paulo, Brazil, using a randomised complete block design with 16 treatments (insecticides applied in the furrow and/or at 40 cm, and an untreated check) and 4 replicates. Sugarcane was planted in plots with five 15 m rows spaced 1.40 m apart, in March 2007. The pest populations were evaluated in periodic samplings and, on November 2007, when there was a flight of adults in the experimental area. The highest yields were observed in plots treated with endosulfan or fipronil. The treatments applied at 40 cm were more effective than the application of insecticides in the furrows. Fipronil or endosulfan applied at 40 cm, with or without additional insecticides in the furrows, increased yields by more than 25% over the untreated check.

Introduction
Migdolus fryanus (Coleoptera: Cerambycidaе) is one of the most important pests of sugarcane in São Paulo State, Brazil. The damage is caused by the larvae that attack both the roots and the stool, where they open large cavities.

As a result of roots and stools destruction, the plants are stunted, can be easily pulled out of the ground, and the stalks get dry and die. Thus, the crop stand, yield and longevity are drastically reduced (Dinardo-Miranda, 2008).

Current management strategies of infested areas involve several measures of control; however, none of them provide satisfactory control (Bento et al., 2004; Dinardo-Miranda, 2008). One of the most popular tactics is the mechanical destruction of infested ratoons, which kills M. fryanus larvae and pupae, due to mechanical damage and exposure to the sun and natural enemies (Arrigoni et al., 1986).

However, in many cases, mechanical destruction is not sufficient to reduce M. fryanus populations below the economic injury level and infested areas need insecticide treatment. The objective of this study was to evaluate the effects of insecticides, under two forms of application, on M. fryanus infestations and on sugarcane yields.
Materials and methods

An experiment was conducted in a sandy soil area, in São Paulo State, Brazil. Plots consisted of five 15-m-long furrows, spaced at 1.40 m, distributed in a random block design with four replicates.

Treatments are presented in Table 1. On 21 March 2007, the plots were demarcated in the experimental area and the insecticides were applied at a depth of 40 cm, in designated plots, with a spraying system placed behind the ploughshare discs. On 27 March 2007, the furrows were opened for each plot, respecting plot delimitations. After planting the variety RB867515, the insecticides were applied in the furrows, according to the treatments. Furrows were immediately closed after insecticide application.

*M. fryanus* infestations were estimated on 20 June, 30 July, 3 October 2007 and 27 July 2008. For all samplings, a hole (0.50 m long, 0.50 m wide, 0.30 m deep) was opened in the first row of each plot. Soil and plant material were observed carefully to visualise biological forms of the pest and its damages.

The experiment was harvested on 27 July 2008. Stalk productivity was obtained by cutting and weighing the stalks from the second to fifth rows in each plot. The first row was not used to obtain the cane yield because many plants were destroyed during the sampling.

Prior to statistical analyses, *M. fryanus* population data were transformed (square root \(x + 1\)). Each sampling date was analysed separately. The analysis of variance was performed using SAS Statistical Analysis Systems software package (SAS Institute, 1995) and all means were compared by Tukey’s test. To verify the interference of the form of application and the insecticides, the analysis was conducted as a factorial experiment, in which one of the factors corresponded to form of application (at a depth of 40 cm or in the furrows) and the other to four insecticide regimes (no insecticide, fipronil, imidacloprid, endosulfan).

Results and discussion

High larval populations were found only on the 27 July 2008 sampling date (Table 2). In November 2007, there was a flight of *M. fryanus* into the experimental area. Because the larvae can
live for 2 years in the deep soil layers, up to 5-m deep, and adults emerge 3 to 4 months prior to a flight (Arrigoni, 1988), it is possible to conclude that the *M. fryanus* larvae were present in the experimental area, during the three first samplings, but were not detected because of their deep location.

When considering treatments individually, differences in *M. fryanus* infestations were only observed during the July 2008 sampling. Treatments with fipronil applied at a depth of 40 cm (treatments I, J and L) produced more than the untreated control (Table 2), suggesting that the treatment with fipronil in depth is important to improve the yield. Insecticides applied only in the furrows (treatments B, C and D) did not contribute to improved productivity.

When considering the treatments applied at a depth of 40 cm, regardless of the treatment applied in the furrows, plots treated with fipronil or endosulfan produced more cane than the check (without insecticides at 40 cm) and the treatment with imidacloprid (Table 3). Since other pests were not observed in the experimental area, these data suggest that both insecticides applied at a depth of 40 cm reduced the *M. fryanus* population and consequently increased yields. No differences in pest infestations were observed among treatments, because the insects were living and eating the roots in the deeper layers of the soil.

Means followed by the same letters in columns are similar by Tukey’s test (P < 0.05).

When considering treatments applied in the furrows, regardless of treatment applied at a depth of 40 cm, no differences in pest populations and sugarcane yield were observed (Table 4). These observations suggest that, for the management of *M. fryanus* infested areas, fipronil or endosulfan applications into the soil profile are more effective than the applications in the furrows.

</tbody>
</table>

Means followed by the same letters in columns are similar by Tukey’s test (P < 0.05).

In conclusion, our data suggest that insecticide treatments applied at a depth of 40 cm were more effective than the application of insecticides in the planting furrows. Fipronil or endosulfan applied at this depth, with or without insecticides in the furrows, increased the yield by more than 25% over the untreated check.

Résumé
LA DESTRUCTION du système radiculaire par les larves de Migdolus fryanus Westwood (Coleoptera :
Cerambycidae) occasionne une baisse de rendement et affecte la pérennité de la canne à sucre. En
raison de ces dégâts, ce ravageur est un des plus importants de la canne à sucre dans l’État de São
Paulo au Brésil. L’étude présente a été élaborée afin d’évaluer l’efficacité des insecticides appliqués
a) à une profondeur de 40 cm en utilisant des socs, pendant la préparation du sol avant la plantation;
b) dans les sillons à la plantation et c) par les deux méthodes à la fois. L’expérimentation a été
effectuée à Santa Rita Sugar Mill, São Paulo au Brésil, en adoptant un dispositif de blocs
complètement randomisés de 16 traitements (insecticides enfouis à 40 cm et/ou appliqués dans les
sillons, et un témoin non-traité) avec 4 répétitions. En mars 2007, la canne a été plantée dans des
parcelles de cinq lignes de 15 m et espacées de 1,40 m. La population du ravageur a été évaluée en
faisant des échantillonnages périodiques dont en novembre 2007, lors des vols des adultes dans la
parcelle expérimentale. Les rendements les plus élevés ont été obtenus dans les parcelles traitées à
l’endosulfan ou au fipronil. L’application d’insecticide à 40 cm de profondeur a été plus efficace
que le traitement dans les sillons. Le fipronil ou l’endosulfan enfoui à 40 cm, avec ou sans
traitement additionnel d’insecticide dans les sillons, a augmenté des rendements par plus de 25%
au-dessus du témoin non-traité.

Resumen

LA DESTRUCCIÓN del sistema de raíces por las larvas de *Migdolus fryanus* Westwood (Coleoptera: Cerambycidae) disminuye la producción y longevidad de los cultivos de caña de azúcar. Debido a este daño, el insecto es una de las plagas más importantes de la caña de azúcar en el Estado de San Paulo, Brasil. El presente estudio se realizó para evaluar la eficacia de los insecticidas, cuando se aplican: a) a una profundidad de 40 cm, usando arados, durante la preparación de la tierra antes de sembrar; b) en los surcos, en la siembra, y c) tanto a 40 cm como en los surcos. El experimento se llevó a cabo en el Ingenio Santa Rita, San Paulo, Brasil, utilizando un diseño de bloques completos al azar con 16 tratamientos (insecticidas aplicados en el surco y/o 40 cm, y un control sin tratar) y cuatro repeticiones. La caña de azúcar se sembró en parcelas con cinco surcos de 15 m de largo, espaciados a 1.40 m, en marzo de 2007. Las poblaciones de la plaga se evaluaron en los muestreos periódicos y en noviembre de 2007, cuando hubo un vuelo de adultos en el área experimental. Las producciones más altas se observaron en las parcelas tratadas con Endosulfán o el Fipronil. Los tratamientos aplicados a 40 cm fueron más eficaces que las aplicaciones de insecticidas en los surcos. El Fipronil o el Endosulfán aplicado a 40 cm, con o sin insecticidas adicionales en los surcos, aumentó las producciones en más del 25% con respecto a la a los testigos sin tratar.
EFFECT OF INSECTICIDES APPLIED AT SUGARCANE PLANTING ON SPHENOPHORUS LEVIS VAURIE (COLEOPTERA; CURCULIONIDAE) CONTROL AND ON THE YIELD OF FIRST TWO HARVESTS

Abstract
RECENTLY, the occurrence of sugarcane fields severely damaged by Sphenophorus levis Vaurie (Coleoptera; Curculionidae) has increased in the Central-South region, the main area where sugarcane is grown in Brazil. The pest management program includes mechanical destruction of infested ratoons, which often is not enough to maintain the populations below economic injury level. The use of insecticides is therefore necessary. The objective of the present work was to evaluate the effect of insecticides applied at sugarcane planting on the pest control and on the yield of the first two harvests. Three experiments were conducted as random block designs with six replicates. In addition to an untreated check, the following treatments were evaluated: carbofuran 2100 g/ha a.i., fipronil 200 g/ha a.i., carbofuran 2100 g/ha a.i. + fipronil 200 g/ha a.i., imidacloprid 960 g/ha a.i., thiamethoxam 375 g/ha a.i. and bifenthrin 250 g/ha a.i.. S. levis infestations and associated plant injury were evaluated by periodic samplings. Yield data were recorded for the first two harvests. No differences between the treatments and the untreated check in relation to pest population and injury were observed. However, the treatments with fipronil, imidacloprid and thiamethoxam were associated with significant yield increases for both harvests. Considering the two harvests, these increases reached 52.2 to 69.0 t/ha or 25% of yield, suggesting that these treatments can be useful in an integrated management program.

Introduction
Recently, the occurrence of sugarcane fields severely damaged by Sphenophorus levis Vaurie (Coleoptera; Curculionidae) has increased in the Central-South region, the main area where sugarcane is grown in Brazil (Dinardo-Miranda, 2000). Damage is caused by the larvae that bore into the stool and, sometimes, the first basal internode, where they open large cavities (Precetti and Arrigoni, 1990). As a result of stool destruction the plants are stunted; the shoots become dry and die. The stand, the yield and the longevity of the crop are drastically reduced (Dinardo-Miranda, 2008).

The management of infested areas involves the mechanical destruction of infested ratoons, killing larvae and pupae of the pest, as well as the use of insecticides at planting.

Despite the importance of S. levis to sugarcane in Brazil, few studies on the efficiency of insecticidal control have been conducted. The objective of this study was to evaluate the effect of insecticides on S. levis control and on the yield at the first two harvests.

Materials and methods
Three experiments were conducted in São Paulo State, Brazil. Experiments 1 and 2 were planted on 15 February 2005 and 28 March 2005, respectively, with the sugarcane variety SP81-3250. Experiment 3 was planted on 11 May 2005 with RB867515. Plots consisted of six 10-m-long furrows, spaced at 1.50 m, distributed in a random block design with six replicates.
In experiment 1, treatments were: a) untreated check, b) carbofuran 2100 g/ha a.i., c) fipronil 200 g/ha a.i., d) carbofuran 2100 g/ha a.i. + fipronil 200 g/ha a.i., e) imidacloprid 960 g/ha a.i., f) thiamethoxam 375 g/ha a.i. and g) bifenthrin 250 g/ha a.i. The same treatments were tested in experiment 2 (except treatment d) and experiment 3 (except treatment b). Treatments were applied in the furrows, before closing them.

*S. levis* infestations and injury were evaluated in plant cane plots 2, 4, 6 and 8 months after planting, except in experiment 3, where the last sampling was not conducted. For ratoon cane sampling, data were collected 3 and 5 months after the first harvest.

For all samplings, a hole (0.50 m long, 0.50 m wide, 0.30 m deep) was opened in the first furrow of each plot. Soil and plant material were observed carefully to determine *S. levis* abundance and the total and injured shoots were counted to obtain the percentage of injured shoots.

Yields were determined for the first two harvests: 13 May 2006 and 26 May 2007 for experiment 1; 10 July 2006 and 4 December 2007 for experiment 2; and 22 May 2006 and 22 May 2007 for experiment 3, by cutting and weighing the stalks from the second to sixth rows in each plot. The first row was not used to obtain the yield because many plants were destroyed during the sampling.

Prior to statistical analyses, *S. levis* population data were transformed to square root ($x + 1$) and injury data to arcsine (square root [$\sqrt{x/100}$]). Each sampling date was analysed separately.

The analysis of variance was performed using SAS Statistical Analysis Systems software package (SAS Institute, 1995) and the treatment means were compared to untreated check means by Dunnett’s test. The experiment group analysis was also conducted using SAS software package, considering three experiments and seven treatments.

**Results and discussion**

The highest infestations and injury were observed in ratoons (Table 1). The destruction of infested crop residues and tillage prior to planting contributed to pest population reduction, due to mechanical damages and exposure to the sun and natural enemies of the larvae and pupae (Pizzano *et al.*, 1987). After planting, soil disturbance is minimised, allowing *S. levis* populations to increase.

Means within columns marked with (*) differ from untreated check (Dunnett’s test, $P < 0.10$).
No differences in *S. levis* infestations and injury were observed between insecticide treated and untreated check plots, except four months after planting, when the bifenthrin treatment presented a higher percentage of shoot damaged than the check (Table 1).

For the plant cane harvest, all insecticide treatments were associated with increased yields. For the second harvest, fipronil, fipronil + carbofuran, imidacloprid and thiamethoxam plots had greater yields than untreated check plots (Table 2).

Carbofuran seems not as effective as fipronil, imidacloprid or thiamethoxam because, in plant cane, this product showed the smallest yield increase, while, in the ratoon cane, it did not contribute to increase the yield.

Since plots treated with fipronil showed the same level of increase as the plots treated with fipronil + carbofuran, it can be argued that effects on yield, in the ratoon cane, were due to fipronil.

**Table 2**—Yields (t/ha) observed at first and second harvest, as a function of treatments and total increase of yield of each treatment in relation to check (Δ) (means of three experiments).

</tbody>
</table>

Means within columns marked with (*) differ from untreated check (Dunnett’s test, P < 0.10).

There was no evident correlation between pest population and yield, because no differences were observed among the treatments in relation to pest population. The sampling method may not have been precise enough to evaluate the pest population. It is evident that the insecticides were not very efficient, probably because they tend to move to the stalks and leaves, staying in low concentration in plant and ratoon stool, where *S. levis* larvae feed. Despite the fact the insecticides were not efficient in controlling *S. levis*, they increased yields.

Although some insecticides like thiamethoxam and imidacloprid contribute to yield increases ranging from 4 to 8 t/ha when applied in fields with low pest pressure, due to their direct effect on the plants, increases like those observed in these experiments can not be attributed to this effect.

Since others pests were not found in the experimental areas, the lower yields observed in untreated plots, compared with treated plots, can be attributed to *S. levis* populations. In fact, commercial areas infested with 0.5 *S. levis* per hole show clear symptoms of the pest attack, like stand and yield drastically reduced.

On average, treatments with fipronil, fipronil + carbofuran, imidacloprid and thiamethoxam applied at planting contributed to yield increases ranging from 56.2 to 69.0 t/ha for the first two harvests combined, suggesting that these insecticides can be useful in an integrated management program.

**Résumé**

RECENTEMENT, la fréquence des champs de canne à sucre sévèrement endommagés par le *Sphenophorus levis* Vaurie (Coleoptera; Curculionidae) a augmenté dans la région méridionale-sud, le partie la plus importante pour la culture de la canne au Brésil. Le programme de gestion du ravageur inclut la destruction mécanique des repousses infestées, qui souvent n’est pas suffisant pour maintenir la population en dessous du seuil de nuisibilité économique. Le recours aux insecticides est donc nécessaire. Le but de la présente étude est d’évaluer l’effet des insecticides appliqués à la plantation de la canne sur le ravageur et sur le rendement obtenu pendant les deux premières récoltes. Trois essais ont été entrepris en adoptant un dispositif de blocs randomisés avec six répétitions. En sus du témoin non-traité, les traitements suivants ont été évalués: carbofuran à 2100 g/ha m.a., fipronil à 200 g/ha m.a., carbofuran à 2100 g/ha m.a. + fipronil à 200 g/ha m.a., imidacloprid à 960 g/ha m.a., thiamethoxam à 375 g/ha m.a. and bifenthrin à 250 g/ha m.a. Les infestations de *S. levis* et les dégâts occasionnés ont été évalués grâce à un échantillonnage périodique. Les données de rendements pour les premières récoltes ont été recueillies. Aucune différence n’a été observée entre les parcelles traitées et celles non-traitées par rapport à l’infestation et les dégâts. Cependant, les traitements au fipronil, à l’imidacloprid et au thiamethoxam ont entraîné une augmentation significative du rendement pour les deux récoltes. Effectivement, les augmentations ont atteint 52.2 à 69.0 t/ha ou 25% de rendement, suggérant que ces traitements puissent être utiles dans un programme de lutte intégrée.
EFECTO DE LOS INSECTICIDAS APLICADOS DURANTE LA SIEMBRA EN EL CONTROL DE SPHENOPHORUS LEVIS VAURIE (COLEOPTERA: CURCULIONIDAE) Y EN LA PRODUCCIÓN DE CAÑA EN LOS DOS PRIMEROS CORTES

Resumen
RECENTEMENTE se ha observado el aumento de campos de caña de azúcar severamente afectados por Sphenophorus levis Vaurie (Coleoptera, Curculionidae) en la región Centro-Sur, principal área donde se cultiva caña de azúcar en el Brasil. El programa de manejo de la plaga incluye la destrucción mecánica de retoños infestados, lo que a menudo no es suficiente para mantener las poblaciones del insecto por debajo del nivel de daño económico, siendo necesario el uso de insecticidas. El objetivo del presente trabajo fue evaluar el efecto de los insecticidas aplicados durante la siembra de caña en el control de la plaga y determinar la producción de los dos primeros cortes. Se realizaron tres experimentos con diseños de bloques al azar y seis répeticiones. Además del control sin tratar, se evaluaron los siguientes tratamientos: Carbofuran, 2100 g/ha de ingrediente activo (i.a.), Fipronil, 200 g/ha de i.a., Carbofuran, 2100 g/ha de i.a.+ Fipronil, 200 g/ha de i.a., Imidacloprid, 960 g/ha de i.a., Tiametoxam, 375 g/ha de i.a. y bifentrina, 250 g/ha de i.a. Se evaluaron las infestaciones y daños asociados con S. levis mediante muestreos periódicos. Los resultados de producción se registraron durante los dos primeros cortes. No se observaron diferencias entre los tratamientos y el control sin tratar en relación con la población de la plaga y el daño causado. Sin embargo, los tratamientos con Fipronil, Imidacloprid y Tiametoxam se tuvieron aumentos significativos de producción de caña, en ambos cortes. Teniendo en cuenta los dos cortes, los aumentos fueron de 52.2 a 69.0 t/ha o aumento de 25% en la producción, lo que sugiere que estos tratamientos pueden tener utilidad en un programa de manejo integral.
SPATIAL DISTRIBUTION OF SUGARCANE SPITTLEBUG, 
*MAHANARVA FIMBRIOLATA*, IN SUGARCANE FIELDS

Abstract

SUGARCANE spittlebug, *Mahanarva fimbriolata* (Stål) (Hemiptera: Cercopidae), is one of the most important pests of sugarcane in the Central-Southern region of Brazil. Information on its spatial distribution in sugarcane fields is important for the development of sampling plans, aimed at their application in integrated management programs. We studied the spatial distribution of *M. fimbriolata* in 10 mechanically harvested green cane fields in Catanduva, São Paulo State, Brazil. In each field of 1.41 ha, 150 samples were collected within a rectangular grid measuring 10 × 10.5 m, between 27 December 2007 and 1 November 2008. The Morisita index was significantly > 1 for eight fields, indicating that, in each of these fields, *M. fimbriolata* has an aggregated spatial distribution and this pattern was not affected by the infestation level. In two fields, *M. fimbriolata* occurred at random. Geostatistical analysis allowed the construction of contour maps through kriging interpolation using the spatial dependence expressed in the semivariograms for five fields. For the other three fields where *M. fimbriolata* has aggregated spatial distribution, it was not possible to construct population maps using kriging interpolation because the distance between sampling points was too large to detect spatial dependence. For the cases where the maps could be constructed, the ranges varied from 23 to 55 m and, using this information, we estimated that it was necessary to sample 6 points/ha to adequately estimate the insect population.

Introduction

Sugarcane spittlebug, *Mahanarva fimbriolata* (Stål) (Hemiptera: Cercopidae), is one of the most important pests of sugarcane in the Central-Southern region of Brazil. Besides noticeably reducing stalk productivity, it causes alterations in the quality of the sugarcane, reducing stalk sugar content and increasing fibre content.

Losses also extend to milling processes, because dead and dry stalks resulting from the attack of the pest reduce the milling capacity as stalks are often cracked and deteriorated, and contaminants make sugar recovery difficult and inhibit fermentation (Dinardo-Miranda, 2008).

To develop sampling plans for application in integrated management programs, we need to know this important pest’s spatial distribution in sugarcane fields. Thus, we sought to characterise the spatial distribution of *M. fimbriolata* in sugarcane fields to provide guidance for sampling procedures.

Materials and methods

We studied the spatial distribution of *M. fimbriolata* in 10 mechanically harvested green cane fields in Catanduva, São Paulo State, Brazil. In each field of 1.41 ha, 150 samples were
collected within a rectangular grid measuring 10 × 10.5 m, between 27 December 2007 and 1 January 2008, when the ratoons were 4–5 months old. Each sample was represented by 2 m of furrow, where nymphs and occasional adults present on the roots were counted. To visualise the insects on the roots, we carefully pushed away the trash from the sugarcane furrow with a wooden stick and removed the insects from the root region, in the subsurface soil layer.

Data were initially analysed by descriptive statistics of mean, standard deviation, coefficient of variation, maximum value, minimum value, skewness and kurtosis. The Morisita index* was calculated in accordance with Bubenicek and Haas (1969). After this, geostatistical analyses were run using semivariograms and kriging interpolation to construct maps.

The semivariogram analyses were conducted using the GEOSTAT software (Vieira et al., 1983). Based on the models fitted to the semivariograms, the jackknifing test was used to verify whether the estimates of semivariogram parameters were adequate and to estimate the number of neighbours that should be used in kriging (Vieira, 2000).

Once the parameters for the model were confirmed and the adequate numbers of neighbours were estimated, values were interpolated for the locations where they were not measured, by the kriging method, using the GEOSTAT software (Vieira et al., 1983). The kriging-estimated values were used in Surfer software (Golden Software, 1999) to construct the maps.

**Results and discussion**

In all fields, *M. fimbriolata* population presented high coefficient of variation, with great differences between the maximum and the minimum value (Table 1). A similar observation was reported by Dinardo-Miranda *et al.* (2007), who also worked in São Paulo State, with the variety RB855536.

The Morisita index was significantly greater than 1 for eight fields, indicating that in these fields the *M. fimbriolata* has aggregated spatial distribution and this pattern was not affected by the infestation level.

In two fields, *M. fimbriolata* occurred at random. Dinardo-Miranda *et al.* (2007) and Stingel (2005), working in several fields in São Paulo State, observed in all studied areas that *M. fimbriolata* presented aggregated distribution patterns.

*Morisita index = Measures the distribution of a field sampling.
* = significant at 5% and ** = Value of F,

Among the 10 calculated semivariograms, those corresponding to areas 1, 4, 7, 8 and 9 exhibited a ‘pure nugget’ effect* (Table 2). In relation to areas 7 and 9, this was because the pest, in these fields, occurred at random, according to the Morisita index.

For the other areas (1, 4 and 8), the distance between sampling points was too large to allow the detection of a spatial dependence between them.

$^1$ Area calculated by $\Pi r^2$, where $\Pi = 3.1416$ and $r = a$.

Pure nugget effect – Value of semivariance when the null distance.

The spherical model was best fitted to the semivariograms of data for areas 2, 3, 5, 6 and 10 (Figure 1, Table 2). Although the $r^2$ values were low, the parameters estimated for the spherical model ($C_0$, $C_1$, $a$) were endorsed by the jack knifing test, since the mean values for the reduced errors were near zero and the values for the variance of reduced errors were near 1 (Table 2). Maps showing the spatial distribution of the insects in areas 2, 3, 5, 6 and 7 are shown in Figure 2.

Fig. 1—Semivariograms for populations of *Mahanarva fimbriolata* in areas 2, 3, 5, 6 and 10. Numbers in parenthesis are nugget effect value ($C_0$), $C_1$ and range ($a$) of spherical model (Sph).
The portion of variability attributed to spatial dependence, given by the $C_0/(C_0 + C_1)$ ratio, ranged from 0.20 to 0.60 (Table 2), indicating a strong or a moderate spatial dependence among samples (Cambardella et al., 1994). The range ($a$), representing the distance at which there is spatial dependence between samples, varied from 23 to 55 m. These data allowed us to estimate that the spittlebug aggregation area ($A = \pi r^2$, where $r = a$), in these fields, varied from 1.662 m$^2$ to
9.503 m², suggesting that 6 and 1 sampling points per hectare would be necessary to obtain a reliable estimate for the pest population in areas 10 and 2, respectively.

Dinardo-Miranda et al. (2007), working with *M. fimbriolata* in sugarcane fields, also found moderate spatial dependence among samples. In that study, the ranges varied from 33 to 56 m allowing those authors to conclude that it was necessary to sample 3 points/ha to adequately estimate the insect population. Using this information, we estimated that it was necessary to sample 6 points/ha to adequately estimate the insect population.

Résumé

La cicadelle écumeuse de la canne à sucre, Mahanarva fimbriolata (Stål) (Hemiptera: Cercopidae), est un des plus importants ravageurs de la région méridionale-sud du Brésil. Les informations sur sa distribution spatiale dans les champs de canne à sucre sont importantes pour l’élaboration des plans de sondages et leur utilisation dans les programmes de gestion intégrée. Nous avons étudié la distribution spatiale de M. fimbriolata dans 10 champs recolts mécaniquement en vert à Catanduva, État de São Paulo au Brésil. Pour chaque champ de 1.41 ha, 150 échantillons ont été prélevés à l’intérieur d’une grille rectangulaire de 10 × 10.5 m, entre le 27 décembre 2007 et 1er novembre 2008. L’index de Morisita était significativement supérieur à 1 pour huit champs, démontrant que M. fimbriolata avait une distribution spatiale agrégée dans chacun de ces champs et cette tendance n’était pas affectée par le niveau d’infestation. Dans deux champs, la distribution de M. fimbriolata était aléatoire. Une analyse géostatistique a permis l’élaboration des cartes hypsométriques par interpolation par krigage. La dépendance spatiale exprimée en semivario grammes a été utilisée pour cinq champs. Pour les trois autres champs, où la distribution spatiale de M. fimbriolata était agrégée, il n’a pas été possible d’établir des cartes de population en utilisant l’interpolation par krigage, l’écart entre les points de prélèvement étant trop grand pour détecter la dépendance spatiale. Pour les cas où les cartes pouvaient être construites, la distance a varié de 23 à 55 m. En utilisant cette information, nous avons considéré qu’il est nécessaire d’échantillonner six points par hectare pour une estimation plus précise de la population de l’insecte.
DISTRIBUCIÓN ESPECIAL DEL SALIVAZO DE LA CAÑA, MAHANARVA FIMBRIOLATA, EN CAMPOS DE CAÑA DE AZÚCAR

Resumen

EL SALIVAZO de la caña de azúcar, Mahanarva fimbriolata (Stal) (Hemiptera: Cercopidae), es una de las plagas más importantes de la caña de azúcar en la región Centro-Sur del Brasil. La información sobre su distribución espacial en los campos de caña de azúcar es importante para el desarrollo de muestreo, con miras a su aplicación en programas de manejo integral. Por tanto, se estudió la distribución espacial de M. fimbriolata en 10 campos de caña cosechada mecánicamente en verde en Catanduva, estado de San Pablo, Brasil. En cada campo de 1.41 hectáreas, se tomaron 150 muestras en una cuadrícula rectangular de 10 × 10.5 m, entre el 27 de diciembre de 2007 y 1 de noviembre 2008. El índice de Morisita de significativamente superior a 1, ocurrió en ocho campos, lo que indicó que en cada uno de esos campos M. fimbriolata tuvo una distribución espacial agrupada y por tanto el patrón no se vio afectado por el nivel de infestación. En dos de esos campos, la presencia de M. fimbriolata fue al azar. El análisis geoestadístico facilitó la construcción de mapas de contorno a través de la interpolación de Kriging en cinco campos, utilizando la dependencia espacial expresada en semivariogramas. Para los otros tres campos en los que M. fimbriolata tuvo una distribución espacial agrupada, no fue posible la construcción de mapas de población mediante la interpolación de Kriging porque la distancia entre los puntos de muestreo era demasiado grande para detectar la dependencia espacial. Para los casos en que los mapas se pudieron construir, las gamas de variación estuvieron entre 23 hasta 55 metros y, con esta información, se estimó que era necesario tomar muestras de 6 puntos/ha para una estimación adecuada de la población de insectos.
FLUCTUATION IN EGG NUMBERS OF THE SUGARCANE STEM BORER
SESAMIA NONAGRIOIDES LEFEBVRE AND EGG PARASITISM
BY PLATYTELENOMUS HYLAS NIXON RELATIVE
TO DIFFERENT STAGES OF CANE GROWTH

KEYWORDS: Sugarcane Stem Borer, Sesamia nonagrioides, Parasitoid, Platytelenomus hylas, Cane Age.

Abstract

SUGARCANE stem borers are the most important pests of sugarcane worldwide and also in Iran. We studied the fluctuation in egg numbers of the stem borer Sesamia nonagrioides Lefebvre and egg parasitism by Platytelenomus hylas Nixon in sugarcane fields of the Karoun Agro-Industry Company (Khuzestan, Iran) in 2005–2006. A ratoon field and plant cane field (both fields were cultivated with variety CP48-103) were selected for sampling. Egg numbers and percentage of parasitised eggs, numbers of sugarcane stalks/hectare and the stalk height were recorded weekly. Results showed that the peak of borer oviposition occurred in mid-August 2005 in the ratoon field, but was in mid-June 2006 in the plant cane field. The percentage of parasitism increased with increasing plant height in ratoon and plant cane fields. Peak percentage of parasitism was 67.8% when the mean of plant height was 96.2 cm in ratoon field in early July 2005 and 78.8% when stalk height was 78 cm in plant cane field (in mid-April 2006).

Introduction

Worldwide, sugarcane is an important tropical and semi-tropical crop (Azizi, 1990). Sugarcane is an important crop in Iran with nearly all 100 000 hectares of sugarcane planted in Khuzestan Province (Anon. 2006). Stem borers are important pests in most of the sugarcane producing areas of the world.

For example, the stem borer Scirpophaga excerptalis Walker infects 16 percent of sugarcane stems in India (Rajendran and Girdharn, 2003). Sesamia nonagrioides Lefebvre and S. cretica Lederer, are the most important pests of this plant in Iran (Ranjbar, 1999).

These pests are multivoltine and their population density varies with each generation (Sayadmansour et al., 2004). They injure the apical meristem producing dead hearts (James, 2004) and eliminate tillers (Askarianzadeh, 2004) of plants. The larval feeding in stalks decreases yields 1.4 percent in refined sugar, 3.92 percent in juice purity and with total losses of 391 kg/ha of white sugar (Sayadmansour et al., 2004).

Seraj (2002) showed that, for each percent internodes infested, there is a decrease of 110 kg white sugar per hectare at Amir Kabir Agro-Ind. Co. Iran (Anon., 2005).

Not surprisingly, varieties differ in their response to stem borer damage. Askarianzadeh et al. (2008a) showed that sugar losses for every 1% bored internodes were 0.17, 0.39 and 0.23%
(equal to 210, 482 and 241 kg sugar) in cultivars of CP70-1143, CP69-1062 and CP48-103, respectively. According to Sayadmansour et al. (2005), the cultivar CP48-103 (with 48.9% and 6.9% bored stalks and internodes, respectively) was the most susceptible, and the cultivar SP71-6163 (with 20.3% and 2.1% bored stalks and internodes, respectively) was the most resistant against stem borer.

The egg parasite, *Platytelenomus hylas* Nixon (Hymenoptera: Scelionidae), has shown promise for biological control of stem borers in Iran. This parasitoid completes its life cycle in 11–14 days and therefore can produce several generations each year. Studies on range of host acceptance showed that only *Sesamia* eggs were attacked by this parasitoid, and it prefers *S. nonagrioides* over *S. cretica* (Abbasipour, 2004).

Different cultivated host and different varieties of cultivated host can influence behavioural characteristics and efficiency of this parasitoid. Research showed that levels of egg parasitism by *P. hylas* on three sugarcane cultivars (CP48-103, CP57-614 and CP69-1062) differed significantly (Askarianzadeh et al., 2008b). Sayadmansour et al. (2008) in olfactometer studies showed that this parasitoid has different responses to corn (cultivar 704) and three sugarcane cultivars (CP48-103, CP69-1062 and CP57-614).

Since parasitism is affected by several factors and much of the variation in parasitism levels is due to direct and indirect influence by the host plant (Faria et al., 2007) and, considering the potential importance of this parasitoid in Iran, fluctuations in oviposition by *S. nonagrioides* and parasitism by the egg parasitoid, *P. hylas*, were studied relative to different stages of cane growth.

**Materials and methods**

An eight hectare ratoon field of the cultivar CP48-103 comprising 264 furrows (200×1.5 m) was selected for our test site. Samplings were conducted from early July until late September 2005. At each sampling time, 30 furrows were selected at random and then 4 stations per each furrow were identified as sample stations. At each station, 0.3 m of row was examined. There were 120 sample stations.

All shoots in each station were removed and examined. The number of egg clutches per station was recorded. Additional information from each station (i.e. number of sugarcane shoots and weekly height measurements) was also recorded.

All egg clutches collected from behind the leaf sheath (the typical oviposition site) were transported to the laboratory. The eggs were then placed in a small Petri dish for 1–2 days. Then, the eggs were inspected for parasitism under a stereo microscope. Also, the height of stalks in each station was measured as described by Sund and Clements (1974).

In September 2005, a plant cane field (21 hectares with 690 furrows) was also selected for survey. The sampling method was the same as for the ratoon field. The sampling program in the plant cane field was continued until late September 2006.

**Results**

**Variation in the number of stem borer eggs in relation to sugarcane weekly growth**

Variations in number of sugarcane stalks per hectare, number of borer eggs and the height of stalks are shown in Figure 1.

Peak number of borer eggs occurred in early September 2005 in ratoon field (333 716 eggs per hectare) when there were about 333 000 stalks per hectare and the height of sugarcane was 208 cm. Therefore, on average, there was nearly one egg per stalk. In the plant field, number of eggs varied more than those in ratoon field (Figure 2).

The peak of the borer eggs occurred early July 2006 (737 865 eggs on 341 112 stalks per hectare). So, there was more than one egg per stalk during September, November and July in plant field.
Variation in percentage of parasitism and sugarcane weekly growth

Variation in percentage of parasitism and weekly growth of sugarcane in the ratoon field is shown in Figure 3. When sugarcane was short (about 21 cm), the level of parasitism was low (near
zero); increasing to 68% parasitism when the height of stalks was 96 cm. In Figure 4, in plant field, the percentage of parasitism was also low when the height of sugarcane was low in September. After that, the parasitism percentage increased gradually until early November when it increased sharply. With regard to the duration of oviposition by the borer in this region, the sharp increase in percentage of parasitism in November could be due to the limited number of borer eggs present in fields, since nearly all eggs are parasitised. After the regrowth of sugarcane in early April 2006, the percentage of parasitism also increased. The peak of parasitism (78.8%) occurred in early May 2006 when the growth rate of sugarcane (plant and ratoon) is increasing.

![Fig. 3—Comparison between weekly growth of cane and percentage of parasitism by P. hylas in raton field.](image1)

![Fig. 4—Comparison between weekly growth of cane and percentage of parasitism by P. hylas in plant field.](image2)
Discussion

Our data show a difference in the number of borer eggs oviposited between ratoon and plant cane fields. In ratoon fields, plants re-generate from stubble and consequently the number of tillers increases rapidly (Kord, 2000). Therefore, 502,000 stalks in ratoon and 302,000 stalks in plant cane field were encountered. According to Figures 1 and 2, when the number of stalks is very high, the oviposition of the pest was low.

Furthermore, when the plants in the ratoon field were starting to re-generate in May, the number of adults of *S. nonagrioides* was low whereas, in plant cane field, the beginning of new plant growth in September corresponded with high numbers of adult moths that were ready for laying eggs on the new plants.

With our knowledge of the biology of sugarcane stem borer (Daniali, 1984) we can estimate the population of adult moths on the first of June from their egg population on the first of May. We can also estimate the size of the adult population in September by monitoring egg numbers on the first of August.

This study showed a positive relationship between sugarcane growth and percentage of parasitism of the stem borer eggs. That is, in ratoon fields, the percentage of parasitism increased with sugarcane growth from early June until the middle of July and then the percentage of parasitism was maintained at a high level. In plant cane fields, since oviposition of the borer was low in November and December, percentage of parasitism was high. This caused difficulty for the parasitoid, as there were limited pest eggs.

In spring, the percentage of parasitism increased with sugarcane growth and peaked in mid-May. Then, with some changes, due to overlap of parasitoid generations, reached a constant level. These results are similar to studies of Oztemis and Kornosor (2007) who reported on the percentage of parasitism by wasp parasitoid *Trichogramma evanescens* on *Ostrinia nubilalis* in corn.

These results are also similar to Abbasipor (2004) who reported on percentage parasitism by *P. hylas* on *S. nonagrioides* in corn fields of Khuzestan Province, Iran. Therefore, because of the high numbers of pest eggs and the low level of parasitism in early September, we plan to release the parasitoid at this time.

Résumé

Les foreurs de tige sont les ravageurs les plus importants de la canne à sucre dans le monde et en Iran. Nous avons étudié la fluctuation du nombre des œufs du foreur de tige Sesamia nonagrioides Lefèbvre ainsi que le parasitisme des œufs par Platytelenomus hylas Nixon dans les champs de canne à sucre de la Karoun Agro-Industry Company (Khuzestan, Iran) en 2005–2006. Un champ en repousse et un en vierge (tous deux cultivés par la variété CP48-103), ont été sélectionnés pour l’échantillonnage. Le nombre des œufs et le pourcentage des œufs parasités, le nombre de tiges/hectare et la longueur de la tige ont été répertoriés chaque semaine. Les résultats ont démontré que le pic d’oviposition se situait mi-août 2005 dans le champ en repousse et mi-juin 2006 dans le champ en canne vierge. Le pourcentage de parasitisme augmentait avec la hauteur de la canne que ce soit en canne vierge ou en repousse. Le pic du parasitisme se situait à 67.8% quand la hauteur moyenne de la canne était de 96.2 cm dans le champ en repousse début juillet 2005 et à 78.8% quand la hauteur des cannes vierges était de 78 cm (mi-avril 2006).
FLUCTUACIÓN EN EL NÚMERO DE HUEVOS DEL BARRENADOR DE LA CAÑA SESAMIA NONAGRIOIDES LEFEBVRE Y EL PARASITISMO DE HUEVOS POR PLATYTELENOMUS HYLAS NIXON EN RELACIÓN CON LOS DIFERENTES ESTADOS DE CRECIMIENTO DE LA CAÑA

Resumen

Los barrenadores del tallo de caña son las plagas más importantes para el mundo de caña de azúcar así como también para Irán. En el presente trabajo se estudió la fluctuación en el número de huevos del barrenador del tallo Sesamia nonagrioides Lefebvre y el parasitismo de huevos por Platytelenomus hylas Nixon en los campos de caña de azúcar de la Agro-Industria Karoun Company (Khuzestán, Irán) en 2005–2006. Se estudió un campo en soca y uno en plantilla (ambos sembrados con variedad CP 48-103), seleccionados ambos para el muestreo. Semanalmente se registró el número de huevos y el porcentaje de huevos parasitados, así como el número de tallos de caña por hectárea y la altura de los tallos. Los resultados mostraron que el pico de oviposición del barrenador ocurrió en el campo en soca, a mediados de agosto de 2005, en cambio ese pico ocurrió para la plantilla, a mediados de junio de 2006. El porcentaje de parasitismo aumentó con la altura de los tallos tanto en plantilla como en soca. El porcentaje máximo de parasitismo en la soca fue de 67.8%, cuando la altura media de los tallos fue de 96,2 cm a principios de julio de 2005 y de 78.8% en la plantilla, cuando la altura media de los tallos fue de 78 cm (a mediados de abril de 2006).

KEYWORDS: Termites, Entomopathogenic Fungi, Traps, Control, Pathogenicity.

ABSTRACT

The subterranean termite, *Heterotermes tenuis* (Hagen), has become a major economic pest in sugarcane fields of Mexico, particularly in Veracruz State, due to the damage and losses they cause to the crop. Colonies are difficult to locate due to termite biology and the habitats they infest. In the absence of effective control tactics, we developed the use of the entomopathogen, *Beauveria bassiana*, combined with attractant traps, as an economic and environmentally friendly method of control. This entomopathogen has been shown to be effective on various agricultural pests. The technique is especially attractive because it has no polluting effects on the environment. For these reasons, we chose it as the control agent for traps constructed out of corrugated cardboard. We evaluated two entomopathogenic fungi: strain CP 095, *B. bassiana* and *Metarhizium anisopliae*, METAMOTZ 093, plus two insecticides (fipronil and imidacloprid). Four trials were conducted in sugarcane fields of Central Motzorongo. Field surveys were conducted weekly. Under laboratory conditions the best results were obtained with *B. bassiana* at 7 days causing 100% mortality, whereas with *M. anisopliae* the highest mortality occurred at 9 days. Pathogenicity of *B. bassiana* based on termites found dead in a growth chamber was 90% but 70% effective when combined with *M. anisopliae*, which diminishes its effectiveness.

Introduction

The subterranean termite, *Heterotermes tenuis* (Hagen) (Isoptera: Rhinotermitidae), is one of the most important pests of sugarcane in Brazil, Guatemala and Mexico. According to Novaretti (1985), infestations at planting, at crop maturity and after harvest can cause yield losses up to 10 t/ha per year.

Control of subterranean termites is currently very expensive and not effective due to the difficulty of targeting colonies which are widely dispersed in the soil. Restrictions on the use of highly toxic chemical insecticides have led to research on alternative management strategies for controlling termites. Insecticide applications are now based on levels of pest infestation as determined from surveys and species identification (Macedo *et al.*, 1997).

Monitoring of termite populations has been a major breakthrough in technological developments in the control of subterranean termites, which is being adopted by sugarcane producers. Surveys of population levels and identification of harmful species in sugarcane fields have allowed for more efficient use of termiticides.

The use of toxic attractants in traps for termite control is a promising alternative that has been investigated in several countries (Macedo *et al.*, 1997; Almeida *et al.*, 1998).

The combined use of traps with attractants to enhance contact of the pest with a toxin is now recommended by researchers. In a control strategy for *H. tenuis* with traps of corrugated cardboard
impregnated with an insecticide and entomopathogenic fungi, it is also important to consider the fungicidal effects of the product to be used (Castiglioni et al., 2003).

In addition to their toxic effects, the products used in traps for control of subterranean termites should be slow-acting, non-repellent and transmitted between individuals of the colony.

Thus, when treating a portion of the community, the toxic agent can be distributed throughout the colony when the workers return from feeding. Such slow-acting insecticides can cause the collapse of a colony of termites (Castiglioni and Vendramim, 2003).

The strategy of monitoring and control of termites using traps as attractants (bait), is based on the principle of contact of the microbe or chemical agents with those insects attracted to the bait and transmitting these back to the entire colony (Almeida et al., 1998).

The corrugated cardboard traps are attractive to termites and have been used for monitoring populations of this pest in sugarcane and forest systems. Biological agents such as B. bassiana can also be used in combination with a sublethal dose of an insecticide in the traps (Almeida, 1994).

Such a monitoring technique has been used with forest termites by Iñiguez and Talavera (2006) in the state of Colima, Mexico, with very good results.

Their procedure consisted of burying a 1 litre plastic bucket with holes drilled in the bottom, sides and the lid. A roll of corrugated paper (cellulose source) that serves as food for termites is placed inside.

The goal of this study was to determine the efficiency and pathogenicity of B. bassiana for biological control of subterranean termites in sugarcane, using traps made of corrugated cardboard in Central Motzorongo.

Materials and methods
This study was carried out in 2008 during the maturation phase of sugarcane (August–November). Traps were monitored every seven days during this four month period.

Two insecticides and two entomopathogenic fungi were assessed as shown in Table 1. Four trials were laid in distinct agroclimatic areas. Each treatment was replicated four times.

| Table 1—Active ingredients evaluated in the traps for the control of termites in Central Motzorongo. |
|-------------------------------------------------|---------------------------------|---------------------|
| **Treatments** | **Rate/hectare** | **Concentration** |
| Beauveria bassiana | 1 kg | $2 \times 10^{12}$ |
| Metarhizium anisopliae | 200 g | $2 \times 10^{12}$ |
| B. bassiana and M. anisopliae | 1 kg and 200 g | $2 \times 10^{12}$ |
| Imidacloprid | 30 g | 15% |
| Fipronil | 20 mL | 30% |
| Control | – | – |

Preparation of the traps
The active ingredient was dissolved in 15 litres of water in a 20 litre container. Corrugated cardboard rolls serving as traps were submerged in this solution for one minute for the impregnation of the active ingredient.

Distribution of traps in the field
The distribution of traps impregnated with the active ingredient for control of subterranean termites in sugarcane was set up with 20 traps per hectare according to procedures outlined by Macedo and Macedo (2004) so that the traps were distributed evenly in treated areas.

The traps used as attractants at Central Motzorongo were made of corrugated cardboard with chemical and biological ingredients as shown in Figure 1.
Fig. 1—Diagram of the distribution of traps per site (one hectare) for control of subterranean termites.

Placement of traps in the field

Traps, 7.5 cm diameter × 23 cm high, made of corrugated cardboard were used. These were buried 20 cm deep so that 3 cm was visible above ground for easy location of the traps for assessments.

Results

Samples were taken fortnightly during September and October 2008. At each sampling date, live termites collected were transferred to the laboratory to determine percent of mortality for each of the treatments.

Dead termites were placed in a growth chamber and incubated at 25°C for 10 days to determine the cause of death.

We determined the average daily mortality of termites at 10 days in the laboratory by placing 20 worker termites in a petri dish containing field soil and bait formulation.

Four replicates per treatment were used to calculate the average mortality of individuals killed for each of the treatments evaluated.

Once the percentage daily mortality in treatments with *B. bassiana* and *M. anisopliae* was determined, termites were again placed in a growth chamber in the laboratory at 25°C, to observe if the death was due to the entomopathogenic fungi.

We placed twenty termites per treatment in each of four petri dishes and noted the development of mycelia on the cadavers.

As shown in Figure 2, *B. bassiana* showed a mortality of 100% of the population evaluated seven days after, whereas treatment with *M. anisopliae* alone and in combination with *B. bassiana*, 100% mortality was attained after eight days, while only 60% mortality was observed at the end of the observation period of ten days for the control.

No live termites were found in the traps impregnated with chemical insecticides because the highly toxic ingredients cause immediate death of the workers.
Fig. 2—Mortality of termites in function of observation time in the treatments evaluated.

Mycelium formation and sporulation occurred on 90% of the termites from the *B. bassiana* treatment, and 70% in the treatment in combination with *M. anisopliae*.

This technique is cost effective due to the low-cost of materials that are used such as the corrugated cardboard and the entomopathogenic agents (Table 2).

**Results and discussion**

Using the corrugated cardboard technique, we found that this material is very attractive to termites, as the cellulose contained in this material is easily digestible by termites. Our results confirm the findings of Macedo *et al.* (2004). On average, 2300 termites were found per trap. The traps cause the termites to divert their attention from the sugarcane, and a reduction in damage to the basal internodes of stalks in the field was observed.

Additionally, there is a ripple effect whereby the entomopathogenic agents are spread to the rest of the colony by the contact of infected termites with uninfected ones. The natural dispersal of entomopathogenic fungi is slow and lengthy in contrast to insecticides. This method therefore enhances the rate of spread of the entomopathogen to the colony and degrades quickly.

**Conclusions**

Corrugated cardboard is a very attractive material to termites, as the cellulose contained in this material is more easily digestible. This control option is ecologically safe as the material is biodegradable.

As for the active ingredients used in the traps, better results were obtained with entomopathogenic fungus *B. bassiana*, with a mortality of 100% of the population and one of pathogenicity 90%.
This technique reduces the cost to control this pest as well as serves as an environmentally friendly method of controlling damaging termite infestations.

Résumé

Le termite souterrain, Heterotermes tenuis (Hagen), est devenu un ravageur majeur dans les champs de la canne à sucre au Mexique, particulièrement dans l’état de Veracruz, de par les dégâts et pertes causées à la culture. Les colonies sont difficilement localisées par la biologie de l’insecte et le type habitat infesté. En l’absence d’une stratégie de lutte efficace, nous avons préconisé l’utilisation de l’entomopathogène Beauveria bassiana en combinaison avec des pièges attractifs, comme moyen de lutte économique et respectueux de l’environnement. Cet entomopathogène a démontré une efficacité contre plusieurs ravageurs agricoles. La technique est
particulièrement intéressant comme elle n’a aucun effet polluant. Pour cette raison, nous l’avons choisi comme agent de lutte en utilisant des pièges construit avec le carton ondulé. Nous avons évalué deux champignons entomopathogènes : la souche CP 095, *B. bassiana* et *Metarhizium anisopliae*, METAMOTZ 093, en sus de deux insecticides (fipronil et imidacloprid). Quatre essais ont été établis dans des champs de canne à sucre au Motzorongo Central. Les prospections ont été effectuées toutes les semaines. Sous les conditions de laboratoires, les meilleurs résultats ont été obtenus avec *B. bassiana* à 7 jours, occasionnant 100% de mortalité, alors qu’avec *M. anisopliae* la mortalité la plus élevée a été observée après 9 jours. Le pathogénicité du *B. bassiana* en fonction des termites morts dans une chambre de culture était de 90%. L’efficacité était réduite à 70% en combinaison avec le *M. anisopliae*.

CONTROL BIOLÓGICO DE LA TERMITA HETEROTERMES TENUIS (HAGEN) (ISOPTERA: RHINOTERMITIDAE) EMPLEANDO BEAUVERIA BASSIANA (BALS.) VUILL EN TABLEROS TRAMPAS, EN EL CENTRAL AZUCARERO MOTZORONGO, VERACRUZ, MÉXICO

PALABRAS CLAVE: Termitas, Hongos Entomopatógenos, Trampas, Control, Patogenicidad.

Resumen

LA TERMITA subterránea, *Heterotermes tenuis* (Hagen), se ha convertido en una plaga económica importante en los campos de México, en particular en el Estado de Veracruz, debido a los daños y perjuicios que causan a los cultivos de caña de azúcar. Las colonias son difíciles de localizar debido a la biología de las termitas y de los hábitats que infestan. A falta de tácticas eficaces de control, se ha desarrollado el uso del entomopatógeno, *Beauveria bassiana*, combinada con trampas atrayentes, como un método económico y ambientalmente amigable de control. Este entomopatógeno ha demostrado ser eficaz en diversas plagas agrícolas. La técnica es especialmente atractiva porque no tiene efectos contaminantes sobre el medio ambiente. Por estas razones, hemos elegido como el agente de control de las trampas construidas de cartón corrugado. Se evaluaron dos hongos entomopatógenos: CP cepa 095 de *B. bassiana* y *Metarhizium anisopliae*, METAMOTZ 093, además de dos insecticides (Fipronil e Imidacloprid). Se realizaron cuatro ensayos en los campos de caña de azúcar del Central Motzorongo. Las evaluaciones de campo se llevaron a cabo semanalmente. En condiciones de laboratorio los mejores resultados se obtuvieron con *B. bassiana* a los 7 días, causando una mortalidad del 100%, mientras que con *M. anisopliae* la mortalidad más alta se produjo en 9 días. La patogenicidad de *B. bassiana* sobre la base de las termitas muertas en una cámara de crecimiento fue del 90%, pero el 70% de efectividad cuando se combinó con *M. anisopliae*, debido a disminución a su eficacia.
IDENTIFICATION OF THREE ARMYWORM SPECIES (LEPIDOPTERA: NOCTUIDAE) USING DNA BARCODES AND RESTRICTION ENZYME DIGESTION

KEYWORDS: Mythimna spp., Armyworms, DNA Barcodes, Species Identification.

Abstract

SIX SPECIES of sugarcane armyworms (Mythimna spp.) are known to occur in Mauritius, namely M. pseudoloreyi, M. loreyi, M. insulicola, M. phaea, M. tincta and M. pyrausta. Due to the close resemblance of the adult moths, morphological distinction among the different species is difficult and may lead to misidentification. One new approach for their characterisation involves the use of DNA barcodes to analyse the sequence diversity within a short standardised segment of their genome. Polymorphism in the 5’ end of the mitochondrial cytochrome oxidase I (COI) gene is extensively used as a DNA barcoding system in Lepidopterans. In 2008, adult moths of M. insulicola, M. phaea and M. pseudoloreyi were reared from field-collected larvae. Two nucleic acid extraction methods were evaluated, both yielding high quality DNA for molecular studies. DNA extractions were performed from different body parts including abdomen, leg and wing. A ~700 bp PCR fragment amplified from the three species, using primers HCO2198/LCO1490, was digested using restriction enzymes. A combination of four enzymes RsaI, TaqI, PvuII and SacI successfully allowed distinction of the three species of armyworms tested. The PCR products from the three species were cloned and sequenced. A 658 bp fragment from each of M. insulicola, M. phaea and M. pseudoloreyi was submitted to Genbank and respectively recorded as Leucania insulicola, GQ353294; Leucania phaea, GQ353295; and Leucania loreyi, GQ353296. Using the Barcode of Life identification engine (BOLD-ID), high sequence identities were obtained with Leucania species (Noctuidae: Hadeninae)– 99.54% for L. phaea and Leucania sp. (from Kenya), 100% for L. loreyi and Leucania sp. and 99.85% for L. insulicola and L. striata (from Madagascar). The L. phaea sequence diverged by 7.3% and 10.6% from those of L. loreyi and L. insulicola respectively. A sequence divergence value of 8.5% was observed between L. loreyi and L. insulicola. DNA barcoding and sequencing could provide useful information for classification and characterisation of armyworms.

Introduction

In Mauritius, infestations of sugarcane fields by armyworms belonging to the genus Mythimna, (Lepidoptera: Noctuidae) were initially reported in 1959 (MSIRI, 1960). In subsequent years, these pests did not pose a major threat to sugarcane and were under control.

With the introduction of mechanised sugarcane harvesting and the adoption of trash blanketing practices, severe outbreaks were observed after 1992. Attacks by armyworms cause retardation in shoot development and this is more pronounced when associated with other stress factors including drought conditions.

During severe outbreaks, total defoliation of affected fields may occur. To-date six species of sugarcane armyworms are known to occur in Mauritius, namely M. pseudoloreyi, M. loreyi, M. insulicola, M. phaea, M. tincta, and M. pyrausta (Ganeshan, 2007).
Control of armyworms is achieved through the use of insecticides. Chemical control can have negative impacts on the cane ecosystem in Mauritius, where a biological control strategy has always been adopted for the management of sugarcane pests. Six species of parasitoids have been identified from *Mythimna* spp. in Mauritius (Ganeshan, 2001) and the entomopathogen *Metarhizium anisopliae*, has also been observed on larvae and pupae (Beehary-Panray and Rajabalee, 1998). However, the application of biological control agents is reliant on accurate identification of the pest species involved and for *Mythimna* spp. this has been a major difficulty. Morphological distinction is problematic due to the close resemblance of the adult moths and this may lead to misidentification of species.

Molecular biology tools, particularly the use of ‘DNA barcodes’, can complement traditional morphologically based taxonomy to determine the identity of insect pest species (Hebert et al., 2003). This method relies on the sequence diversity in the *cytochrome-c oxidase* I (COI) gene of the mitochondrial DNA. Application of DNA barcodes in taxonomy is gaining momentum and there are currently various efforts worldwide in this area namely: Consortium for the Barcode of Life, All Lepidoptera Barcode of Life Initiative, Fish Barcode of Life Initiative, Canadian Centre for DNA Barcoding, Canadian Barcode of Life Network and All Birds Barcode of Life Initiative. These form part of the International Barcode of Life Initiative, which aims to have a global barcode system for all the species present on earth (Savolainen et al., 2005). The Barcode of Life Data Systems (BOLD) has thus been set-up (http://www.barcodinglife.org) and can be considered as an online barcoding information system for collection, management and analysis of DNA barcodes.

For Lepidoptera, which constitute the second most diverse insect order, with more than 180 000 known species and many more unknown ones, DNA barcodes are expected to identify more than 95% of species. In Costa Rica, in a study comprising of 4260 specimens of which 521 were *Lepidoptera* species, Hajibabaei et al. (2006) unambiguously identified 97.9% of the test species. Using DNA barcodes, it was shown that the sequence of *Diatraea saccharalis* shared 99% homologies with members of the Crambidae family (Bravo et al., 2008). Previously, there was confusion regarding classification of these moth borers in either the Pyralidae or Crambidae families. Similarly, it is expected that barcodes will provide more insight into the classification of the six *Mythimna* spp. in Mauritius. The genus *Leucania* has been reviewed and several species belonging to this genus were assigned to the *Mythimna* genus (Holloway et al., 1987). However, there is still some confusion on the taxonomic nomenclature of this genus, which needs revision.

The main objective of this project is to investigate the usefulness of DNA barcodes for distinguishing the six *Mythimna* spp. present in Mauritius.

**Material and methods**

**Armyworm collection**

Larvae were collected from sugarcane fields in 2008 and were reared to adult in the laboratory. Adult moths were identified using morphological characters (Ganeshan, 2007). The adult specimens were preserved in 90% ethanol until processed. Only three species were encountered: *M. pseudoloreyi*, *M. insulicola* and *M. phaea*. DNA was extracted from the three species (Table 1).

**DNA extraction**

An appropriate DNA extraction technique is a critical step for successful application of a DNA barcoding system for insects. It is important to have good quality DNA for amplification of the mitochondrial DNA fragment by the polymerase chain reaction (PCR). Two DNA extraction protocols were evaluated. Before homogenising, the specimens were removed from the alcohol and allowed to dry.

In the first method, the protocol described by Zhou et al. (2000) was followed for extraction of DNA from single moths. After removing the wings and legs, the moth was homogenised using a sterilised mortar and pestle (with 1 mL of extraction buffer – 10 mM Tris HCl (pH 7.5), 60 mM NaCl and 10 mM EDTA). 600 μL of the homogenate were transferred to a 2 mL microcentrifuge tube and an
equal volume of post-grinding buffer (200 mM Tris HCl pH 9.0, 30 mM EDTA and 2% SDS) were added. 140 μg of proteinase K was added and the tubes were incubated in a water bath at 50°C overnight. Sodium acetate (pH 4.8) was added to a final concentration of 0.3 M. The contents of the tubes were transferred to a 15 mL falcon tube and an equal volume of phenol was added and centrifuged at 8000 rpm. The aqueous phase was recovered and extracted with an equal volume of chloroform: isoamyl alcohol (24:1). To the supernatant, two volumes of 95% ethanol were added and DNA precipitated at –20°C for 2 h. The DNA was recovered by centrifugation and after air-drying, was resuspended in 100 μL of sterile distilled water.

In the second method, a modified CTAB method was adopted. Adult moths devoid of wings and legs were homogenised in 1 mL CTAB buffer (2% CTAB, 1.4 M NaCl, 20 mM EDTA pH 8.0, 100 mM Tris-HCl pH 8.0, 0.1% mercaptoethanol and 200 μg proteinase K) using a mortar and pestle. 1 mL of the homogenate was transferred to a centrifuge tube and incubated for 45 min at 60°C. An equal volume of phenol: chloroform: isoamyl alcohol (25:24:1) was added and centrifuged for 10 min at 14 000 rpm. A second extraction step was performed on the supernatant using an equal volume of chloroform: isoamyl alcohol (24:1). DNA was precipitated with 1/10 volume of sodium acetate (3.0 M) and an equal volume of 95% ethanol (–20°C for 2 h). The DNA was pelleted by centrifugation and following air-drying, was resuspended in 500 μL of sterile distilled water.

Improvements to the two methods included an optional RNA digestion step. This was performed after the chloroform:isoamyl alcohol step; the supernatant was treated with 100 μg of RNase A and incubated at 37°C for 3 h. Attempts were also made to extract DNA from detached wings and legs of specimens (Table 1).

Amplification of DNA barcodes

Primer pair LCO1490/HCO2198 (Folmer et al., 1994) amplifies a ~700 bp fragment of the mitochondrial COI gene. PCR was performed in a total volume of 50 μL with 0.2 mM dNTPs, 1X PCR buffer, 0.3 μM of forward primer (LCO1490, 5’-GGTCAACAAATCTAATAAGATATTGG and reverse primer HCO2198 (5’-TAAACTTCAGGGTGACCAAAAAATCA) and 1 U of Taq polymerase (Roche diagnostics, USA) and 1.5 μL of template DNA. The mixtures were set in a thermal cycler using the following thermal profile: denaturation at 94°C for 10 min followed by 35 cycles of 94°C for 30 s,
50°C for 30 s and 72°C for 1 min, and a final elongation step at 72°C for 10 min. Amplified fragments were separated by 1% agarose gel electrophoresis and visualised under UV light.

**Restriction fragment length polymorphism (RFLP)**

The ~700 bp PCR fragments amplified using HCO1490/HCO2198 were digested with enzymes *RsaI*, *PvuII*, *TaqI* and *SacI* as per manufacturer’s instructions (Roche Diagnostics). Digestion products were separated by 1% agarose gel electrophoresis and visualised under UV light.

**Cloning and sequencing**

One ~700 bp fragment amplified from each of the three species (*M. pseudoloreyi, M. insulicola* and *M. phaea*) was purified from agarose gel using the QIAquick Gel Extraction Kit (Qiagen) and cloned using the pGEM T Easy Vector system (Promega). Subsequently, the inserts were sequenced using an ABI 310 Genetic Analyser using the Big dye 3.1 Sequencing Kit (Applied Biosystems, USA) using universal primers.

**Sequence analysis**

COI DNA sequences from *M. pseudoloreyi, M. insulicola* and *M. phaea* were compared with other sequences from Genbank. The sequences were also used for species identification using the BOLD-IDS (barcode identification engine http://www.barcodinglife.org/). In order to establish the phylogenetic relationship of the three *Mythimna* spp., the primer sequences were trimmed and sequences were aligned with other sequences retrieved from BOLD and Genbank (Table 2) using Clustal X. Mega3 was used to construct a neighbour-joining phylogenetic tree based on Kimura 2 parameter (K2P) genetic distances and 1000 replicated bootstrap values.

Results and discussion

Amplification of DNA barcodes

The ~700 bp fragment was successfully amplified with all 20 DNA extracts, AR001-AR020 (Figure 1).

Extracts obtained using the Zhou et al. (2000) method (AR001-004 and AR013-016) as well as the remaining ones (CTAB method) were suitable for the generation of DNA barcodes from *Mythimna* spp.

The optional RNase step was performed for only three extracts (AR011, AR017 and AR018 in Lanes 11, 17 and 19 respectively) and there was not much difference in product amplification.

![Fig. 1](image)

Fig. 1—Amplification of the ~700 bp mitochondrial COI DNA fragment from extracts AR001-AR020 (Lanes 1–20), Lanes 21–22 are water controls and M is 100 bp marker XIV (Roche).

Restriction fragment length polymorphism (RFLP)

The ~700 bp products amplified with primers HCO1490/LCO2198 were digested using restriction enzymes *Rsa*I, *Taq*I, *Sac*I and *Pvu*II (Figure 2). A combination of restriction patterns with at least two enzymes allowed discrimination between the three *Mythimna* spp. tested. *Rsa*I and *Taq*I could differentiate *M. pseudoloreyi* and *M. insulicola* from *M. phaea*.

The *Sac*I recognition site, which is only present in the *M. pseudoloreyi* fragment, was used to separate *M. pseudoloreyi* from *M. insulicola*. Enzyme *Pvu*II also confirmed the slight difference existing between *M. pseudoloreyi* and *M. insulicola* (Figure 2), but the digested product was very close to 700 bp.

The PCR-RFLP described above is a simple technique for differentiating the three armyworm species *M. pseudoloreyi, M. insulicola* and *M. phaea*. In 2009, additional specimens including *M. loreyi, M. tincta,* and *M. pyrausta* will be collected and the method further validated.

Sequence analysis

Sequences obtained from cloned HCO1490/LCO2198 PCR products of *M. insulicola, M. phaea* and *M. pseudoloreyi* were edited to remove the primer region and deposited in Genbank. The curators have accepted the entries as *Leucania insulicola, L. phaea* and *L. loreyi* respectively (GQ353294-6). These names will be used for further discussion in the current paper in order to avoid confusion. It is expected that, with further analysis of barcode data from the three other *Mythimna* species in Mauritius (*M. loreyi, M. tincta* and *M. pyrausta*), the issue of classification will be clearer.
Analysis in the Barcode of Life Identification Engine (BOLD-ID) was performed using the full barcodes and very high (99%) homologies were obtained with specimens belonging to the *Leucania* genus (Noctuidae; Hadeninae) (Table 3). However, these sequences are not currently publicly available and requests were made to the authors for access. Interestingly, the closest matches were either regional specimens, e.g. *L. striata* (LTOL390-09) was collected in Madagascar while the unclassified *Leucania* sp. (PMANL304-09) was collected in Kenya, or pests of sugarcane: specimen *L. stenographa* (ANICB181-06) originates from Australia where this species (=*L. loreyi*imima) is known to infest sugarcane plantations (Edwards, 1992).

Table 3—Sequence similarities of *Leucania (Mythimna)* from this study with those from related species.

<tr>
<td><em>L. loreyi</em></td>
<td>100 % with unidentified <em>Leucania</em> sp. (PMAN310-09) - 98.1 % with <em>Leucania stenographa</em> (ANICB181-06) - from Australia</td>
</tr>
</tbody>
</table>

The sequences from this study were compared with those from other *Mythimma* and *Leucania* species publicly available from BOLD. The COI sequence of *L. insulicola* (GQ353294) diverged by 10.6% from *L. phaea* while there is a divergence of 7.3% from *L. loreyi*. For *L. 
insulicola and *L. loreyi*, there is a sequence divergence of 8.5% (Table 4). With such high divergence at nucleotide level, it is very easy to distinguish between the three species being studied. The average overall mean divergence for the 15 species considered in Table 4 is 8.5% (±0.7% SE). It should be noted that only *Mythimna* and *Leucania* sp. have been included in Table 4.

Using sequences of the mitochondrial COI gene of moths, Hebert *et al.* (2003) showed that there is an average sequence divergence of 0.25% for conspecific individuals while for congeneric species, an average of 6.5% was observed. For the sugarcane stem borer, *Busseola* sp., interspecific divergence of > 4.5% has been reported (Assefa *et al*., 2007). However, caution should be made using COI sequence divergence information for species delimitation (Whinnett *et al*., 2005). It is also important to consider morphological characteristics for taxonomy purposes.

A phylogenetic tree was constructed using the three *Leucania* (*Mythimna*) spp. from this study and selected related sequences from Genbank and BOLD (Figure 3). These species clustered within the *Mythimna/Leucania* group.

**Conclusions**

A simple and quick method for distinguishing among *L. insulicola*, *L. phaea* and *L. pseudoloreyi*, based on PCR-RFLP of part of the mitochondrial COI gene is described in this study.

At nucleotide level, the three species shared high homologies with moths of *Leucania* spp., which occur either in neighbouring countries e.g Madagascar or as pests of sugarcane in Australia.

These sequences have currently been deposited in Genbank as *L. insulicola*, *L. phaea* and *L. loreyi*. The high percentage divergence among the three sequences indicates the occurrence of three
distinct species. Divergence of 7.3% and 10.6% was observed between *L. phaea* sequence and those of *L. pseudoloreyi* and *M. insulicola* respectively. The latter two species had 8.5% sequence divergence. DNA barcoding is effective and very convenient for distinguishing closely related and morphologically similar species.

*Fig. 3—Neighbour-Joining phylogenetic tree based on Kimura-2 parameter genetic distances. *Plutella xylostella* is an out group. Only bootstrap values (1000 replicates) greater than 50% are shown.*

Résumé

SIX ESPÈCES de chenilles légionnaires de la canne à sucre (Mythimna spp.) sont connues à Maurice, notamment M. pseudoloreyi, M. loreyi, M. insulicola, M. phaea, M. tincta et M. pyrausta. En raison de la ressemblance morphologique des adultes et de la difficulté de distinguer les papillons, des erreurs d'identification sont existantes. Une nouvelle approche implique l'utilisation des barcodes moléculaires. Le polymorphisme, sur une courte séquence d’un fragment d’ADN conservé du gène mitochondrial codant pour la première sous-unité de la cytochrome oxydase (COI), est couramment utilisé comme barcodes pour identifier des Lépidoptères. En 2008, les larves collectées aux champs provenant de trois espèces M. insulicola, M. phaea et M. pseudoloreyi ont été élevées en laboratoire. Deux méthodes d'extraction d’ADN ont été testées sur les pattes, les ailes et l’abdomen des adultes. Les deux méthodes ont donné des résultats satisfaisants. Des fragments de ~ 700 pb, amplifiés des trois espèces par la technique PCR avec les amorces HCO2198/LCO1490, ont été coupés à l'aide des enzymes de restriction. La distinction des trois espèces de chenilles légionnaires a été possible avec une combinaison de quatre enzymes notamment Rsal, TaqI, PvuII et SacI. Les produits PCR amplifiés de M. insulicola, M. phaea et M. pseudoloreyi ont été clonés et séquencés et un fragment de 658 pb pour chaque espèce a été enregistré dans Genbank comme suit: Leucania insulicola (numéro d’accession GQ353294), L. phaea (GQ353295) et L. loreyi (Q353296). L'analyse de ces barcodes avec le moteur de recherche de BOLD-ID (base de données ‘Barcode of Life Datasets’) indique une forte identité de séquence avec les membres du genre Leucania (Noctuidae: Hadeninae): 99.54% entre L. phaea et Leucania spp. (de Kenya), 100% entre L. loreyi et Leucania spp. et 99.85% entre L. insulicola et L. striata (de Madagascar). L. phaea présentait un pourcentage de variation de 7.3% et de 10.6% par rapport à L. loreyi et L. insulicola respectivement. D’autre part, une divergence de 8.5% au niveau de la séquence a été observée entre L. loreyi et L. insulicola. Les informations obtenues avec les barcodes ADN seront très utiles pour déterminer les espèces de chenilles légionnaires.
IDENTIFICACIÓN DE TRES ESPECIES DE GUSANOS COGOLLEROS (LEPIDOPTERA: NOCTUIDAE) USANDO CÓDIGOS DE ADN Y DIGESTIÓN POR ENZIMO DE RESTRICCIÓN

PALABRAS CLAVE: Mythimna spp., Gusano Cogollero, Códigos de Barras del ADN, Identificación de Especies.

Resumen
Seis especies de gusanos cogolleros de la caña de azúcar (Mythimna spp.) existen en Mauricio, en específico, M. pseudoloreyi, M. loreyi, M. insulicola, M. phaea, M. tincta y M. pyrausta. Debido al gran parecido de las mariposas adultas, la identificación morfológica entre las distintas especies se dificulta. Un nuevo enfoque para su caracterización involucra el uso de códigos de barra del ADN para analizar la diversidad de secuencia dentro de un pequeño segmento estándar de su genómico. El polimorfismo en el extremo 5′ del gen mitocondrial citocromo oxidasa I (COI, por sus siglas en Inglés) es usado ampliamente como un sistema de código de barras de ADN en los Lepidópteros. En 2008, mariposas adultas de M. insulicola, M. phaea y M. pseudoloreyi fueron criadas a partir de larvas colectadas en el campo. Dos métodos de extracción de ácidos nucléicos se evaluaron, ambos rendiendo ADN de alta calidad para estudios moleculares. Extracciones de ADN se efectuaron a partir de distintas porciones corpóreas, que incluyeron abdomen, pata y ala. Un fragmento de ~700 pares de bases (pb) de cada una de las tres especies se amplificó por medio de la reacción en cadena de la polimerasa (PCR, por sus siglas en Inglés) usando los iniciadores (primers) HCO2198/LCO1490, luego de lo cual se digirió usando enzimos de restricción. Una combinación de cuatro enzimos Rsa1, TaqI, PvuII y SacI permitió distinguir exitosamente a las tres especies de gusanos cogolleros evaluados. Los productos de PCR de las tres especies fueron clonados y secuenciados. Un fragmento de 658 pb de cada una de las especies M. insulicola, M. phaea y M. pseudoloreyi fueron enviadas a la base de datos ‘Genbank’ y registrados, respectivamente, como Leucania insulicola, GQ353294; Leucania phaea, GQ353295; y Leucania loreyi, GQ353296. Usando el mecanismo de identificación de Código de Barras de la Vida (en Inglés, Barcode of Life identification engine, BOLD-ID), se identificaron (con gran probabilidad) secuencias con las especies de Leucania (Noctuidae: Hadeninae)- 99.5% para L. phaea y Leucania sp. (de Kenia), 100% para L. loreyi y Leucania sp., y 99.8% para L. insulicola y L. striata (de Madagascar). La secuencia de L. phaea fue diferente en un 7.3% y 10.6% de aquellas de L. loreyi y L. insulicola, respectivamente. Un valor de divergencia de 8.5% se observó entre L. loreyi y L. insulicola. La secuencia de L. phaea fue divergente en un 7.3% y 10.6% de aquellas de L. loreyi y L. insulicola, respectivamente. El código de barras de ADN y la secuenciación pueden proveer de información útil para la clasificación y caracterización de gusanos cogolleros.
OCCURRENCE OF THREE GENOTYPES OF SUGARCANE YELLOW LEAF VIRUS IN A VARIETY COLLECTION IN MAURITIUS

By

N. JOOMUN and A. DOOKUN-SAUMTALLY
Mauritius Sugar Industry Research Institute, Réduit, Mauritius
njoomun@msiri.intnet.mu

KEYWORDS: Sugarcane, SCYLV, Virus Genotypes, Virus Diversity.

Abstract

SUGARCANE yellow leaf virus (SCYLV) is widely distributed in Mauritius, but so far the characterisation of genotypes of the virus has not been determined. RT-PCR primers were used to identify genetic diversity of the virus in a variety collection plot. Total nucleic acids were extracted from leaves of thirteen introduced varieties infected by SCYLV and a two-step RT-PCR was optimised for each of the three genotype-specific primer pairs CUB-F/CUB-R, REU-F/B-REU, and PER-F/PER-R tested. The presence of three SCYLV genotypes namely the BRA-PER, CUB and REU was confirmed in the germplasm collection. Genotype REU was observed in 10 varieties while 4 varieties were infected by genotype BRA-PER. Mixed infection with genotypes CUB and REU was observed in variety Co6304 while Q88 was co-infected by genotypes BRA-PER and REU. PCR fragments of 363 bp (BRA-PER), 452 bp (CUB) and 905 bp (REU) amplified from varieties PR67245, Co6304 and S17 were cloned and sequenced. Blast analysis of these three sequences showed high homologies with the corresponding genotype sequences from GenBank – 100% similarity with isolate Taiwl (AJ491144, BRA genotype), and > 99% similarity with isolates CUB-YL1 (AM083988) and REU-YL2 (AM072756) respectively. Recent screening of some local commercial cultivars revealed infection by REU and BRA-PER genotypes. Further intensive surveys are being carried out to assess the distribution of the three SCYLV genotypes in sugarcane fields in Mauritius.

Introduction

Yellow leaf disease of sugarcane (previously called yellow leaf syndrome) occurs in all major sugarcane producing countries of the world (Lockhart and Cronjé, 2000). The causal agent, Sugarcane yellow leaf virus (SCYLV), belongs to the genus Polerovirus of the family Luteoviridae (D’Arcy and Dormier, 2005).

SCYLV is transmitted mainly by infected cane setts and aphid vectors, Melanaphis sacchari and Rhopalosiphum maidis.

The disease is characterised by an intense yellowing of the midrib on the abaxial surface of the leaf, extending to the whole leaf as the disease progresses. Necrosis of leaves, accumulation of sucrose in leaves and shortening of terminal internodes resulting in a fan-like appearance can also be observed in diseased plants.

These symptoms, nevertheless, can also be associated with other biotic and abiotic factors including water stress. Plants may also be infected without exhibiting outward symptoms.

Leaf yellows disease caused by sugarcane yellows phytoplasma is also responsible for similar symptoms in sugarcane in some countries, including Mauritius (Cronjé et al., 1998; Aljanabi et al., 2001; Arocha et al., 2005).
SCYLV infection has been reported to result in yield losses. In Brazil up to 20% yield loss has been observed in cultivar SP71-6163 (Vega et al., 1997). Yield losses may occur even in the absence of visible symptoms (Rassaby et al., 2003; Grisham et al., 2009).

Various studies have shown that SCYLV is quite a variable virus (Abu-Ahmad et al., 2006a,b; Moonan and Mirkov, 2002). Phylogenetic studies by Abu-Ahmad et al. (2006b) identified four genotypes of SCYLV of different geographical origins (genotypes BRA from Brazil, PER from Peru, CUB from Cuba and REU from Réunion). Specific reverse-transcription PCR was developed for these genotypes, but due to the close similarity between BRA and PER genotypes, they were aggregated into a single group termed BRA-PER. Variations in infection capacity and virulence have also been reported among the different genotypes (Abu-Ahmad et al., 2007a,b).

The presence of SCYLV in Mauritius was confirmed in 1996 (Saumtally and Moutia, 1997). Recent studies on the prevalence of the virus in commercial sugarcane cultivation showed infection rates of more than 50% in certain varieties (MSIRI, 2008). However, there has not been any extensive study regarding the occurrence of genotypes present in Mauritius. From only a few samples screened by Abu-Ahmad et al. (2006b), REU and BRA-PER genotypes were observed in Mauritian cultivars. However, the diversity of SCYLV in Mauritius may be much higher since SCYLV isolate MUS1 from Mauritius (variety M 99/48) could not cluster with genotypes BRA, PER and REU (Abu-Ahmad et al., 2006a).

The current study was initiated to verify the occurrence of genotypes of SCYLV in a variety collection plot.

Material and methods

Total nucleic acid extractions

Leaf samples were collected from 13 introduced varieties in a collection at Réduit (Table 1) and total nucleic acids were extracted using the CTAB protocol. 1.0 g of leaf tissue was ground in liquid nitrogen and transferred to 15 mL tube with 5 mL CTAB buffer (2% CTAB, 1.4 M NaCl, 20 mM EDTA pH 8.0, 100 mM Tris-HCl pH 8.0, 0.2% w/v β-mercaptoethanol). After incubation at 60°C for 1 h, an equal volume of chloroform:isoamylalcohol (24:1) solution was added and centrifuged at 9000 rpm for 10 min. The extraction step was repeated once more and the nucleic acids were precipitated using two-third volume of isopropanol. Following two washes in 70% ethanol, the pellets were recovered, allowed to dry and resuspended in 500 μL of sterile distilled water.

Reverse transcription PCR

(i) Primers YLS 462/111
The presence of SCYLV in the samples was confirmed first using RT-PCR with SCYLV specific primers YLS 462/111 (Irey, unpublished)

(ii) Genotype specific primers (BRA-PER, CUB and REU)
RT-PCR for each of the BRA-PER, CUB and REU genotypes was optimised separately. Sequences of primers used (Abu-Ahmad et al., 2006b) are detailed in Table 2.

Table 2—Primers for specific amplification of SCYLV genotypes BRA-PER, CUB and REU.

1.5 µL of total nucleic acids was mixed with 1.0 µL of reverse primer (10 mM) RT-PCR and made to 10 µL using sterile distilled water. Denaturation was performed at 95°C for 1 min followed by immediate quenching on ice for at least 2 min.

The reverse transcription mix (10 µL) was then added. It comprised 4 µL of 5X RT buffer (Roche), 1.0 µL of dNTPs (10 mM each), 0.5 µl of RNase Inhibitor (20 U/µL), 1.0 µL of 40 U/µL M-MuLV RT (Roche) and sterile distilled water to 10 µL. The RT reaction mix was incubated at 42°C for 1 h and then denatured at 95°C for an additional 3 min.

1 µL of cDNA was used as template for PCR including 1X PCR buffer (including Mg), 200 nM of each of forward and reverse primers, 0.2 mM of each nucleotide, 1 U of Taq polymerase (Roche) and sterile distilled water to a final volume of 50 µL.

The amplification consisted of a denaturation phase of 95°C for 3 min, followed by 35 cycles (94°C for 30 s, 57°C for 1 min- genotype REU (or 61°C for genotypes CUB and BRA-PER), and 72°C for 1 min and 15 s), followed by a final cycle at 72°C for 10 min in a thermal cycler (Veriti, Applied Biosystems). PCR products were separated by electrophoresis in a 1% agarose gel, stained using ethidium bromide and visualised under UV light.

Cloning and sequencing
The pGEM T Easy Vector system (Promega) was used to clone three PCR products (corresponding to each genotype- REU from S17, CUB from Co6304 and BRA-PER from PR67245) according to manufacturers’ recommendations. Following plasmid extraction with the QIAprep Spin Miniprep kit (Qiagen), sequencing was performed using an ABI 310 Genetic Analyser.

Analysis of cloned sequences was performed using Bioedit software and alignment with ClustalW. All sequences from this study were deposited in the Genbank database. Additionally, sequences of SCYLV genotypes were retrieved from Genbank (Table 3) and used for phylogenetic analysis.
Table 3—Isolates of SCYLV used for comparison.

* This study

Results and discussion

Sugarcane yellow leaf virus was present in all 13 varieties tested by RT-PCR with general primer pair YLS 462/111. Subsequently, separate RT-PCRs were optimised for each of the three genotypes (BRA-PER, CUB and REU). Using the 61°C annealing temperature as utilised by Abu-Ahmad et al. (2006), only the BRA-PER and CUB genotypes could be amplified with their respective primers. Further optimisation was required for the REU fragment and the final annealing temperature chosen was 57°C for successful amplification of the REU fragment using REU-F/B-REV.

Using the optimised RT-PCR, the presence of all three genotypes of SCYLV was confirmed in the variety collection plot, with amplification of a fragment of 362 bp, 450 bp and 905 bp representing the BRA-PER, CUB and REU genotypes respectively (Figure 1a,b,c). Genotype REU was observed in 10 varieties (Figure 1c), 4 varieties were infected with BRA-PER genotype (Figure 1b), and CUB genotype was present only in variety Co6304 (Figure 1c). Two varieties were co-infected with two genotypes of SCYLV, notably REU/BRA-PER (variety Q88, Lane 9) and CUB/REU (variety Co6304, Lane 4).

The PCR fragments from the three genotypes were cloned and sequenced (BRA-PERmu from PR67245-363 bp, CUBmu from Co6304, 452 bp and REUmu from S17-905 bp). Blast sequence analysis confirmed the occurrence of the BRA, CUB and REU genotypes in Mauritius. The BRA-PERmu fragment shared highest homology with isolate Taiw1 (AJ491144, BRA genotype), while the CUBmu fragment shared > 99% similarity with isolate CUB-YL1 (AM083988) and similarly for REUmu and REU-YL2 (AM072756).

Sequences of the genotypes from this study and those retrieved from Genbank were compared and a phylogenetic tree constructed for fragment CUB (Figure 2). The CUBmu genotype clustered with the CUB-YL1 genotype (Var C132-81) from CUBA and diverged from other genotypes of SCYLV. Abu-Ahmad et al. (2006a) analysed the amino acid identity of part of the open reading frame I of this genotype and compared with BRA, PER and REU. The CUB-YL1 genotype shared only 77–80% amino acid sequence identity with other genotypes prompting the suggestion of occurrence of a new virus.
Fig. 1—Amplification of fragments of three genotypes of SCYLV. (a- BRA-PER, b- CUB and c- REU genotypes). Lanes 1–13 are sugarcane varieties as per Table 1, lane 14 is an extract from a disease free sugarcane plantlet, lane 15 is water control and M is 100 bp molecular weight marker, Roche).

Variety Co6304 (infected with CUB genotype) was introduced in 2003 in Mauritius from India and recent studies have confirmed the presence of isolate CUB in India (Viswanathan et al., 2008). Studies of Abu-Ahmad et al. (2006b) showed the geographical grouping of SCYLV genotypes and implied different virus introduction and evolution histories in the respective environments.

SCYLV diversity in Mauritius may be more complex as a Mauritian isolate, MUS1, was previously found not to cluster with the three groups (Abu-Ahmad et al., 2006a). This is also supported by the existence of the three genotypes in the variety collection plot observed in the present study. In recent tests of local cultivars, only isolates BRA-PER and REU have been recorded, but there is a need to establish more precisely the diversity of SCYLV present by
screening a larger number of samples. Variations in virulence and infection capacity of SCYLV genotypes exist, as well as reaction of different varieties to the virus. It is necessary to investigate further the nature of the variation of SCYLV and its impact on sugarcane cultivation in Mauritius. For instance, SCYLV has also been detected in the aphid *Melanaphis sacchari* (MSIRI, 2008), and it would be of epidemiological interest to characterise the genotype(s) harboured by this vector.

![Diagram of SCYLV isolates]

**Fig. 2**—Neighbour-joining tree of SCYLV isolates. The CUB-mu fragment (This study) cluster with genotype CUB-YL1.

**Conclusions**

The present study confirmed the occurrence of three genotypes of SCYLV in a sugarcane germplasm collection in Mauritius. During an initial screening of commercial fields, the REU and BRA-PER genotypes have been found predominant while the CUB genotype detected in this study is from a germplasm collection. Further investigations are warranted for a more precise assessment of the distribution of the genotypes, their epidemiology and their impact on yield.

Résumé

QUOIQUE LE Sugarcane yellow leaf virus (SCYLV) est très répandu à Maurice, les génotypes du virus n'ont pas été déterminés. Des amorces RT-PCR ont été utilisées pour identifier la diversité génétique du virus dans treize variétés infectées provenant d’une collection variétale. Les acides nucléiques totaux extraits à partir des feuilles des treize variétés ont été soumis à un test RT-PCR en deux étapes. Le protocole a été optimisé pour chaque génotype avec les paires d'amorces spécifiques CUB-F/CUB-R, REU-F/B-REU et PER-F/PER-R. Trois génotypes de SCYLV notamment BRA-PER, CUB et REU ont été confirmés dans les variétés testées. Le génotype REU a été observé dans 10 variétés tandis que 4 variétés étaient infectées par le génotype BRA-PER. Une infection mixte causée par les génotypes CUB et REU a été observée dans la variété Co6304, tandis que la Q88 était co-infectée par les génotypes BRA-PER et REU. Les produits d’amplification de 363 pb (BRA-PER), 452 pb (CUB) et 905 pb (REU), provenant des variétés PR67245, Co6304 et S17 respectivement, ont été clonés et séquencés. Les trois séquences analysées par l’algorithme Blast démontrent de fortes homologies avec les génotypes correspondants du SCYLV dans Genbank; pour le génotype BRA, 100% de similarité avec Taiwl (AJ491144), et plus de 99% de similarité avec les isolats CUB-YL1 (AM083988) et REU-YL2 (AM072756) respectivement. Récemment les génotypes REU et BRA-PER ont été révélés dans des variétés commerciales, d’où la nécessité de faire des prospections intensives au champ pour évaluer la répartition des différents génotypes de SCYLV à Maurice.
EXISTENCIA DE TRES GENOTIPOS DE VIRUS DE HOJA AMARILLA DE LA CAÑA DE AZÚCAR EN UNA COLECCIÓN DE VARIEDADES DE MAURICIO

PALABRAS CLAVE: Caña de Azúcar, SCYLV, Genotipos de Virus, Diversidad de Virus.

Resumen

El virus de la hoja amarilla de la caña de azúcar (SCYLV, por sus siglas en Inglés) está ampliamente distribuido en Mauricio, pero al momento la caracterización de genotipos del virus no ha sido determinada. Iniciadores (primers) de RT-PCR fueron usados para identificar la diversidad genética del virus en una parcela con una colección de variedades. Los ácidos nucleicos completos se extrajeron a partir de las hojas de una trece variedades introducidas, infectadas por el SCYLV, y se evaluaron con una RT-PCR de dos pasos optimizada para cada uno de los pares de iniciadores específicos de los tres genotipos (CUB-F/CUB-R, REU-F/B-REU, y PER-F/PER-R). La presencia de los tres genotipos de SCYLV, en específico BRA-PER, CUB y REU, se confirmó en la colección de germoplasma. El genotipo REU fue observado en 10 variedades, en tanto que 4 fueron infectadas por el genotipo BRA-PER. La infección mixta de genotipos CUB y REU fue observada en la variedad Co6304, mientras que Q88 fue co-infectada con los genotipos BRA-PER y REU. Los fragmentos derivados de la PCR de 363 pares de base (bp) (BRA-PER), 452 pb (CUB), 905 pb (REU) fueron amplificados de las variedades PR67245, Co6304 y S17, clonándose y secuenciándose. El análisis Blast de estas tres secuencias mostró gran homología con las secuencias de genotipo correspondientes en la base de datos "Genbank" - 100% en sínimilitud con el aislado Taiwl (AJ491144, genotipo BRA), y > 99% en sínimilitud con los aislados CUB-YL1 (AM083988) y REU-YL2 (AM072756), respectivamente. La reciente criba de algunos cultivares comerciales reveló una infección por los genotipos REU y BRA-PER. Inspecciones intensivas adicionales serán conducidas para los tres genotipos de SCYLV en campos de caña de azúcar de Mauricio.
MAPPING OF SUGARCANE VARIETY M 134/75
USING EST-SSR MARKERS

KEYWORDS: EST-SSR, Linkage Map, Sugarcane And Yellow Spot Disease.

Abstract

The construction of sugarcane linkage maps has been largely limited to the use of non-genic marker systems like AFLP and genomic SSRs. Moreover, map comparison among the Saccharum genus has been hampered by the lack of common markers. In this study, an AFLP- and genomic SSR-based linkage map of sugarcane variety M 134/75 consisting of 95 linkage groups (LGs) was enhanced with genic marker systems in order to further dissect the sugarcane genome and to enable intra- and inter-species genome comparisons. The ultimate aim of this project is to identify markers linked to the yellow spot disease resistance QTL and their introgression into sugarcane marker assisted breeding. The mapping parents M 134/75 and R 570 were screened with 25 sugarcane and 425 sorghum EST-SSR primers. On average, 1.5 polymorphic bands were detected for M 134/75 with sugarcane EST-SSR primers. Two hundred and ninety-one sorghum EST-SSR primers were found polymorphic for the mapping parent M 134/75, with an average of 2.6 polymorphisms per primer. The progeny population of 226 individuals was screened with five sugarcane and 37 sorghum EST-SSR primers. One hundred and two single dose coding markers were combined with 985 available non-coding markers and analysed by GMendel to produce a partial map of M 134/75 containing 143 linkage groups (LGs). This enabled integration of 58 sorghum EST-SSR markers into 26 LGs. Based on common SSRs, LGs were grouped into ten homologous groups (HGs), among which four contained sorghum EST-SSRs. LG 68 containing the yellow spot resistance QTL was equated to HG VIII and was enhanced by three sorghum markers. Comparative mapping will be exploited to fine-map the yellow spot disease resistance QTL.

Introduction

The construction of sugarcane linkage maps has been largely limited to the use of non-genic marker systems like AFLP and genomic SSRs (gSSR). Intra-species and intra-genus comparisons have not been possible using these markers, as they were non-coding and locus unspecific.

Over the past decade, there has been an exponential increase in the availability of expressed sequence tags (EST) sequence data from a wide variety of taxa.

This abundance of EST sequences has become an attractive potential source of microsatellite markers after the findings that gene transcripts can also contain SSRs (Kantety et al., 2002). Deriving SSR markers from EST sequences (EST-SSRs) has an intrinsic advantage over gSSR because they can be easily obtained by data mining of EST databases.

This is a much cheaper alternative to the conventional isolation and characterisation of gSSRs via DNA libraries and is also less time consuming. The usefulness of these genic SSRs also lies in their cross-species transferability because the primers are from coding sequences that are more conserved across species. These EST-SSRs are also useful as anchor markers for comparative
mapping and have the added advantage of being directly associated with traits of interest. Hence, they provide a more targeted approach to identification of markers linked to genes or quantitative trait loci (QTL).

Over the past few years, several projects for the sequencing of sugarcane ESTs have been initiated in South Africa (Carson et al., 2000), Brazil (http://sucest.lad.ic.unicamp.br/en/) and Australia (Casu et al., 2001), allowing the development of EST-SSRs for the Saccharum genus (Cordeiro et al., 2001; Pinto et al., 2004).

The application of sugarcane EST-SSR for diversity studies has been previously reported (Cordeiro et al., 2001), but its use in genetic mapping of sugarcane has only been recently reported (Oliveira et al., 2007). In this work, 149 EST-SSRs were used in the construction of an integrated sugarcane map derived from a cross between Brazilian hybrid cultivars SP80-180 and SP80-4966. Combined with RFLP and AFLP marker data, a linkage map was constructed containing 149 functionally associated EST-SSR markers scattered among 79 LGs.

At the Mauritius Sugar Industry Research Institute (MSIRI), emphasis is being placed on the integration of marker assisted selection (MAS) into its sugarcane breeding program. The aim of this study is to identify markers linked to putative sugarcane yellow spot (YS) disease resistance gene(s).

This is a major disease of sugarcane and can account for 10–25% reduction in sucrose content among susceptible varieties grown in the superhumid zones of Mauritius. It is caused by the fungus Mycovellosiella koepkei. The selection for resistant varieties in the current breeding program is costly, time-consuming and not fully reliable as disease expression is dependent on abiotic factors such as weather conditions and high disease pressure.

In a previous study (Aljanabi et al., 2007), a population of 227 progenies derived from a biparental cross between a yellow spot disease resistant parent (M 134/75) and a susceptible parent (R 570) was screened with AFLP and gSSR. A genetic linkage map was constructed for variety M 134/75 containing 95 LGs onto which 567 single dose markers were mapped.

Field disease resistance data of the mapping population scored over two ratoon crops coupled with molecular marker data enabled the identification of a major quantitative trait locus (QTL) responsible for 23.8% field phenotypic variation in the trait. This QTL is flanked on one side by an AFLP marker actctc10 and an SSR marker mSSCIR12284 at 14 cM and 18 cM respectively. These markers are, however, not close enough to the yellow spot QTL to validate their use in sugarcane MAS. The ultimate aim of this project is to identify markers located at approximately 5 cM to this QTL that can be used for MAS.

Map enhancement of M 134/75 was thus considered from a set of sugarcane EST-SSR primers (sequences, kindly provided by E. Ulian). The use of orthologous EST-SSR was also investigated to facilitate the comparative mapping of sugarcane to closely related species. The most appropriate candidate is sorghum, which diverged from a common ancestor 8–9 million years ago (Jannoo et al., 2007). Sorghum RFLP probes have been previously used in sugarcane mapping and have shown perfect synteny with sugarcane (Guimares et al., 1997; Ming et al., 1998). The application of EST-SSR marker systems to the linkage mapping of sugarcane is thus being reported.

**Materials and methods**

DNA was extracted from mapping parents M 134/75 and R 570 and their 226 mapping progeny population as described by Aljanabi et al. (1999). Resuspended DNA was diluted to 20 ng/µL for further use.

**Sugarcane EST-SSR PCR**

The mapping parents M 134/75 and R 570 were screened with 25 sugarcane EST-SSR primers by PCR in 20 µL reaction volumes using the following conditions; 1X reaction buffer
(Roche), 0.4 µM dNTPs (Roche), 1 unit Taq polymerase (Roche), 0.4 µM forward primer, 0.4 µM $^{33}$P labelled reverse primer and 50 ng DNA template. PCR conditions were as follows: an initial denaturation at 94°C for 3 min followed by 32 cycles at 94°C, annealing at 54°C and extension at 72°C each for 1 min and a final extension at 72°C for 5 min.

Selected polymorphic primers (5) were used to genotype the mapping population. PCR products were run for 2 h on 6% polyacrylamide gels, pre-warmed at 60°C. Gels were blotted on filter paper, vacuum dried and exposed to X-ray films (Kodak X-OMAT). Depending on the intensity of the $^{33}$P signal, films were developed 2–5 days after exposure.

**Sorghum EST-SSR primer testing**

Two sets of sorghum EST-SSR were used, 30 primer pairs (SOR1-30) previously used in a cross-species transferability study (Wang *et al.*, 2005) and 600 primer pairs (SAT0100-SAT1250) from ICRISAT (sequences kindly provided by Dr T. Hash) were initially tested for cross-species transferability at an annealing temperature of 50°C by PCR in 20 µL reaction volumes using the same reaction mix as above.

PCR conditions were as follows: an initial denaturation at 94°C for 3 min followed by 32 cycles at 94°C for 45 s, annealing at 50°C for 45 s and extension at 72°C each for 30 s and a final extension at 72°C for 5 min. The PCR products were run on agarose gels (2%) and visualised over a UV transilluminator after staining with ethidium bromide.

The SOR primers were screened for polymorphism with the mapping parents and five selected primers were used for population genotyping. The SAT primers were also tested for cross-species transferability and 425 initially selected primers were used to assess the level of polymorphism between the mapping parents.

Thirty-two out of 134 primers showing distinct profiles with prominent bands were further used for population genotyping on polyacrylamide gels.

**Marker scoring and nomenclature**

A pseudo-testcross strategy was followed to score the polymorphisms (Grattapaglia and Sederrof, 1994). The bands were scored for the presence or absence when heterozygous in M134/75, null in R570 and segregating progeny population.

Each marker was given a unique identifier as follows: the first three letters referred to the origin of the primer; SOR or SAT. For SOR markers, the next digit or two digits referred to the primer number (1–30) and the last digit referred to the allele number (eg SOR 202 refers to allele number 2 from primer SOR20). For ICRISAT markers, the 4 digits next to SAT referred to the primer number and the last digit referred to the allele number.

Alleles from the same primer were numbered according to the position of the marker on the gels depending on their molecular weights. The highest molecular weight polymorphic marker was named as *Primername1* and sequentially increased by one unit with decreasing sizes.

Likewise, sugarcane EST-SSR markers were named according to the name of the primer ESTSC or ESTD followed by the allele number. AFLP and gSSR markers nomenclature was as described as Aljanabi *et al.* (2007).

**Linkage map construction and homology grouping**

A chi-square test was performed to select for single dose markers i.e those segregating in a 1:1 ratio. GMendel (Holloway and Knapp, 1994) from iMAS platform (an integrated marker assisted selection software [http://localhost:8080/iMAS](http://localhost:8080/iMAS)) was used for linkage map construction.

All markers with more than 15% missing values and genotypes (5) missing at >15% were excluded from the analysis. Two-point analyses between single dose markers were performed at a LOD score threshold of five and recombination fraction threshold of 0.30. Markers within each
linkage group (LG) were then ordered by using the Kosambi mapping function. The LGs were graphically represented using Mapchart 2.1 (Voorrips, 2002). LGs were pooled into the same HGs when they had at least two common SSR markers.

A number of LGs with only one common SSR marker were grouped into unassigned HGs (UAHG). The nomenclature of the HGs was in accordance to Rossi et al. (2003) whenever possible.

**Results**

Among the twenty-five sugarcane EST-SSR primers, only 12 primers (48%) were found polymorphic. The average level of polymorphism for the resistant parent M 134/75 was only 1.5 as compared to 2.0 for gSSR (unpublished data). Twelve markers were scored after genotyping with five EST-SSR primers.

All SOR primers were transferable to sugarcane as observed on agarose following amplification, whereas 95% of SAT primers correspondingly amplified an orthologous target in sugarcane.

As compared to sorghum, sugarcane amplification with sorghum EST-SSR primers showed a more complex profile.

A higher number of amplicons and a wider distribution of amplicons along the gels were observed when sorghum primers were used on sugarcane. In most cases, the level of polymorphism is higher in sugarcane than in sorghum probably due to the higher ploidy level of the sugarcane genome.

There was also no apparent size correlation between sorghum and sugarcane amplicons (data kindly provided by R. Punna, ICRISAT).

Sixteen SOR primers produced markers polymorphic to M 134/75 revealing an average 2.3 polymorphisms. Among the 425 SAT primers screened, 275 primers were found polymorphic for the resistant parent M 134/75. These revealed 712 polymorphisms averaging 2.6 polymorphisms per primer.

The 32 SAT primers used to genotype the mapping population revealed 102 polymorphisms. These were combined with 13 SOR markers and 12 sugarcane EST-SSR markers. The 127 markers were trimmed to 102 markers segregating into a 1:1 ratio. These data were pooled with existing 985 non-coding AFLP and gSSR primers to produce a combined marker data set of 1087 markers.

The final data were analysed by GMendel from iMAS. A partial genetic map of sugarcane hybrid cv M 134/75 was produced containing 640 markers, 143 LGs and with a total map length of 9530 cM. Among these, 58 EST markers were mapped into 26 LGs, 8 of which (30%) contained solely EST-SSR markers.

Grouping of LGs into homologous groups was carried out according to Rossi et al. (2003) whenever applicable. Using this nomenclature system, LGs belonging to HG I, II, III, VI, VII and VIII were identified and assigned to their respective HG.

No grouping was possible into HG IV and HG V since no mSSCIR marker (Table 1) has been assigned to these HGs. Using the system of grouping of LGs containing at least two common SSR markers, four additional HGs were identified, HG IX –HG XII. LGs containing only one common SSR marker were classified into five unassigned HGs (UAHG 1-UAHG 5).

This method of nomenclature enabled classification of EST-SSR from 26 primers into four HGs, II, III, VIII and X.

Markers from only two primers were shared between HGs i.e markers SAT0918 and SAT0203 were present in both HG II and HG VIII.

Twenty-two LGs were classified into HG VIII, which represented the highest frequency found in any HG.
Table 1—Classification of LGs according Rossi et al. (2003) and identification of EST-SSR markers belonging to their respective HG. (Classification according to: a = Rossi et al., 2003, b = Aljanabi et al. 2007, na = not available).

In a previous work (Aljanabi et al. 2007), a putative QTL for resistance to yellow spot was identified on LG87 flanked by markers Actctc10 and CIR12284 (Figure 1). In this study, this LG has been enhanced with three sorghum EST-SSR markers SAT1225, SAT0203 and SAT0612 and sugarcane ESTSC2 of newly named LG68 classified into HG VIII (Figure 1).

![YS QTL](image)

Fig. 1—Map enhancement of LG 68 harbouring the YS resistance QTL with sorghum EST-SSR primers SAT1225, SAT0203 and SAT0612 and sugarcane derived EST-SSR primer ESTSC2.
Fig. 2—Synteny across sugarcane LG based on sorghum EST-SSR markers. Arrows shows marker linkage conservation between markers SAT1225, SAT0203 and SAT0612 on LG 5, LG 68 and LG 44.

Synteny across the LGs is exemplified between markers of LG 5, LG 44 and LG 68 (Figure 2). SAT0203 and SAT0612 are linked on LG 5, SAT0612 and SAT1225 are linked on LG 44. All three markers are linked on LG 68.

Discussion

The use of sugarcane EST-SSR in the genetic mapping of sugarcane has so far been reported by Oliveira et al. (2007) whereby an integrated map of sugarcane was constructed from a cross between hybrid cultivars SP80-180 and SP80-4966.

The application of sugarcane EST-SSR mapping to variety M 134/75 was investigated from a set of 25 primers. However, a low level of polymorphisms was detected between the mapping parents. From 12 sugarcane EST-SSR SDMs scored, six (50%) were successfully assigned to LGs. On average, the same percentage of integration was observed by Oliveira et al. (2007).

The use of sorghum EST-SSR in the mapping of sugarcane has not been described before. Documentation is available mostly on cross-transferability studies and their potential use in diversity studies and linkage mapping. In a similar study (Wang et al., 2005), the transfer rate EST-SSR from hexaploid wheat to tetraploid wheat was found to be 80% despite them belonging to the same genus.

The transfer rate from sorghum to maize (both belonging to the same family –Panicoideae) was only 61%. The few sorghum EST-SSR primers (less than 5%) that could not be transferred to sugarcane could be attributed to sequence divergence between the two genera or to experimental errors. Average polymorphism level of 2.3 and 2.6 for SOR and SAT primers respectively indicated excellent potential of such orthologous marker systems applied to sugarcane mapping.

Sorghum EST-SSR primers produced a complex PCR profile with several bands when amplifying sugarcane as compared to sorghum where only 1–2 amplicons can be observed. This complexity can be attributed to the polyploid genome of sugarcane. With eight genomes contributed by *S. officinarum* and combined to the genome contributed by *S. spontaneum*, at least nine ‘homoeologous’ regions can be targeted by the primers.

Also, since target regions may vary in sequence between sorghum and sugarcane combined with a low annealing temperature (50°C), primers could be targeting non-orthologous regions adding to the complexity of the profile. Finally, variation in the number of repeats coupled with the
presence of indels/introns of different sizes across species could explain the lack of correlation in fragment size between sorghum and sugarcane.

Data from 102 single dose EST-SSR (sugarcane and sorghum) markers were combined with existing 985 non-coding AFLP and gSSR markers to produce a partial genetic map of sugarcane variety M 134/75 of 143 LGs. By grouping together LGs carrying common SSR markers as described by Rossi et al. (2003), it has been possible to equate the LGs into their respective HGs. Using this approach, LGs were assigned to HGs I, II, III, VI, VII and VIII. LGs belonging to HG IV and V were not identified due to lack of common gSSR markers. LG 68, harbouring the yellow spot disease resistance QTL was thus assigned into group VIII.

Of interest is that a sugarcane rust resistance gene was located on LG 3 of an R 570 map, which also belongs to HG VIII and where three resistance gene analogue clusters are also present (Raboin et al., 2006). Now that the location of the yellow spot disease resistance QTL has been confined to HG VIII, more effort can be channelled into the mapping of markers known to be located in this HG.

A framework of markers common to HG VIII is already available (Piperidis et al., 2008) after comparison of genetic maps of varieties Q 165, Q117 and MQ77-340 to R 570. This will be used to enhance LGs assigned to HG VIII of M 134/75 instead of targeting the sugarcane cv M 134/75 entire genome.

LG 68 harbouring the yellow spot disease resistance QTL has also been enhanced by three SAT markers i.e SAT1225, SAT0203 and SAT0612. The nomenclature of these SSR markers is based on their location on the rice chromosomes, i.e the first two digits of the primer name represents the EST location on the rice chromosome (R. Punna, personal communication).

In this respect, fragments of rice chromosomes 12, 2 and 6 could be collinear to the regions within LG 68. Channelling efforts into the mapping of a maximum of sorghum EST-SSR primers along these 3 series of primers (i.e SAT1201-1250, SAT0601-0650 and SAT0200-0250) could further enhance this LG and identify markers closer to the yellow spot gene.

However, synteny between rice and sugarcane is known to have been disrupted by a number of rearrangements and translocations (Asnaghi et al., 2000). A more accurate alternative is to identify the region into sorghum harbouring the SAT1225, SAT0203 and SAT0612 markers and eventually to describe the collinear region in the vicinity of the yellow spot gene.

A detailed study of LGs 5, 44 and 68 belonging to HG VIII provides an interesting example of the conservation of gene order among different chromosomes. LG 5 harbours markers SAT0203 and SAT0612, LG 44 links SAT1225 and SAT0612. LG 68 harbours all three SAT markers i.e SAT1225, SAT0612 and SAT0203 thus showing the conserved gene order between these three markers.

Therefore, through the use of sorghum EST-SSR markers, it has been possible to demonstrate the existence of collinearity among sugarcane homoeologous chromosomes and confirms the fact that comparative genetics remains a powerful tool to study genome organisation especially in complex polyploids like sugarcane.

Résumé

La construction de cartes génétiques de canne à sucre a été largement limitée à l'utilisation des marqueurs non-géniques tels les AFLP et les SSR génomiques. En outre, la comparaison entre les cartes génétiques du genre *Saccharum* pose des difficultés en raison de l’absence des marqueurs en commun. Dans cette étude, une carte génétique de la variété M 134/75 de canne à sucre réalisée avec les marqueurs AFLP et SSR-génomiques et composée de 95 groupes de liaison a été couplée avec des marqueurs géniques dans le but de disséquer le génome de la canne à sucre et de permettre des comparaisons génomiques intra- et inter- spécifiques. Le but ultime de ce projet consiste à identifier des marqueurs liés au QTL de résistance de la maladie de taches jaunes (yellow spot) et à leur application dans la sélection assistée par marqueurs. Les parents M 134/75 et R 570 ont été criblés avec 25 amorces EST-SSR dérivées des séquences de canne à sucre. Au total 291 amorces EST-SSR-sorgho ont produit des bandes polymorphes dans la variété M 134/75, avec une moyenne de 2.6 polymorphismes par amorce. Une descendance de 226 progénitures a été évaluée avec cinq amorces EST-SSR dérivées de la canne à sucre et 37 du sorgho. Cent deux marqueurs EST-SSR qui ségréguaient selon un ratio de 1:1 (simplex) ont été couplés avec 985 marqueurs non codant et les résultats analysés à l'aide du logiciel Gmendel. Une carte partielle de la variété M 134/75 comprenant 143 groupes de liaison a été réalisée. Cela a permis l’intégration de 58 marqueurs EST-SSR du sorgho dans 26 groupes de liaison génétique. En comparant les marqueurs SSR communs, les groupes de liaison ont été rassemblés en dix groupes homologues, parmi lesquels quatre comprenaient des marqueurs EST-SSR du sorgho. Le groupe de liaison 68 sur lequel le QTL pour la résistance aux taches jaunes est présent, a été aligné avec le groupe homologue VIII (HG VIII). Trois marqueurs EST du sorgho ont aussi été placés sur le groupe de liaison 68. La cartographie comparative sera exploitée pour une cartographie fine du QTL responsable pour la résistance aux taches jaunes.

PALABRAS CLAVE: EST-SSR, Mapa de Ligamiento, Caña de Azúcar y Enfermedad de la Mancha Amarilla.

Resumen

LA CONSTRUCCIÓN de mapas de ligamiento de caña de azúcar ha sido limitada en gran medida por el uso de sistemas no génicos, como los AFLP y los genómicos SSR. En adición, la comparación de mapas entre el género Saccharum ha sido obstaculizado por la falta de marcadores en común. En este estudio, el mapa de ligamiento de la variedad M 134/75 de la caña de azúcar (construido con marcadores AFLP y SSR) consistente de 95 grupos de ligamiento (GL) fue mejorado con sistemas de marcadores génicos a fin de disectar, subsecuentemente, al genómio de la caña de azúcar y hacer posible comparaciones genómicas dentro y entre especies. El objetivo esencial de este proyecto es identificar marcadores asociados con los QTL de la resistencia a la enfermedad de la mancha amarilla y su introgresión en el fitomejoramiento asistido con marcadores de la caña de azúcar. La criba de los progenitores usados en la cartografía, M 134/75 y R 570, fue efectuada con 25 iniciadores (primers) EST-SSR de la caña de azúcar y 425 del sorgo. En promedio, 1.5 bandas polimórficas fueron detectadas para el M 134/75 con iniciadores EST-SSR de la caña de azúcar. Doscientos noventa EST-SSR iniciadores de sorgo fueron identificados como polimórficos para el progenitor M 134/75, con un promedio de 2.6 polimorfismos por iniciador. La progenie que constituyó la población de 226 individuos fue evaluada con cinco iniciadores EST-SSR de la caña de azúcar y 37 de sorgo. Ciento dos marcadores que codifican para una sola secuencia fueron combinados con 985 marcadores de no codificación que se encontraban disponibles, los cuales fueron analizados con la aplicación GMendel para producir un mapa parcial de M 134/75 constituido por 143 GL. Esto hizo posible la integración de 58 marcadores EST-SSR de sorgo con 26 GL. Con base en los SSR en común, los GL fueron agrupados en diez grupos homólogos (GH), entre los que se encontraban cuatro EST-SSR de sorgo. Los 68 GL que contenían los QTL de resistencia a la mancha amarilla fueron equiparados al GH VIII, el cual fue adiciona con tres marcadores del sorgo. La cartografía comparada será aprovechada en la cartografía fina de los QTL de la resistencia a la enfermedad de la mancha amarilla.
THE SUCEST-FUN REGULATORY NETWORK DATABASE: DESIGNING AN ENERGY GRASS

Abstract
Modern sugarcane cultivars are complex hybrids resulting from crosses among several Saccharum species. Traditional breeding methods have been employed extensively in different countries over the past decades to develop varieties with increased sucrose yield and resistance to pests and diseases. Conventional variety improvement, however, may be limited by the narrow pool of suitable genes. Thus, molecular genetics is seen as a promising tool to assist in the process of developing improved varieties. The SUCEST-FUN Project (http://sucest-fun.org) aims to associate function with sugarcane genes using a variety of tools, in particular those that enable the study of the sugarcane transcriptome. An extensive analysis has been conducted to characterise, phenotypically, sugarcane genotypes with regard to their sucrose content, biomass and drought responses. Through the analysis of different cultivars, genes associated with sucrose content, yield, lignin and drought have been identified. Currently, tools are being developed to determine signalling and regulatory networks in grasses, and to sequence the sugarcane genome, as well as to identify sugarcane promoters. This is being implemented through the SUCEST-FUN (http://sucest-fun.org) and GRASSIUS databases (http://grassius.org), the cloning of sugarcane promoters, the identification of cis-regulatory elements (CRE) using Chromatin Immunoprecipitation-sequencing (ChIP-Seq) and the generation of a comprehensive Signal Transduction and Transcription gene catalogue (SUCAST Catalogue).

Introduction
The increased importance of sugarcane as a bioenergy feedstock has increased pressure to generate new varieties optimised for energy production. The generation of improved varieties has relied largely on traditional breeding methods, which is limited by the narrow pool of suitable genes and the time-consuming process of selection of plants with desired agronomic traits. In this sense, molecular genetics can assist the process of developing improved varieties by generating molecular markers that can be used in the breeding process or by introducing new genes into the sugarcane genome (Menossi et al., 2008).

In the last few years, the use of many high-throughput methods has exponentially increased the amount of data available to molecular geneticists. As a result, bioinformatics and efficient data management are essential in order to generate useful information. Furthermore, most of the available biological data are complex and stored in dozens of smaller databases (Lacroix and Critchlow, 2003). These databases are frequently not easy to identify and integrate, making the use of information very difficult because of the variety of semantics, interfaces, and data formats used by the underlying data sources (Lacroix and Critchlow, 2003).
The aim of this paper is to describe the SUCEST-FUN Regulatory Network Database (CaneRegNet), which contains data and tools of interest for sugarcane functional genomicsists and molecular breeders. This database has been developed in the concept of the mediator approach that incorporates concepts from Data Warehouse and Federation approaches (Lacroix and Critchlow, 2003). It also has flexible data integration to assemble heterogeneous distributed data sources, experimental data, resources, the applications of scientific algorithms and computational analysis.

The database community has extensively investigated architectures and tools for data integration (Lacroix and Critchlow, 2003). A key disadvantage of the warehouse approach is the need for local administrators to maintain the data, while providing control over the contents of the warehoused data. Mediators and heterogeneous Database Management Systems (DBMS), on the other hand, submit the queries directly to the wrappers; program routines that take data from Internet websites or any other data repositories and convert the information into a structured format, and integrate the results locally (Boulcelma et al., 2003).

A geographic data warehouse must provide an expressive query language that may be difficult to maintain and less expressive than those available at remote sources. On the other hand, non-materialised approaches must not only integrate data, but also support all these query capabilities of interest. The purpose of the mediator approach is to integrate both data and source capabilities.

**Methods**

The databases were developed using MySQL Server (http://www.mysql.com) while the interface and search systems were based on the WebServer Apache (http://www.apache.org).

The website uses the Joomla platform, as a Content Management System. This platform is developed using PHP (server-side HTML-embedded scripting language). Both Joomla and PHP are free software released under the GNU/GPL Licence. Joomla provides a more interactive website, which allows keyword searches and also manages the access control for groups of users. Moreover, Joomla has a toolkit that provides flexibility in the integration of scripts and programs developed in other languages.

The tools and scripts developed and implemented in the website were produced using CGI (Simple Common Gateway Interface Class), PHP (http://www.php.net), PERL (http://www.perl.org) and R (http://www.r-project.org) a statistical environment. The data are available to the SUCEST-FUN community through the integration of other platforms such as the Gbrowse (Generic Genome Browse – http://www.gmod.org) and BioPerl (Stajich et al., 2002) modules.

**Results**

The CaneRegNet has been developed following the concept of the mediator approach, which integrates concepts from the Data Warehouse and the Federation approaches. Accessed data are up-to-date, but access can be costly. In addition, wrappers (Boulcelma et al., 2003) must be maintained since data providers may change the entry points to the data sources as well as the database organisation. Neither materialised into data warehouses nor non-materialised approaches address the problem to access or maintain sophisticated tools that enhance data manipulation. Indeed, in addition to standard data manipulation such as those performed by SQL, geographic languages usually express spatial selections, metric or topological queries and allocations among other features (Boulcelma et al., 2002).

The SUCEST-FUN Regulatory Network Database (CaneRegNet) assembles different sugarcane databases such as the SugarcaneExpressed Sequence Tags (SUCEST) Genome Project (http://sucest.lad.ic.unicamp.br/en/) (Vettore et al., 2003), the SUCAST and the SUCAMET Catalogues, which include expression data (http://sucest-fun.org), the GRASSIUS database (Yilmaz et al., 2009) and records of the agronomic, physiological and biochemical characteristics of
sugarcane cultivars. This database is part of the SUCEST-FUN Regulatory Network Project (http://sucest-fun.org), which aims to study gene expression regulation through the use of tools that will allow a System Biology approach for the study of sugarcane. This database is based on five main topics: 1) Gene annotation, 2) Gene Expression, 3) Public Resources, 4) Sequencing Projects and 5) Functional Genomics (Figure 1).

Fig. 1—Diagram of the CaneRegNet database and data abstraction. The CaneRegNet is based on five main topics: Gene Annotation, Gene Expression, Public Resources, Sequencing Projects and Functional Genomics. The topics and source arrows are bidirectional allowing the interaction and relationship between them. TFs stand for Transcription Factors.

1) Gene Annotation

The Gene Annotation resource integrates the many catalogues generated from the annotation and categorisation of the putative transcripts sequenced by the SUCEST project (http://sucest.lbi.ic.unicamp.br/public/), which is the largest sugarcane EST collection and is represented by 43,141 putative transcripts known as the Sugarcane Assembled Sequences (SAS).

The SUCAST Catalogue (Sugar Cane Signal Transduction—http://sucest-fun.org/cane_regnet/en/database-tools/gene-catalogue/sucast-catalogue) is the first characterisation of the putative transcripts sequenced by the SUCEST project.

It contains more than 3500 components involved in several aspects of signal transduction, transcription, development, cell cycles, stress response and pathogen interaction (Souza et al., 2001).

The SUCAST Catalogue Tool allows the search of genes by categories and contains genes involved in signal transduction pathways that integrate with the sugarcane kinome based on a phylogenetic categorisation (Rocha et al., 2007).

The SUCAMET Catalogue (Sugar Cane Metabolism) contains genes involved in metabolic pathways. As in the SUCAST Catalogue, the SUCAMET Catalogue Tool was developed to enable the search for genes by categories.

Both the SUCAST and SUCAMET projects were used to generate cDNA-arrays for the study of the sugarcane transcriptome.

More recently, a Cell Wall Catalogue and a Transcription Factor Catalogue were included in the CaneRegNet. The Transcription Factor Catalogue was generated as part of a collaborative effort.
to develop the GRASSIUS Platform (Grass Regulatory Information Services) (Yilmaz et al., 2009). GRASSIUS holds information on transcription factors (TFs) from maize, sorghum, sugarcane and rice classified into families.

The TFs for grasses can be accessed by either browsing family members or searching by name or by sequence similarity through BLAST searches or by phylogenetic homology. The GRASSIUS Platform contains 1647 TFs catalogued for sugarcane, which represents about 83% of the number estimated to be present in sugarcane (Yilmaz et al., 2009).

The identification of sugarcane TFs is an essential step in the process of building regulatory networks, which also requires the identification of promoters, CREs and knowledge on their interactions with TFs (Schlitt and Brazma, 2007).

2) Gene Expression

The Gene Expression resource is focused on the comparison of the expression profile of different sugarcane varieties, different tissues within one individual and individuals subjected to different biotic and abiotic stimuli.

The expression profiles were made from two different custom cDNA microarrays. One cDNA microarray contained 2208 elements from the SUCAST Catalogue and was designed to identify the transcriptome changes in response to drought, phosphate starvation, stress in response to herbivory and N2-fixing endophytic bacteria.

Also investigated was the response of sugarcane to phytohormones, such as abscisic acid (ABA) and methyl jasmonate. The other cDNA microarray (SUCAMET Catalogue) contained 4594 elements that are involved in cellular process, stress response and basal metabolism.

An outliers searching method resulted in the identification of 179 genes that were considered differentially expressed in at least one of the treatments analysed (Rocha et al., 2007). qRT-PCR was used to validate the expression profiles obtained using the cDNA arrays.

Expression data were stored in different stages and formats in flat files and Relational Databases, which can be visualised and grouped by correlation, Venn diagrams or experiments using different cut-offs and levels of confidence. The analysis of both cDNA arrays resulted in the development of several tools that allow the search for differentially expressed genes. For example, a virtual Matrix of expression profile by tissues was constructed using data from the SUCAST microarray, which allowed the identification of sugarcane genes that are tissue specific.

Furthermore, a Self Organising Map (SOM) tool was implemented to select differentially expressed candidate genes to make hierarchical clustering analysis (Rocha et al., 2007). The Gene Expression database in CaneRegNet allows the identification of genes that are co-regulated by different treatments.

For example, a comparison between the transcripts from sugarcane treated with 100 μM ABA and those present in drought tolerant and drought sensitive sugarcane varieties subjected to water deficit stress showed that 14 of the 24 genes differentially regulated by ABA also had different expression levels in one of the sugarcane varieties.

In addition, 115 of the 184 genes regulated in tolerant varieties submitted to drought were also differentially expressed in sensitive varieties (Figure 2). Among the ABA treatment and the drought tolerant varieties submitted to drought and between ABA treatment and drought sensitive varieties, the four gene categories that were more represented included stress, carbohydrate metabolism, hormone biosynthesis and no matches.

Eleven genes were differentially expressed in the three samples. These genes belonged to stress, carbohydrate metabolism, hormone biosynthesis, no matches, protein phosphatase and unknown protein functional categories.

Another example of co-regulation has recently been described for genes associated with sucrose content and drought responses (Papini-Terzi et al., 2009).
Fig. 2—Comparison of differential gene expression associated with ABA treatment and drought stress in sugarcane. Genes were identified as associated with ABA if they were differentially expressed when treated (for 0.5, 1, 6 and 12 h) and untreated plants were compared. Genes regulated during drought stress were identified by comparing plants with irrigation and without irrigation after 24, 72 or 120 h of water deficit. The figure represents a Venn diagram of the three differential expression data sets. The credibility level used to define outliers was 0.96 in all three data sets.

A new platform 60-mer Agilent oligoarray technology with a custom-designed array (44k = 44 000 elements) has been developed recently to improve the investigation of the sugarcane transcriptome. Approximately 40% of the unique genes in the SUCEST database are represented in this array, with a total of 21 902 specific probes replicated twice and designed in the sense and antisense direction with high specificity. This oligoarray will allow the identification of antisense expressed sequences and the sugarcane regulatory networks associated with sucrose content and drought stress.

3) Public Resources

A great number of databases and resources have been developed for general genome analysis, such as the National Center for Biotechnology Information (NCBI), Gene Ontology (GO)(Ashburner and Lewis, 2002) and Kyoto Encyclopedia of Gene and Genomes (KEGG) (Kanehisa and Goto, 2000), and for the study of grass genomes, such as MaizeGDB (Lawrence et al., 2004) Sorghum Phytozome (Paterson et al., 2009) and Rice Genome Annotation (Yuan et al., 2003). These databases allow the integration of a variety of data types and analyses in a single framework. The flexibility of these generic data abstractions will allow the integration of all data and joint analysis of sugarcane and other grasses, and will provide a simple and fast searching platform.

4) Sequencing Projects

The CaneRegNet database contains the sequences produced by the SUCEST Project (http://sucest.lad.ic.unicamp.br/en/; (Vettore et al., 2003). This project produced 237 954 high quality ESTs, obtained from 27 cDNA libraries from different sugarcane tissues of different developmental stages and stress conditions. This collection of ESTs was assembled into 43 141 putative genes referenced as Sugarcane Assembled Sequences (SAS) that can be analysed with the following tools:

- **Tissue and Library Search**—gives access to the names, descriptions and EST sequences by library or tissue specific
- **Cluster alignment viewer**—shows the cluster assembly of an EST
- **Object Search**—permits direct access to any object, such as ESTs or a SAS name
• **Generic SQL Query**—allows users to create generic queries typed in a web form and the results are exhibited in a tabular format

• **SAS Information Viewer**—integrates and exhibits all SAS information available in the CaneRegNet database.

Sugarcane and sorghum are syntenic organisms that show co-linearity between the genes and striking homology in most of the coding parts of the genome (Jannoo *et al.*, 2007). When SUCEST was compared with the sorghum CDS sequences using the pairwise alignments, 4212 orthologue candidates were identified (Table 1). These putative orthologues were identified using stringent parameters of e-value, coverage and identity. Because SAS are expected to contain UTRs and some of them are incomplete transcripts, a more rigorous coverage threshold was applied to sorghum. Less stringent parameters may result in a larger number of candidates, at the cost of increase in false positives.

A number of SAS (19,418) were mapped onto the sorghum genome using tools that allowed the identification of intron/exon boundaries spanning 10 chromosomes and 3294 supercontigs. The best match of each SAS between all chromosomes and supercontigs was selected. Next, a threshold of 90% of coverage and 90% of identity was used to select the orthologue candidates. Further work is needed in order to extend the SAS and identify more orthologue candidates.

The EST sequences from the SUCEST database are essential for the Gene Expression and the Gene Annotation databases. However, they lack information about the promoters, and other regulatory elements, that are essential for the understanding of gene regulatory networks. A major sequencing effort has recently started in order to generate more information about regulatory elements of sugarcane genes. The Sugarcane Genome Sequencing Initiative ([http://bioenfapesp.org](http://bioenfapesp.org)) is focused in sequencing the sugarcane gene space using next generation sequencing tools. One approach is the use of massively parallel pyrosequencing in association with gene-enrichment methods. The CaneRegNet database is currently being prepared to integrate these sequences to the SUCEST database and the sorghum genome using GBrowser. Sequencing strategies are expected to include BAC sequencing, surveys of several cultivars using the shot-gun approach, ChIP-Seq (Chromatin Immunoprecipitation followed by sequencing), those targeting gene promoters and full length cDNA sequencing.

### 5) Functional Genomics

The vast amount of data contained in Gene Annotation, Gene Expression, Public Resources and Sequencing Projects databases must be organised in the context of the plant in order to provide new understanding of gene function and gene interaction, which are instrumental for the discovery of genes that regulate agronomic traits of interest. These genes can be used as molecular markers in breeding programs or to generate transgenic sugarcane plants.

Physiology studies and transgenic sugarcane plants will be used to test hypotheses regarding gene regulatory networks and for assigning function to the genes identified. The CaneRegNet database will store information on all plant samples, including agronomic traits such as growth...
rates, water use efficiency, photosynthesis parameters, and sugar and cell wall content of sugarcane genotypes. Information on the protocols, experiments, clones, vectors and primers as well as the results generated will be stored and visualised by a web interface and integrated into the Relational database with the other resources.

Discussion and future directions

An evolving integrated platform has been developed to integrate and store a large amount of data from diverse sources and experimental conditions. The SUCEST-FUN db provides the infrastructure for storage, retrieval and integration especially for deep sequencing genomics, DNA methylation filtration experiments, Molecular Markers, ChIP-Seq data, expression data, gene catalogues and information on sugarcane physiology and from the analysis of transgenic plants. The mediator approach will allow the running of parallel queries, do parallel loads into multiple SUCEST-FUN db instances, and provide unlimited data storage and management. The SUCEST-FUN db will be an important tool for scalable storage and interpretation of these data. New datasets will be available as soon as the accompanying papers are released.

The search and analysis tools developed in the project have allowed correlations to be made among gene expression experiments as well as among groups of experiments treating different conditions and treatments. The tools have also permitted the consolidation of the data with manually curated genes, gene catalogues and aggregated public resources such as GO and KEGG.

The extent of genetic and genomic information available on several species, such as barley, wheat, maize, rice, and sorghum, which belong to different tribes in the grass family, has enabled the most comprehensive comparative genomic studies in plants (Eckardt, 2008). The SUCEST-FUN db will be fundamental for the development of new tools and analysis of the sugarcane genome and functional genomic studies.

In the future, this platform will be composed of new algorithms and analysis tools, which are to be based on mathematical and statistical methodologies and draw on numerous biological resources. These resources will exploit the whole sugarcane genome sequence, the transcriptome and functional genomic data. This will allow the application of a Systems Biology approach to sugarcane in order to identify regulatory gene networks, discover new genes and develop improved ‘energy’ cultivars.

Résumé

LES CULTIVARS modernes de la canne à sucre sont des hybrides complexes résultant de croisements entre plusieurs espèces de Saccharum. Au cours des dernières décennies, des méthodes d’amélioration génétique traditionnelles ont été surtout employées dans différents pays pour développer des variétés à fort rendement en saccharose et résistantes aux ravageurs et aux maladies. Cependant, l’amélioration des variétés par ces méthodes, est limitée par la gamme restreinte de gènes appropriés. Ainsi, la génétique moléculaire est considérée comme un outil prometteur pour aider au processus d’amélioration variétale. Le projet SUCEST-FUN (http://sucest-fun.org) vise à associer des fonctions à des gènes de la canne à sucre en utilisant une variété d'outils, en particulier ceux permettant l'étude du transcriptome. Une analyse approfondie a été menée afin de caractériser, les génotypes de canne à sucre basés sur les phénotypes suivants: la teneur en saccharose, la biomasse et la réponse à la sécheresse. Grâce à l'analyse de différents cultivars, les gènes responsables pour la teneur en saccharose et la lignine, ainsi que pour une réponse à la sécheresse ont été identifiés. Actuellement, des outils sont en cours de développement pour déterminer les réseaux de signalisation et de régulation parmi les graminées, ainsi que pour le séquençage du génome de la canne à sucre, et pour identifier des promoteurs de la canne. Ces projets sont réalisés par l'intermédiaire du programme SUCEST-FUN (http://sucest-fun.org) et les bases de données GRASSIUS (http://grassius.org), avec le support du clonage des promoteurs de la canne à sucre, l'identification des éléments cis-régulatoires (ECR) à l'aide de la méthode ChIP (Chromatin Immunoprecipitation-sequencing), et la génération d’un catalogue SUCAST détaillé (Signal Transduction and Transcriptome Gene catalogue).

Resumen

Los cultivares de la caña de azúcar son híbridos complejos resultantes de las cruzas interespecíficas de *Saccharum*. Métodos convencionales de fitomejoramiento han sido extensivamente usados en diferentes países a lo largo de las pasadas décadas para desarrollar variedades con un rendimiento mayor de sacarosa y resistencia a plagas y enfermedades. Sin embargo, el fitomejoramiento convencional puede limitarse por una reducción en la poza de genes adecuados. Por tanto, la genética molecular es vista como una herramienta prometedora para apoyar el proceso de desarrollo de variedades mejoradas. El proyecto SUCEST-FUN (http://sucest-fun.org) tiene como objetivo asociar la función de genes de la caña de azúcar usando una gama de herramientas, en particular aquellas que permiten el estudio del transcriptomo de la caña de azúcar. Un análisis extenso ha sido conducido para caracterizar, fenotípicamente, genotipos de caña de azúcar con respecto de su contenido de sacarosa, biomasa y respuesta a la sequía. A través del análisis de diferentes cultivares, han sido identificados los genes asociados con el contenido de sacarosa, el rendimiento, la lignina y la respuesta a la sequía. Actualmente, se están desarrollando herramientas para determinar las redes de señalización y regulación en gramineas, y para secuenciar el genomio de la caña de azúcar, así como para identificar promotores de caña de azúcar. Esto ha sido implementado a través de las bases de datos SUCEST-FUN (http://sucest-fun.org) y GRASSIUS (http://grassius.org), la clonación de promotores de caña de azúcar, la identificación de elementos *cis* de regulación (CRE, por sus siglas en Inglés) usando la Inmunoprecipitación–Secuenciación de Cromatina (ChIP-Seq, por sus siglas en Inglés) y la generación de un catálogo exhaustivo de Señalización de Transducción y Transcripción (Catálogo SUCAST).
PROSPECTS OF CELLULOSIC ETHANOL FROM SUGARCANE BAGASSE

KEYWORDS: Biomass, Biofuels, Cellulosic Ethanol, Cellulases, Enzymes.

Abstract

Agricultural residues such as grain straws and corn stover are abundant, readily available biomass feedstocks for the production of next generation biofuels, with collection and transport costs being a major component of their cost. Sugarcane bagasse is thus an especially attractive biomass feedstock in that it is an agricultural residue already present in large quantities at sugar and ethanol mills. The efficient conversion of bagasse lignocellulose to fermentable sugars is the major techno-economic challenge to the commercially viable production of ethanol from this feedstock. Bagasse is first pre-treated by a combination of high temperatures and pressures in the presence of chemicals, to facilitate subsequent enzymatic hydrolysis to break down the cellulose and hemicellulose to fermentable sugars. The sheer volume (an estimated 15–25 kg/t bagasse) and costs of the enzymes required for hydrolysis make the process economically unfeasible using current fermentation-based enzyme production technologies. The expression of enzymes in crop plants represents a promising approach to reduce the costs of enzyme production, and is an area in which Syngenta has strong intellectual property and advanced proprietary technologies. Syngenta’s corn amylase, currently undergoing regulatory approval in the United States, features a thermostable \(\alpha\)-amylase expressed in the grain for dry grind ethanol production applications, the first of a series of Syngenta traits designed for the biofuels industry. To enable the \textit{in planta} production of cell wall-degrading hydrolases for commercial next generation biofuels production requires an integrated approach within an overall engineering process model, incorporating upstream pre-treatment and downstream fermentation methodologies in addition to enzyme expression, extraction, storage and hydrolysis technologies. Progress in the development of this suite of technologies for the conversion of bagasse lignocellulose to fermentable sugars will be described.

Biofuels

Global production and use of plant-derived transport fuels tripled from 2000 to reach 76.5 billion litres in 2008 (Sims et al., 2008). The increase in biofuels is due to several factors, including increasing petroleum supply uncertainty and rapidly rising demand for transport fuels, primarily from emerging economies. Government policies have promoted biofuels, driven by energy security concerns and political support for rural economies. Global biofuels production is dominated by the US, Brazil, the European Union and China, all of whom have strong policies supporting biofuels.
Concerns over greenhouse gas emissions have also contributed to increasing interest in biofuels. Replacement of gasoline with ethanol is estimated to reduce greenhouse gas emissions by approximately 30% to 85% compared to gasoline, depending on whether corn or sugarcane feedstock is used (Fulton et al., 2004). Importantly, biofuels are unique in their general compatibility with our existing liquid transport fuel infrastructure, despite the potential for ethanol-mediated corrosion of existing pipelines.

The United States and Brazil produce 52% and 37% of 2008 global fuel ethanol production, respectively (http://www.ethanolrfa.org/industry/statistics/#E – accessed 2 Oct 2009). US ethanol production is primarily from corn starch converted to fermentable glucose by the addition of enzymes. Limitations on available acreage and price pressures will likely restrict US grain-based ethanol to an estimated 8% of gasoline consumption on an energy-equivalent basis, or about twice current production (Tyner, 2008). Sugarcane ethanol production in Brazil was approximately 24.5 billion litres in 2008, but is estimated to increase to 79.5 billion litres by 2022 (Goldemberg and Guardabassi, 2009), consistent with projected increases of 50–100% in global sugarcane tonnage in the coming decade (Kline et al., 2008). However, ethanol production from sugarcane will eventually also be limited by lack of suitable land and by competing demand by alternative uses, in this case sugar production.

New technologies are needed for biofuels to significantly contribute to the global energy matrix and to greenhouse gas emission reduction. Biofuels currently represent less than 3% of our transport fuel (Koonin, 2006). The enzymatic hydrolysis of biomass to sugars that are fermented to ethanol represents the most attractive technology for continued expansion of biofuels production. Advantages of this technology include a high carbohydrate recovery efficiency, potential for continuous improvement through biotechnology, and lower capital costs (Carroll and Somerville, 2009; Wyman et al., 2005).

Cellulosic ethanol

Cellulosic ethanol has the potential to supply a significant portion of our transport fuel needs, while reducing greenhouse gas emissions (Wang et al., 2007). An estimated 30% of total gasoline consumption could be provided by biofuels from agricultural crop residues alone (Kim and Dale, 2004; Koonin, 2006). Cellulosic ethanol technology research has accelerated as a result of increasing funding and investment, but significant interrelated techno-economic challenges remain.

High production costs make commercial cellulosic ethanol production unviable at present. These are estimated at between US$102-123 per barrel (Tyner, 2008), or more than US$0.66 per litre (Coyle, 2007). Capital expenses and operating (feedstock, processing and enzyme) costs combine to make cellulosic ethanol production expensive relative to first-generation ethanol. In addition, cost estimates are based on models and pilot-scale research due to the lack of operational commercial-scale cellulosic ethanol plants, increasing the investment risk profile (Galbe et al., 2007).

To overcome this hurdle, the US and other governments and companies are providing research funding and subsidies to give incentives for the development of next generation biofuels, including subsidies for biomass crop production, transport and storage.

Sugarcane bagasse

Plant biomass (lignocelluloses) is composed primarily of cellulose, hemicellulose and lignin linked by a complex web of covalent and hydrogen bonds. Cellulose primary structure consists of a linear homopolymeric chain of β1,4 linked cellobiose (glucose dimer) subunits. Primary chains are organised into higher level structures, finally comprising a 7–30 nm cellulose microfibril of hundreds of primary chains within a hemicellulose matrix, and coated with lignin (Zhang and Lynd, 2004). Importantly, cellulose exists mostly in crystalline form in plant cell walls, and is thus insoluble in water and commonly used solvents.
Hemicellulose is a heterogeneous branched polymer of pentose (C5) and hexose (C6) sugars whose composition varies according to species. In grasses, glucuronoxylans are the primary hemicelluloses, comprising a β1,4 linked xylose backbone and branching arabinose and glucuronic acid side chains. Grass hemicellulose also contains mixed (β1,3– and β1,4) linkage glucose polymers (β-glucans (Vogel, 2008). Hemicellulose acts as the filler between cellulose microfibrils and provides structural rigidity.

Lignin is a complex phenylpropanoid heteropolymeric network of coumaryl, coniferyl and sinapyl alcohols that acts as the glue linking and strengthening the polysaccharide components (Jorgensen et al., 2007). Unlike cellulose and hemicellulose, the complex structure and diversity of chemical bonds in lignin make enzymatic deconstruction difficult (Weng et al., 2008).

Sugarcane bagasse is an economically attractive biomass feedstock for cellulosic ethanol production, already present in substantial quantities at sugar and ethanol mills, and commonly burned to provide energy for the mill and, increasingly, for electricity cogeneration. The average composition of sugarcane bagasse (dry) is approximately 39% cellulose, 23% hemicellulose (with 89% of this being xylan), 24% lignin and 5% ash content (US Department of Energy, 2009). By comparison, corn stover and grain straw used for cellulosic ethanol production will incur collection and transport costs and will thus have a higher cost basis than sugarcane bagasse feedstock.

Pre-treatment

Biomass must be pre-treated to reduce the recalcitrance of lignocellulose to enzymatic hydrolysis. In untreated material, lignin and hemicellulose reduce enzymatic activity by steric hindrance, and crystalline cellulose slows cellulase action. In addition, lignin, ash and other components can irreversibly bind to and inactivate enzymes, or reduce their activity (Himmel et al., 2007).

Biomass recalcitrance can be reduced by chemical as well as physical pre-treatment methods. Reducing biomass particle size and increasing porosity can reduce recalcitrance by facilitating substrate access by hydrolytic enzymes, but is likely too energy-intensive to be cost-effective. Chemical pre-treatments also act to improve substrate access, by removing or altering deposition of hemicellulose and/or lignin, or by changing the cellulose characteristics such as crystallinity. Pre-treatment typically involves treatment with either acid or alkalis at high temperatures (100–200°C) and pressure. Acid-based pre-treatments act primarily by converting hemicelluloses to component pentose sugars, with reaction conditions being a trade-off between improvement of subsequent enzymatic hydrolysis, and loss of sugars and generation of inhibitors of downstream processes caused by increasing pre-treatment severity. Alkali pre-treatments remove lignin rather than hemicellulose, minimising inhibitor formation but requiring the use of hemicellulases and of microbial strains capable of mixed C5/C6 sugar fermentation.

Commercially viable pre-treatments minimise the costs associated with energy and chemical inputs, removal of inhibitors, water usage and waste disposal, while maximising the recovery of fermentable sugars (Galbe and Zacchi, 2007; Jorgensen et al., 2007). Pre-treatment typically represents about 18% of total production costs and also impacts the efficiency of downstream processes (Yang and Wyman, 2008). Most pre-treatment methodologies involve high capital expenses due to the materials and engineering designs required (Eggeman and Elander, 2005).

Enzymes

Cellulases and hemicellulases belong to the large glycosyl hydrolase (GH) family of enzymes. Cellulose hydrolysis requires at least three enzymes: an endo-glucanase, an exo-glucanase and a β-glucosidase. Endo-glucanases (EG) act by hydrolysing internal glucosidic bonds, freeing up ends that are attacked by exo-glucanases or cellobiohydrolases (CBH) that move progressively along the cellulose chain, cleaving cellobiose units. Cellobiohydrolases come in two forms, CBH1 and CBH2, that work from the reducing and non-reducing ends of the cellulose polymer,
respectively. Finally, β-glucosidases (BG) hydrolyse cellobiose to glucose to produce fermentable sugar and relieve product inhibition of CBH by cellobiose.

Enzyme cost reduction is a key issue in the commercialisation of cellulosic ethanol. On a mass basis, enzyme production costs are similar, yet it takes an estimated 40–100 times more enzyme to digest cellulose compared to starch (Merino and Cherry, 2007). Low activity requires high loadings of approximately 15–25 kg of hydrolytic enzymes per tonne of biomass (Houghton et al., 2006; Taylor et al., 2008). Long reaction times require large vessel sizes and hence high capital costs. Enzyme costs for corn dry grind ethanol production range from US$2.64–5.28 per m^3 (= 1000 litres) of ethanol produced (Houghton et al., 2006), compared to about US$79.25 per m^3 of cellulosic ethanol (Lynd et al., 2008), or at least 20–40 times more (Somerville, 2007). Enzymes thus comprise an estimated 20–40% of cellulosic ethanol production costs.

Expression of enzymes in crops

Efficient enzymatic hydrolysis of biomass substrates remains the major economic and technical challenge in the development of cellulosic ethanol (Himmel et al., 2007; Wyman, 2007). Enzyme cost reduction is critical to favourable cellulosic ethanol process economics; since enzyme loadings have been extensively optimised, improvements in enzyme activity and/or reduction in production costs are required. Cellulases can be improved by protein engineering to have higher specific activity, reduced allosteric inhibition, high temperature tolerance and altered pH optima. Expression of cellulases and hemicellulases in crop plants has the potential to significantly reduce production costs, by getting around the capital and operating costs associated with fermentation (Sainz, 2009; Sticklen, 2008; Taylor et al., 2008). In combination, the expression of multiple improved enzymes in crop plants would dramatically improve cellulosic ethanol process economics.

Plants can produce enzymes at much lower cost than fermentation methodologies, and can also provide additional benefits. Syngenta (www.syngenta.com) is currently seeking deregulation from the United States Department of Agriculture for the first crop-produced enzyme product, designed for corn grain ethanol production. Amylase is used in the conversion of starch to fermentable glucose in corn grain ethanol production. Syngenta corn event 3272 expresses an α-amylase gene with an improved temperature and pH profile, replacing commercial amylase enzymes produced by fermentation, with additional benefits that reduce production costs (Syngenta, 2009).

The environmental benefits of Syngenta Corn Amylase (Enogen™) include estimated reductions of 8% in processing water and 6–11% in greenhouse gas emissions (Urbanchuk et al., 2009). While actual benefits are likely to depend on plant configuration, adoption of transgenic corn amylase technology has the potential to significantly improve the efficiency and environmental footprint of the US corn ethanol industry.

The technology for crop-based expression of cellulases and hemicellulases has significantly progressed over the past 15 years. A potential problem with the expression of hydrolytic enzymes in plants is that of impaired structural integrity of plant cell walls and, consequently, on crop standability. Strategies to effectively address this problem have included the use of appropriate expression tools, such as suitable promoters and subcellular targeting of enzymes.

Work done at Syngenta in the mid-1990s provided the first example of the expression of active cellulases in plants. Two endoglucanases (EG) and a cellobiohydrolase (CBH) sourced from Thermonospora fusca (since renamed Thermobifida fusca) were expressed from constitutive and inducible promoters and targeted to either the cytoplasm, the vacuole by use of targeting sequence, or to the chloroplast using direct transformation of the organelle (Lebel et al., 2008).

Nuclear transformants of tobacco, corn and wheat were generated that exhibited chemically induced cellulase expression. The Lebel et al. (2008) patent thus demonstrates cellulase expression in plants, and highlights thermostable enzymes, subcellular targeting sequences and inducible promoters as among the tools available to do so.
The importance of subcellular targeting in the expression of cell wall hydrolysing enzymes in plants has been confirmed in numerous reports. Successful targeting of cellulases and hemicellulases has been reported to chloroplasts, vacuoles, peroxisomes, mitochondria, endoplasmic reticulum, apoplast and cytoplasm (Sainz, 2009 and references therein). More recently, EG and CBH1 expressed in corn seed were targeted to different subcellular compartments (Hood et al., 2007).

Activity of ER-targeted versions was high for both enzymes, but EG also had activity when targeted to the vacuole but not the apoplast, whereas the reverse was true for CBH1. These results suggest that expression optimisation through targeting will likely depend on enzyme type. In other experiments, the highest activity was observed in plants with dual targeting of a xylanase to both the chloroplast and the peroxisome, compared to either compartment alone, suggesting a multiple targeting strategy to maximise expression (Hyunjong et al., 2006). Additional research on targeting multiple enzymes to subcellular compartments would help identify potential limitations to this strategy, e.g. whether localisation in certain compartments can interfere with enzyme accumulation in others.

Hydrolytic enzymes active at physiological temperatures have the potential to negatively impact plant structural characteristics. To limit this potential damage, the strategy of using cellulases and hemicellulases with high temperature optima and low activity at physiological temperatures has also been validated. Most reported experiments on cellulase expression in plants have used endoglucanases, principally using thermostable enzymes such as the *A. cellulolyticus* E1 EG and derivatives. Expression of thermostable CBH have been reported in several plant species (Sainz, 2009 and references therein), an important result given the need for relatively large amounts of CBH activity in biomass conversion.

Besides reducing the risk of unintended effects on plant structure, the use of thermostable enzymes has other potential advantages, including improved enzyme extraction, activity and stability, and lower process flow viscosities (Taylor et al., 2008; Viikari et al., 2007). Stable *A. cellulolyticus* E1 EG activity was demonstrated in dried leaf material from tobacco and alfalfa (Dai et al., 2000; Teymouri et al., 2004; Ziegelhoffer et al., 1999), and in frozen crude extracts (Sticklen, 2006). Stability, extraction and storage are important considerations for the effective use of plant-expressed enzymes in processing.

High-level enzyme expression in an agricultural setting is the main challenge in delivering inexpensive, plant-produced cellulases and hemicellulases for cellulosic ethanol production. *A. cellulolyticus* EG has been expressed as high as 2% total soluble protein (TSP) in corn stover (Biswas et al., 2006; Mei et al., 2009), although an estimated 10% of TSP is needed for complete hydrolysis (Sticklen, 2008). In contrast, both EG and CBH1 constituted about 16–18% TSP in maize seed in the best expressing lines (Hood et al., 2007), or about 0.05% of dry grain weight. It is estimated that approximately 9 times this enzyme yield would be required to use the grain produced to process the corn stover from the same hectare (Sainz, 2009). Target yields for different plant-expressed hydrolytic enzymes will depend on various factors, including the type of pretreated feedstock and the activity, loading and optimal ratios of the enzymes needed for efficient biomass hydrolysis, together with consideration of any losses incurred during extraction and storage prior to use.

Significant levels of cellulase expression in corn leaves (7–10% of TSP) have been obtained in experiments conducted at Syngenta Biotechnology, Inc. (Warner et al., unpublished data). Importantly, the performance of the corn leaf-expressed exoglucanase on pre-treated sugarcane bagasse was roughly comparable to the activity of microbially produced enzyme when assayed in defined composition enzyme cocktails. Similar studies on cellulase expression in sugarcane are being conducted at the Queensland University of Technology (QUT) in the Syngenta Centre for Sugar Cane Biofuels Development, a unique public-private research collaboration between
Syngenta and QUT (Sainz and Dale, 2009). Preliminary experiments using the constructs shown to be functional in corn have generated events with cellulase activity, mirroring the results observed in corn (Sainz et al., unpublished data). Taken together, these results are important in demonstrating the viability of crop-expressed hydrolytic enzyme product concepts for cellulosic ethanol production from both corn stover and sugarcane bagasse.

**Conclusions**

Increasing global energy demand will drive the development of technologies for environmentally sustainable transport fuels. Cellulosic ethanol and other advanced biofuels can help to meet future energy needs with a more favourable environmental profile than first-generation biofuels (Woods et al., 2009). Given existing infrastructure, enzymatic hydrolysis represents the most attractive near-term approach for biomass to biofuels conversion, with ongoing improvements through biotechnology (Wyman et al., 2005). Process models identify conversion of lignocellulosic biomass into fermentable sugars as the key challenge in reducing cellulosic ethanol production costs (Lynd et al., 2008). Longer-term, biomass feedstock modification to improve yield and processing characteristics, the development of improved organisms for fermentation, and improved engineering designs will increase process efficiencies, reducing capital costs per litre of cellulosic ethanol produced, costs that are currently about three times higher than equivalent costs for a corn ethanol plant (Galbe et al., 2007).

Sugarcane bagasse is the most cost-effective feedstock for cellulosic ethanol production, but commercial viability will depend on being able to lower the cost and improve the effectiveness of cellulases, and to develop pre-treatment technologies compatible with an optimised, integrated process, especially downstream enzymatic hydrolysis and fermentation. In the future, success in improving the cost basis of cellulosic ethanol production will likely require increasingly integrated technical solutions drawing from diverse disciplines, including agronomy, plant breeding and microbiology, in addition to biotechnology, enzymology and engineering. Process modelling will be important in guiding research, by identifying the most promising areas for improvements and cost reductions in making cellulosic ethanol production economically viable. In addition, standardised life cycle analysis methodologies will need to be developed to account for environmental costs and benefits in effectively comparing different options towards meeting our future energy needs.

MOTS-CLÉS: Biomasse, Biocarburants, Éthanol Cellulosique, Cellulases, Enzymes.

Résumé
Les résidus agricoles comme la paille et les résidus du maïs sont abondants et facilement disponibles comme matières premières pour la production de la deuxième génération de biocarburants. Cependant, la collecte et le transport demeurent les composantes principales au coût. La bagasse de canne représente une matière première intéressante dans le sens que c’est un résidu disponible en grande quantité dans les sucreries et usines d’éthanol. La conversion efficiente de la bagasse ligno-cellulosique en sucres fermentables est un défi technico-économique majeur pour une production industrielle viable d’éthanol. La bagasse est d’abord prétraitée par une combinaison de haute température et de pression en présence de produits chimiques, afin de faciliter l’hydrolyse enzymatique subséquente pour la décomposition de la cellulose et de l’hemicellulose en sucres fermentables. Le volume conséquent (estimé à 15–25 kg/t bagasse) et le coût des enzymes nécessaires pour l’hydrolyse font que le processus n’est pas économiquement envisageable avec la présente technologie de fermentation enzymatique. L’expression des enzymes dans des plantes représente une approche prometteuse pour une réduction du coût de l’enzyme, et c’est dans ce domaine que Syngenta a une propriété intellectuelle solide et une technologie propriétaire avancée. L’amylase de maïs de Syngenta qui se caractérise par un α-amylase thermstable avec expression dans le grain pour le broyage à sec dans les applications de production d’éthanol, fait actuellement l’objet de la recherche d’approbation réglementaire aux États Unis. C’est le premier d’une série de caractères que Syngenta a l’intention de destiner à l’industrie des biocarburants. La production in planta des hydrolases pour dégrader la paroi cellulaire requiert une approche intégrée à l’intérieur du modèle de l’ensemble du processus d’ingénierie. Elle incorpore des méthodologies de fermentations de pré-traitements en amont et en aval en sus des technologies ayant trait à l’expression d’enzyme, d’extraction, de préservation et d’hydrolyse. Le progrès dans le développement de cette suite de technologies pour la conversion de la bagasse ligno-cellulosique en sucres fermentables est décrit.

Resumen

RESIDUOS agrícolas tales como la paja derivada de cereales y el rastrojo del maíz son abundantes materias primas, las cuales se encuentran fácilmente disponibles para producir biocombustibles de siguiente generación; sin embargo, los costos de colecta y de transporte son grandes componentes en su costo. El bagazo de caña de azúcar es, por tanto, una materia prima especialmente atractiva puesto que se encuentra presente en grandes cantidades en molinos de azúcar y etanol. La conversión eficiente de la lignocelulosa del bagazo en azúcar fermentable es el mayor reto tecnológico y económico para una viable producción comercial del etanol a partir de tal materia prima. El bagazo cursa un pretratamiento con una combinación de altas temperaturas y presiones en presencia de reactivos químicos, a fin de facilitar subsecuentes hidrólisis enzimáticas, degradar la celulosa y hemicelulosa y convertirlas en azúcares fermentables. El volumen puro (estimado en 15-25 kg/tn de bagazo) y los costos de producción de los enzimos requeridos para la hidrólisis hacen económicamente inviable al proceso de usarse las actuales tecnologías de producción de enzima para la fermentación. La expresión de enzimas en cultivos vegetales representa un enfoque promisorio para reducir los costos de la producción de enzimas, y es una área en la que Syngenta posee un gran propiedad intelectual y avanzadas tecnologías propietarias. La amilasa de maíz de Syngenta, actualmente bajo aprobación regulatoria en los Estados Unidos, presenta características de una α-amilasa termoestable expresada en el grano para aplicaciones en la producción de etanol a partir del molido seco, siendo la primera de una serie de caracteres de Syngenta diseñados para la industria de biocombustibles. Para facilitar la producción in planta de hidrolasas degradantes de pared celular para la producción comercial de siguiente generación de biocombustibles, se requiere un enfoque integrado dentro de un modelo completo de ingeniería de procesos, incorporando pretratamientos en fases superiores del proceso y metodologías de fermentación en fases resultantes del proceso, adicionales a aquellas de expresión enzimática, extracción, almacenaje e hidrólisis. El avance en el desarrollo de esta serie tecnológica para la conversión de lignocelulosa del bagazo en azúcares fermentables será descrito.

KEYWORDS: *Aeneolamia postica*, *Saccharum* spp., Entomopathogenic Fungus, Biological Control, Molecular Characterisation.

Abstract

*Metarhizium anisopliae* (Metschn.) Sorokin (Moniliaceae: Moniliaceae) is an entomopathogenic fungus used as a biological control agent against the sugarcane froghopper *Aeneolamia postica* (Wlk.) (Hemiptera: Cercopidae), one of the main insect pests of sugarcane in Tabasco State, Mexico. Since 2005, multiple isolates of *M. anisopliae* have been applied by farmers in the crop areas; however, the current genetic diversity of the fungus population in the field is unknown. The aim of this study was to characterise isolates of *M. anisopliae* collected in sugarcane fields to better understand their genetic and virulence characteristics against *A. postica*. In particular, the impact of introduced isolates on the genetic diversity of native strains was determined. Sampling of mycosed insects was conducted in soils from the main sugarcane fields of Tabasco. Twenty isolates of *M. anisopliae* were obtained and a monosporic culture from each one was used for the characterisation studies. The isolates were characterised using both morphological characteristics and rDNA analysis. The genetic diversity of the fungus was analysed by means of RAPD molecular markers. One of the isolates was significantly similar to the isolate introduced by farmers. RAPD analysis revealed a homogeneous group among the native isolates collected in sugarcane fields in Tabasco. These results suggest a very low incidence of recombination between native and introduced isolates. The implications of the findings on the genetic diversity of *M. anisopliae* and the use of this pathogen for biological control products for *A. postica* are discussed in this paper.

Introduction

Sugarcane (*Saccharum* spp.) has given rise to an agro-industrial system in Mexico, which plays a significant role in its economic and social activity and is currently the most important agro-industry of the country (Bautista and González, 2005; Hernández-Rosas *et al.*, 2007). Seven hundred thousand ha distributed over 15 states are devoted to sugarcane cultivation and 58 sugar factories operate with an average yield of 76 tonnes/ha and 11% final product manufactured (Hernández-Rosas *et al.*, 2007). Mexico is one of the ten main producers of sugarcane in the world.
and, with a per capita consumption of 50 kg, it is the second highest sugar consumer. It is estimated that three million Mexicans depend on this economic activity, which also generates an important amount of foreign currency (Hernández-Rosas et al., 2007).

The production and quality of sugarcane is limited by the sugarcane froghopper *Aeneolamia postica* (Wlk.) (Hemiptera: Cercopidae), the most damaging insect pest present over extensive areas of the Gulf of Mexico and Pacific Ocean coastal plains (Bautista and González, 2005). This pest provokes reductions in sugarcane yield of up to 60% and is controlled by means of pesticides, which increases production costs as well as having a negative impact on the environment (Hernández-Rosas et al., 2007).

Due to the fact that the froghopper has become resistant to many insecticides, sugarcane producers of the State of Tabasco, Mexico, have searched for alternative control methods. One such alternative available is *Metarhizium anisopliae* (Metschn.) Sorokin (Moniliales: Moniliaceae), an entomopathogenic fungus that is widely used in biological control of insect pests (Guerrero et al., 1999; Hernández-Rosas et al., 2007).

Since 2005, farmers have introduced several isolates of *M. anisopliae* as part of an integrated pest management strategy in sugarcane fields of Tabasco (Bautista and Gonzalez, 2005). However, the persistence of these isolates in the sugarcane fields after their application and their impact on the native populations are not known.

The present study was conducted in order to generate knowledge related to these issues and to characterise the genetic diversity of the entomopathogenic fungus *M. anisopliae* isolates originating from the main sugarcane growing areas in the Rios region of Tabasco State, Mexico.

**Materials and methods**

**Study area**

The study was carried out in sugarcane fields found in the Rios region, municipality of Tenosique, Tabasco, Mexico. These fields supply the AZSUREMEX S.A. de C.V. sugar factory, which is located on the La Palma highway, Tenosique at 17° 25’ N, 91° 24’ W, and 60 m altitude. The area cultivated with sugarcane in the Rios region is 4209.83 ha.

**Sampling**

Two types of sampling were undertaken to collect *M. anisopliae* from the sugarcane fields. Samples were taken from either the soil or from mycosed insects. As applications of *M. anisopliae* have been made since 2005, samples were taken from fields with and without fungus application history belonging to 33 farmers, representing 5.06% of the total number of sugarcane producers and 4.7% of the total sugarcane cultivated area in the Rios region. On average, each farmer possessed 6 ha of sugarcane.

The farmer’s sugarcane fields were sampled. A five point sample was carried out, one in each corner of the field and another in the centre, taking the sample at a depth of 10 cm within the rhizosphere. The technique suggested by Almeida et al. (1997) was followed for the collection of soil samples, which consisted in taking five 0.5 kg soil sub-samples from the upper 10 cm of soil, close to the crop’s rhizosphere and with 5.0 cm between each sample. The soil samples were placed in plastic bags and transported to the laboratory in dry ice boxes at 4°C. The samples were collected between September and December of 2007 and 2008.

**Isolation**

In order to isolate *M. anisopliae* from the soil, *Galleria mellonella* L. (Lepidoptera: Pyralidae) larvae were used (Vanninen, 1997). The soil samples were sieved through a 2.0 mm metallic mesh sieve and 300 g of soil was moistened and placed in a 500 mL plastic tumbler. Subsequently, five larvae were introduced into each tumbler, sealed with sellotape and incubated for seven days at 25°C (Bedding and Akurst, 1975; Doberski and Tribe, 1980). After incubation, the larvae were examined.
The diseased insects were separated from the soil and disinfected in 5% sodium hypochlorite (NaOCl) for one min followed by 70% alcohol for five seconds. They were then rinsed three times with sterile distilled water, and excess water removed using tissue paper (Douglas et al., 2008).

The larvae were then placed in a 100 mm × 15 mm Petri dish with a double layer of damp filter paper and subjected to the aforementioned incubation conditions to favour fungus development (Hatting et al., 1999).

Mycosed insects were observed with a stereoscopic microscope to detect the body areas with highest sporulation. In order to isolate *M. anisopliae* from field-collected samples of mycosed insects of *A. postica*, the procedures mentioned above for *Galleria mellonella* mycosed larvae were followed.

The isolated fungi were identified by their reproductive structures using the keys elaborated by Tulloch (1976) and Harper and Haung (1986).

The isolates obtained from the sugarcane fields in the Rios region of Tabasco are presented in Table 1. Isolate 9 was the reference isolate of *M. anisopliae* and was obtained from the ‘Tiemelonlà Nich Klum’ laboratory in Palenque, Chiapas, Mexico; this isolate was applied on Mr Barrada’s land in 2005. The first 10 isolates (1–10) were analysed by the Random Amplified Polymorphic DNA (RAPD) technique.

Subsequently, all the isolates were analysed by means of rDNA analysis, restriction analysis of amplified products and digestion with the *Hae* II enzyme.

**Table 1**—Isolates of entomopathogenic fungi analysed in this study.

¹*Metarhizium anisopliae* isolate provided by the ‘Tiemelonlà Nich Klum’ laboratory located in Palenque, Chiapas, Mexico.

²Centro Nacional de Referencia en Control Biológico, Tecomán, Colima, México.
Genomic DNA

Monosporic cultures were used to obtain the inoculum, which was grown on potato dextrose agar (PDA) (Hernández-Rosas, 2002). The inoculum was incubated and agitated for three days at 27°C in potato dextrose broth and the mycelium was recovered on a sterile filter paper using a funnel and a vacuum pump.

The mycelium was then placed in a sterilised, cooled mortar and ground with (L) N₂ to a fine dust, which was transferred to a sterile 1.5 mL tube before application. The protocol described by Gómez-Leyva et al. (2008) for the extraction of genomic DNA from M. anisopliae was followed.

The samples were stored at 4°C until required. The DNA was analysed on 0.8% of sodium borate agarose gel, stained with ethidium bromide and visualised under ultraviolet light (UV).

RAPD analysis

The RAPD technique described by Williams et al. (1990) was utilised to generate molecular patterns. The OPB07 (GGTGACGCAG) and OPB09 (TGGGGGACTC) Series B Operon primers were used (Operon Technologies Inc., Alameda, EUA) (Cobb and Clarkson, 1994; Guerrero, et al., 2000; Kendall and Rygiewicz, 2005). The reaction mixture consisted of a mixture of 0.2 mM dNTPs, 10 μM of primer, 2.5 U of Ta q polymerase DNA (Promega, Madison, Wisconsin, USA) and 100 ng of DNA.

The Polymerase Chain Reaction (PCR) amplifications were carried out in a MJ Research thermocycler programmed as follows: 2 min at 94°C followed by 40 cycles of 1 min at 94°C, 1 min at 36°C and 90 seconds at 72°C; 7 min at 72°C and 4°C until removed. The amplified fragments were separated by horizontal gel electrophoresis in 1.2% agarose (Ultrapure, Gibco BRL, Gaithersburg, Maryland, US). The gels were stained with ethidium bromide and photographed on a UV Cole Palmer 97500 transilluminator.

Amplified ribosomal DNA restriction analysis (ARDRA)

The Internal Transcribed Spacer (ITS) region of the rDNA from each sample was amplified using the following reaction mixture: buffer 1X pH 8.5, primers ITS1 and ITS4 (White et al., 1990) at 20 pmol each, 0.2 mM dNTPs, 2.0 mM of MgCl₂, 2.5 U of Taq polymerase DNA and 100 pmol of DNA under the following thermocycler conditions: 3 min at 94°C followed by 30 cycles of: 1 min at 94°C, 1 min at 55°C, 1 min at 72°C with a final extension of 7 min at 72°C. The amplified products were digested with the Hae II restriction enzyme and separated in a 1.6% agarose gel.

Estimation of genetic diversity

M. anisopliae genetic diversity was analysed through polymorphism expressed by the primers. A 0, 1 matrix, referring to the absence or presence of bands in each M. anisopliae isolate, was recorded from the RAPD amplifications and ARDRA results.

The variations in band intensity were not assigned as differences. The matrix was prepared using the Neighbor-Join coefficient. The dendrograms were made by means of a UPGMA analysis with the NTSYS 2.0 (Numerical Taxonomy and Multivariate Analysis System) program (Rohlf, 1993).

Results

RAPD analysis

The RAPD amplification of DNA of M. anisopliae isolates 1 to 10 with OPB09 is presented in Figure 1. Genetic variation was observed among the isolates, with polymorphic bands ranging between 250 bp and 1000 bp. Bands of 250, 400, 500, 700 and 800 bp were amplified for isolates 1 and 4; 1, 2, 5, 6, 8, 9, 13 and 10 respectively. The isolates 1 and 8 (from Field of Mr Miguel Mujica and Field Mr Gustavo Barradas belonging to A. postica) and isolates 2, 3, 4, 5, 6, 7 and 10 all collected from the technique insect-tramp with G. mellonella. The isolate 9 was the reference isolate provided by the ‘Tiemelonlà Nich Klum’ laboratory located in Palenque, Chiapas, Mexico.
ARDRA analysis

The results of the rDNA amplification and restriction analysis of the amplified products of the isolates studied are presented in Figure 2. The approximately 600 bp fragment was amplified with ITS1/ITS4 primers (Figure 2A) in all isolates with the exception of isolate 12 which produced a 850 bp band.

Digestion using the Hae II enzyme (Figure 2B) resulted in the generation of 200 to 400 bp. Some bands did not follow the general pattern, possibly a result of incomplete digestions. These bands were not analysed in this study.

In the dendrogram generated from the restriction analysis of the isolates (Figure 3), three principal groups were observed; the first group consisted of isolates 1, 2, 3, 4, 5 and 6. The second group consisted of isolates 7, 8, 9, 10 and 11.

The third main group was made up of isolates 14 and 16, followed by four isolates; 70 and 74 provided by the Centro Nacional de Referencia en Control Biológico (CNRCB) and isolates 12 and 13.

Discussion

As expected, the results indicated genetically similar patterns between the reference isolate (number 9) applied three years ago in the cane fields at Barradas and isolate 1 that was collected in the same locality. There is a high probability that this isolate originated from the reference isolate, demonstrating that M. anisopliae is capable of persisting in the environment with relatively low variation. These results are consistent with those reported by Milner et al. (2003) where it was found that M. anisopliae conidia survived 3.5 years post application in fields in Australia.

Genetically similar patterns were also observed between the reference isolate 9 and isolates 5, 6, 10 and 13 collected from fields where the former had not been applied. Bidochka et al. (1994) mentioned that *M. anisopliae* could be a cryptic species; in a genetic diversity study in two regions where this fungus had already been applied, the authors found a very low degree of recombination.

It seems that the host insect exerts the predominant influence on entomopathogenic fungi population genetics (Bidochka et al., 1994). Douglas et al. (2008) mention that ecological zones play an important role in the study of *M. anisopliae* genetic diversity.

In this study, the habitat was purely sugarcane which possibly provides another reason for the low genetic variability found in *M. anisopliae*. It has also been found that selection pressure exerted by biotic and abiotic factors affect the pathogenic capacity of this entomopathogen (Zimmerman, 2007).

According to Hajeck and St. Leger (1994) who tried to explain the high intraspecific genetic variability observed between *M. anisopliae* isolates, many of these isolates are included in a few
geographically distributed genotype classes and whose persistence over time and space suggests that in many situations they originate from a clonal population structure.

The results of this study also demonstrate that isolates 1–2, 8–9, 14–16 were genetically similar and isolates 4, 5, 6, 3, 7, 8 and 9 displayed the least genetic similarity. This demonstrated the natural occurrence of genetic variation in the *M. anisopliae* fungus.

The question that arises from this information is whether this genetic variability affects the virulence of the entomopathogen towards *A. postica*. According to Fegan et al. (1993) who carried out a RAPD analysis on *M. anisopliae* var. *anisopliae*, the high degree of observed genetic diversity would be related to both its geographical origins and groups of pathogenicity.

Fig. 3—Dendrogram based in the amplified ribosomal DNA restriction analysis (ARDRA) in different strains of entomopathogens.

Hajek and St. Leger (1994) point out that geographic isolation and limited dispersion capacity of *M. anisopliae* spores could be important in the evolution of different genotypes.

These authors also mentioned that the intra-specific variability of fungi has been characterised by differences regarding pathogenicity.

Documented cases of variability in host susceptibility to the pathogen showed the potential occurrence of co-evolution between the host insect and the pathogenic fungus.

Other authors have discovered that the pathogenicity of *M. anisopliae* is genetically distinct, in accordance with different soil types present in the sugarcane zones (Milner, 1992) and that this fungus develops different adaptations in function of the prevailing soil type and/or rhizosphere where it is present (Meyling and Eilenberg, 2007).

Future research will aim to understand the relationship between genetic diversity of *M. anisopliae* isolates collected in this study and their pathogenicity on *A. postica*. 
Conclusions

The following conclusions can be made from the molecular studies of *M. anisopliae* carried out in this research:

1) There exists a high probability that at least one of the isolates originated genetically from the reference isolate, thus implying that *M. anisopliae* is capable of persisting in sugarcane fields three years after being applied.

2) Observed variations in genomic DNA of *M. anisopliae* suggest the presence of a high natural genetic diversity among the studied isolates.

MOTS-CLÉS: *Aeneolamia postica*, *Saccharum* spp., Champignon Entomopathogène, Lutte Biologique, Caractérisation Moléculaire

Résumé

Le *METARHIZIUM anisopliae* (Metschn.) Sorokin (Moniliiales: Moniliaceae), un champignon entomopathogène, est utilisé dans la lutte biologique contre la cicadelle écumuse de la canne à sucre *Aeneolamia postica* (Wlk.) (Hemiptera: Cercopidae), un des principaux ravageurs de la canne à sucre de l’État de Tabasco au Mexique. Depuis 2005, plusieurs isolats de *M. anisopliae* ont été appliqués par les fermiers dans les champs sous culture ; toutefois, la diversité génétique de la population du champignon demeure inconnue. L’objectif de cette étude consistait à caractériser les isolats de *M. anisopliae* collectés dans les champs de canne à sucre afin de mieux comprendre leur diversité et leur virulence contre *A. postica*. En particulier, l’impact des isolats introduits sur la diversité génétique des isolats indigènes a été déterminé. Un échantillonnage des insectes mycosés a été effectué dans les principaux sols de Tabasco. Vingt-deux isolats de *M. anisopliae* ont été obtenus et une culture monospore de chaque isolat a été utilisée pour les caractérisations morphologiques et les analyses d’ADN ribosomique. La diversité génétique a été analysée grâce aux marqueurs moléculaires RAPD. Un des isolats était significativement similaire à l’isolat introduit par les fermiers. L’analyse par RAPD a démontré que les isolats indigènes formaient un groupe homogène. Les résultats suggèrent un faible taux de recombinaison entre les isolats indigènes et ceux introduits. Les implications de ces résultats sur la diversité génétique de *M. anisopliae* et l’utilisation du pathogène pour la lutte biologique contre *A. postica* sont discutées dans cet article.

PALABRAS CLAVE: *Aeneolamia postica*, *Saccharum* spp., Hongo Entomopatogénico, Control Biológico, Caracterización Molecular.

Resumen

*METARHIZIUM anisopliae* (Metschn.) Sorokin (Moniliáceas: Moniliaceae) es un hongo entomopatogénico usado como un control biológico en contra del insecto de la caña de azúcar *Aeneolamia postica* (Wlk.) (Hemiptera: Cercopidae), uno de las mayores plagas de la caña de azúcar en el Estado de Tabasco, México. Desde 2005, múltiples aislados de *M. anisopliae* han sido aplicados por agricultores en las áreas de cultivo; sin embargo, se desconoce la diversidad genética actual de la población fungal en el campo. El objetivo de este estudio fue caracterizar aislados de *M. anisopliae* colectados en campos de caña de azúcar para comprender mejor sus características genéticas y de virulencia contra *A. postica*. En particular, para determinar el impacto de aislados introducidos en cepas nativas. El muestreo de insectos con micosis fue conducido en suelos de los principales campos de caña de azúcar de Tabasco. Veinte aislados de *M. anisopliae* fueron obtenidos y un cultivo monospórico de cada uno fue usado para estudios de caracterización. Los aislados fueron caracterizados usando características morfológicas y de análisis de rADN. La diversidad genética del hongo fue analizada por medio de marcadores moleculares RAPD. Uno de los aislados fue significativamente similar al aislado introducido por los granjeros. El análisis RAPD reveló un grupo homogéneo entre los aislados nativos colectados en campos de caña de azúcar en Tabasco. Estos resultados sugieren una muy baja incidencia de recombinación entre aislados nativos e introducidos. En este artículo se discuten las implicaciones de los descubrimientos sobre la diversidad genética de *M. anisopliae* y el uso de este patógeno para productos de control biológico para *A. postica*.
MOLECULAR CHARACTERISATION AND APPLICATION OF BEAUVIERA BASSIANA (BALSAMO) VUILLEMIN IN THE BIOLOGICAL CONTROL AGAINST DIATRAEA SACCHARALIS (FABRICIUS)

KEYWORDS: Diatraea saccharalis, Biological Control, Beauveria Bassiana Molecular Characterisation, Inter-Microsatellite, Sugarcane.

Abstract
MASSIVE application of the entomopathogen Beauveria bassiana in sugarcane fields is important both from an agronomic and ecological perspective. This has attracted interest for the development of reliable tools for the identification of the various species in use. The present work had as objectives the molecular characterisation of B. bassiana by inter-microsatellite (ISSRs) markers and the evaluation of the application of the hyphomycete in the biological control of Diatraea saccharalis (Fabricius). Genomic DNA was extracted from lyophilised mycelia. The amplified products were analysed with 100 ISSR primers. A high level of polymorphism (near 80%) was found among eleven isolates using fourteen ISSR primers selected. Seven different isolates showed exclusive bands and ISSR primer 873 distinguished all of them. The application of B. bassiana in the field was able to diminish live larvae of D. saccharalis by 43.7%, therefore demonstrating their potential as a biological control agent for sugarcane borer.

Introduction
Diatraea saccharalis (Fabricius) is the main pest of sugarcane in Cuba and it causes serious losses and damage to plantations. In order to reduce the population levels of the borer, the entomopathogenic fungus Beauveria bassiana (Bals.) Vuill. is used.

Natural occurrence of the fungus in Cuba was reported in larvae and pupae of D. saccharalis by Estrada et al. (2004). The pathogenicity of different isolates of the fungus was also determined in larvae of this Lepidopteran by Estrada et al. (1995).

There are several reports on the molecular characterisation of B. bassiana with the objective to study their genetic structure (McGuirre et al. 2005) and on the monitoring of the application of the fungus in the field (Wang et al. 2003).

The objective of the present work was to conduct a molecular characterisation of B. bassiana by intermicrosatellites, Inter Simple Sequence Repeats (ISSRs) and to determine the efficacy of application of the fungus in the biological control against D. saccharalis. The variability and the phylogenetic relationships between the eleven isolates of B. bassiana were analysed using ISSR markers as described by Estrada et al. 2007.

Materials and methods
Molecular characterisation of isolates of B. bassiana by ISSRs
Fungal isolates
Eleven isolates of B. bassiana from different geographic and entomological origins were used (Table 1). The isolates were grown in static liquid medium as described by Adamek (1965) and incubated at 25°C for four days. The fresh mycelia were harvested and lyophilised for 24 h.
Table 1—*Beauveria bassiana* isolates used in this study.

**Genomic DNA extraction**

The lyophilised mycelia were used for genomic DNA extraction. The extraction was carried out using a small-scale DNA isolation method using Dneasy Plant Mini Kit, from Qiagen.

**Primers used in the PCRs test**

One hundred primers based on dinucleotide, tetracinucleotide or pentanucleotide repeats were used. These oligonucleotides were obtained from the University of British Columbia (UBC primer set 100/9). A total of fourteen oligonucleotides were selected based on the number and consistency of the amplified fragments.

**PCR and analysis of the amplified profiles**

Each amplification reaction (final volume of 20 µL) consisted of 1 µL of total genomic DNA (10 ng/µL), 1 µL of the corresponding primer (5 µM), 10 µL of Taq-PCR master mix (Qiagen) and 8 µL of ultra pure distilled water. DNA amplifications were performed in a PTC-100 Thermocycler with an initial step of 5 min at 94°C, followed by 45 cycles of 30 s at 94°C, 45s at 52°C and 2 min at 72°C with a final 6 min extension at 72°C.

The amplification reactions were stored at 4°C until resolved by electrophoresis. Samples of 20 µL PCR products were analysed on 1.5% agarose gels after running at 90 V for 2 h and staining with ethidium bromide.

ISSR markers behave as dominant markers. They were scored as presence (1) or absence (0) of homologous bands (bands with the same size) for all the isolates. Dendrograms were constructed by UPGMA (unweighted pair-group method, arithmetic average).

The cluster analysis was performed using different coefficients—the simple matching coefficient (SM), the DICE coefficient and the Jaccard coefficient (J) and using the NTSYS-pc version 1.6 package.

**Evaluation of the application of *B. bassiana* in field trials**

A randomised block design was used which consisted of eight plots of 96 m² each with 120 stools of a three-months old first ratoon crop of variety CB4452.

The plots were in parallel and separated by a distance of 200 m. To assure a homogeneous population of the pest, all the stools of the plots were infested artificially with egg batches of *D. saccharalis* ‘in black head’ stage (non developed embryos).

The infestation was carried out with 960 egg batches and the average number of eggs/batch was 26.71. Before the application of *B. bassiana*, the percentage of larvae hatching was calculated and it was 76.78%. *B. bassiana*-isolate 3 (MG1) was applied at a rate of 10¹² conidial/ha in the form of an aqueous suspension at a concentration of 6 × 10⁹ conidial/g.

It was applied in four experimental plots by means of a hand-operated knapsack sprayer. The control plots were treated with water.
Samplings were carried out at day 7, 15, 30, 45, 60 and 101 after the application of the fungus. In each sampling, four stools/plot were selected at random which were cut and analysed in the laboratory.

The number of affected stalks and internodes, the presence of live larvae of D. saccharalis, and presence of other natural enemies of the pest were recorded.

Considering the development cycle of the pest, at 30 days of sampling, the percentage of efficacy of the application of B. bassiana was determined by means of the Abbott formula (CIBA-GEIGY, 1981), which is used when the infestation of the pest is homogeneous before the application of the treatments:

\[
\text{% efficacy} = \frac{(C_d - T_d) \cdot 100}{C_d}
\]

where:

- \(C_d\): number of live individuals in the control plots after the treatment.
- \(T_d\): number of live individuals in the treated plots after the treatment.

A simple classification variance analysis was carried out and the means were compared by means of Newman Keuls's test (\(p < 0.05\)) (STATITCF, 1988).

**Results and discussion**

**Molecular characterisation of isolates of B. bassiana using ISSRs**

**ISSR amplification**

The sequences of these 14 primers used seem to indicate that the microsatellites that are more frequent in B. bassiana contain the repeated dinucleotides (AG)\(_n\), (AC)\(_n\) and (GT)\(_n\) (Table 2).

The 14 ISSR primers used for the PCR amplifications of DNA from the 11 isolates of B. bassiana were selected from the primers from the set 100/9 UBC, and gave reproducible amplification products (Figure 1).

The total number of bands (TNB), number of polymorphic bands (NPB), percentage of polymorphic bands (P\%), number of different genotypes (NG), resolving power (Rp) (Prevost and Wilkinson, 1999) and number of exclusive bands (NEB) obtained with each primer are shown in Table 3.

The total number of amplified products was 172 with an average of 12.28 bands/primer, ranging from 300 to 3000 bp, with 135 (78.49%) polymorphic DNA fragments.

The maximum number of amplified products was 18 (primers 809 and 810) and the minimum was 6 (primer 818) (Table 3).
Seven different isolates (five from Cuba, one from Bulgaria and one from USA), showed a total of 11 exclusive bands that could be transformed in Sequence Tagged Site (STS) markers.

ISSR is easy to employ and highly reproducible. In this study, nearly 80% of the bands generated, using ISSR, were polymorphic. This shows the high level of genetic variation that exists between the different isolates.

These fungi display parasexual reproduction, which normally confers high genetic variability. In the same way, the ISSR markers proved to be an efficient marker system because of their capacity to reveal several informative bands in a single amplification (a mean of 9.6 bands/primer). Furthermore, it was possible to identify all the isolates with a single primer (873) (Figure 2).

The dendrograms obtained using the SM, DICE and J coefficients showed similar structure with the same clusters. The dendrograms generated have two distinct clusters (Figure 3). Cluster A contained the isolates from the Caribbean region and B had the isolates from other geographical locations.

The bootstrap values for the Cluster A and B were very high, 97% and 100%, respectively. The different isolates of cluster A exhibited nearly 75% similarity. Sub-cluster A1 contained just one isolate, MG1 from Cuba. This isolate is clearly different from the rest of the Caribbean isolates.
group consisting of isolates, which are to the right of the fork occurred.

This information is valuable because this isolate shows higher virulence than any of the other isolates used in Cuba. Also, it has been used in the sugarcane plantations in Cuba for biological control of the larval populations of *D. saccharalis*.

A specific diagnostic band for this isolate was obtained, and in future it could be possible to obtain a specific molecular marker for this isolate. The other Caribbean isolates exhibited a similarity greater than 82%, and are grouped in sub-cluster A2. It also had a high bootstrap value (100%).

The isolates from regions other than the Caribbean are in cluster B, and displayed more than 80% similarity. Between the two clusters, the similarity exhibited is less than 50%. This is a low value of homology, and showed the high genetic variability present between the isolates from the Caribbean region and the rest of the isolates.

The worldwide distribution of the *B. bassiana* isolates analysed using AFLPs was found to be very dissimilar (Uma et al., 2006). In another study involving 50 *B. bassiana* isolates of worldwide distribution, a very close similarity (80%) in AFLP fingerprints was reported by De Muro et al. (2003). The differences in the two studies could be explained by the fact that the different markers used detected polymorphisms in different regions of the genome.

**Application of *B. bassiana* isolate 3 in field trials**

Table 4 shows the results of the larval populations of *D. saccharalis*, the damage originated in the treated and untreated plots with the isolate 3 of *B. bassiana*. A significant difference among the evaluated treatments is observed in all the samplings carried out. The number of live larvae in the plots where the hyphomycete was applied was significantly inferior to the number of live larvae in the untreated plots.

Similarly the number of bored internodes was significantly lower in the treated plots. There was also a correlation between the presence of live larvae and the number of bored internodes showing that the fungus reduces the number of *D. saccharalis* larvae and consequently reduces damages caused to sugarcane fields.

Percentage of efficacy (%): 43.7

( ) Newman Keuls’s test (p< 0.05). Difference significant between treated and untreated plots.

The percentage of efficacy of the application of *B. bassiana* was 43.7% (Table 4). This value is very important by considering that, at 30 days after the application of the hyphomycete, it is possible to reduce the 43.7% of the live larvae of *D. saccharalis* that are able to bore into the sugarcane stalk and therefore to cause damage to the crop.

Alves et al. (1985) obtained similar results in Brazil when applying suspensions of conidia of *B. bassiana* at different concentrations in artificially infested plots with *D. saccharalis* larvae.

These authors found 47% and 56% of efficacy and they demonstrated that, in the treated plants, the hyphomycete not only diminished the number of live larvae but also reduced the level of
damage caused by the pest.

Conclusions

ISSR fingerprints provide a useful tool for establishing a rapid and rational approach for differentiating between isolates of entomopathogenic fungi.

In the National Programme of Biological Control against D. saccharalis, it is very important to apply B. bassiana in the field because this imperfect filamentous fungus reduces larval population and the damage caused by this pest.

The results indicate that intermicro-satellites could be used to evaluate the efficacy of different isolates of B. bassiana and their persistence in sugarcane fields. Using these markers, a genetic profile that identifies the most important isolates currently used in the biocontrol of the sugarcane borer in Cuba was obtained.

Résumé

L’APPLICATION massive de l’entomopathogène Beauveria bassiana dans les champs de canne est importante dans une perspective agronomique et écologique. Ceci a suscité de l’intérêt pour le développement des outils pour identifier les espèces utilisées. Cette étude avait pour objectifs de caractériser B. bassiana par marqueur moléculaire en utilisant les inter-microsatellites (ISSRs) et d’évaluer l’application du hyphomycète dans la lutte biologique du Diatraea saccharalis (Fabricius). L’ADN génomique a été extrait à partir des mycéliums lyophilisés. Les produits amplifiés ont été analysés avec 100 amorces ISSRs. Un fort pourcentage de polymorphisme (presque 80%) a été observé parmi onze isolats caractérisés avec les quatorze amorces ISSRs sélectionnées. Sept isolats ont produit des bandes uniques avec l’amorce 873 et cela a permis de les différencier. L’application de B. bassiana au champ a réduit le nombre de larves vivant de D. saccharalis par 43.7%, démontrant ainsi le potentiel de l’entomopathogène dans la lutte biologique du foreur de la canne à sucre.

Resumen

EL INTERÉS agronómico y ecológico de las aplicaciones masivas de B. bassiana precisan de métodos confiables que permitan su identificación en el agrosistema cañero. El presente trabajo tuvo como objetivos la caracterización molecular de B. bassiana por intermicrosatellites (ISSRs) y la evaluación de la aplicación del hifomicete en la lucha biológica contra Diatraea saccharalis (Fabricius). Para ello el ADN genómico fue extraído del micelio lyophilizado. Se analizaron los productos de amplificación con 100 cebadores de ISSRs. El mayor polimorfismo (80%) fue encontrado en 14 de los cebadores ISSR seleccionados. Siete aislamientos diferentes mostraron bandas exclusivas y el cebador SSR 873 distinguió una banda entre todas. La aplicación de B. bassiana en el campo logró disminuir el 43.7% de las larvas vivas del barrenador lo que demostró su potencialidad como agente para el control biológico de esta plaga.
SUGARCANE GENETIC ENGINEERING RESEARCH IN SOUTH AFRICA:

KEYWORDS: \textit{In vitro} Micro-Propagation, Genetic Transformation,
Gene Promoters, Sugarcane.

Abstract

DURING the past 15 years, recombinant DNA and \textit{in vitro} culture technologies have been used in concert at the South African Sugarcane Research Institute (SASRI) to genetically engineer sugarcane. The purpose of such research has been two-fold, \textit{viz.} to establish proof-of-principle regarding the delivery of novel input and resistance traits to sugarcane and to investigate the genetic basis of sucrose accumulation. Underpinning these goals has been the in-house development of essential genetic resources, including the isolation of appropriate transgenes and gene promoter elements, and the optimisation of transformation and tissue culture technologies. With regard to the latter, emphasis has been placed on the development of tissue culture strategies that minimise the potential for somaclonal variation, while maximising the efficiency of germplasm transformation, selection, regeneration and acclimation. The isolation of promoters to drive high-level and targeted transgene expression, as well as the identification of DNA sequences with the potential to deliver the desired phenotype, have been strongly driven by advances in gene discovery and expression technologies. Early approaches relied on the analysis of Expressed Sequence Tag libraries constructed from sugarcane tissues at different developmental stages or challenged with selected abiotic and biotic stress agents. Subsequent improvements in DNA subtractive hybridisation technologies (e.g. suppression subtractive hybridisation) and gene expression analysis (e.g. Affymetrix \textsuperscript{\textregistered} Sugarcane Genome GeneChip) provided new and powerful means for gene and promoter discovery. Reviewed here are the advances in \textit{in vitro} culture, gene discovery and transgene expression research, which have formed the foundation of the genetic engineering program at SASRI. Also discussed are the opportunities and challenges in these areas of research that are presented by the availability of ultra-high throughput DNA sequencing (e.g. the 454 Sequencing System) for transcriptome analysis and technologies for rapid and accurate profiling of the sugarcane metabolomes.

Developing capacity for genetic engineering

Since the release of the first ‘N’ variety, N53/216, in 1964, the South African Sugarcane Research Institute (SASRI) has released 45 varieties that have been bred and selected by conventional means for the five major agro-bioclimatic zones comprising the South African sugar belt.

In the late 1980s, the industry recognised that rapid advances in molecular biology, \textit{in vitro} plant propagation, and recombinant DNA technology offered the potential to serve as powerful adjuncts to conventional breeding; an insight which led to the establishment of a dedicated
biotechnology facility in 1992. The Institute further recognised the value that could be derived from participation in consortia and collaborations to enhance capacities in biotechnology, particularly those pertaining to molecular breeding and genetic engineering.

As a result, SASRI became a founding member of the International Consortium for Sugarcane Biotechnology (ICSB) and entered into agreements with research service providers, such as the Institute for Plant Biotechnology (IPB) at Stellenbosch University, South Africa. The development of in-house capacities at SASRI over the past 15 years, together with outcomes from collaborative and contract research, has led to a thrust in genetic engineering research. Research in this area has focused on establishing Proof-of-Concept for the engineering of resistance and novel input traits, as well as in the investigation of the genetic basis of sucrose accumulation.

Establishing a genetic engineering toolkit

Several technologies and resources are required for effective sugarcane genetic engineering, including: (1) a high throughput plant transformation platform that effectively discriminates for desired transformation events but which also minimises somaclonal variation; (2) sequences of endogenous genes to be targeted for up- or down-regulation and of heterologous genes for the delivery of novel phenotypes; and (3) gene promoters to drive high-level transgene expression that is targeted to the appropriate plant organ or tissue.

Technologies: tissue culture and genetic transformation

In vitro culture is an integral part of plant genetic transformation, with the former technology having been investigated in sugarcane since the late 1960s (e.g. Heinz and Mee, 1969) and which has been recently reviewed by Lakshmanan and co-authors (2005). The availability of such information, together with the protocol for sugarcane transformation described by Bower and Birch (1992), facilitated the development of an effective technology platform for the transformation of South African genotypes (Snyman et al., 1996, 2001a; Snyman, 2004).

Initial protocols for gene delivery involved the use of embryogenic Type 3 callus with morphogenesis proceeding via indirect embryogenesis (Snyman et al., 1996; Snyman, 2004). With these protocols, the time required for the production of a transgenic plant for acclimation ranged between 24 and 36 weeks (Snyman et al., 2000, 2001a). A period of 8 to 12 weeks in culture is required for each of three stages, viz.: callus initiation and proliferation; secondary embryogenesis on a selection agent; and germination of embryos which give rise to transgenic plantlets.

Although this timeframe was considered acceptable in a research and development context, SASRI researchers recognised that a reduction in the culture period would be essential to meet commercial imperatives. It was further recognised that an important additional advantage would result from such a reduction, viz.: reduced duration of exposure to growth hormones would minimise the risk of somaclonal variation.

Consequently, a novel approach for gene delivery was developed at SASRI, based on the use of leaf discs containing floral initials as recipient material, with subsequent plant regeneration via direct embryogenesis (Snyman et al., 2006). Application of this method has resulted in the production of transgenic plants within 14 weeks and also increased the range of germplasm that may be targeted for effective genetic transformation. This high throughput and benign transformation protocol has proven to be an essential element of SASRI’s genetic engineering toolkit.

Genetic resources: accessing transgenes

Over the last 20 years many tools have been developed to study gene structure and function. One of the most powerful of these has been the construction of large public DNA databases, readily accessible via the Internet. When it was demonstrated in the 1980s that partial nucleotide sequences of random clones from cDNA libraries could be aligned to sequence data of known genes contained
in such databases, the capacity for the assignment of putative identities to genes of relatively uncharacterised organisms became a reality. These partial gene sequences, termed Expressed Sequence Tags (ESTs), formed an invaluable resource for research on organisms with complex and non-sequenced genomes, such as sugarcane.

SASRI pioneered EST–based genomic research for sugarcane in the mid 1990s, which was closely followed by similar projects in Australia, USA and Brazil. The SASRI effort was modest in comparison to these later initiatives (Carson and Botha, 2000). For example, Brazilian researchers constructed 26 cDNA libraries from several sugarcane tissues at various stages of development, which yielded a collection of several hundred thousand ESTs (Vettore et al., 2001). SASRI, in contrast, elected to pursue a more targeted strategy, whereby a limited number of cDNA libraries were constructed with a focus on specific targets. As an important SASRI research goal was to determine the genetic basis of sucrose accumulation, considerable effort was devoted to the development of EST libraries that reflected key shifts in gene expression associated with sucrose accumulation.

Two tissue-types were targeted for cDNA library construction, viz. the apical meristem (leaf roll) and maturing culm (internode 7). It was hypothesised that ESTs derived from the meristem would provide access to a wide range of genes associated with growth and development, while those from the maturing internode would provide insights into the identity of genes associated with sucrose accumulation (Carson and Botha, 2000; Carson and Botha, 2002). As expected, meristem ESTs reflected genes encoding products associated with active growth, viz. cell wall synthesis, protein synthesis and protein modification.

Surprisingly, however, the maturing culm yielded very few ESTs depicting enzymes directly associated with sucrose metabolism. Hence, to increase resolution of the EST-based approach, reciprocal subtractive cDNA hybridisation was deployed to enrich for transcripts differentially expressed between internode two (immature) and internode 7 (maturing) (Carson et al., 2002a). Despite this more focused approach, only 10% of ESTs from the subtracted libraries matched genes associated with carbohydrate metabolism; none of which were direct participants in sucrose metabolism. Those results revealed that growth and maturation of the culm is associated with the expression of genes encompassing a wide variety of processes, suggesting that the mechanisms regulating sucrose accumulation were comprised of a complex interplay between various aspects of primary metabolism.

While the SASRI EST collections provided direct access to genes for use in transgenesis, additional value was extracted from the libraries through comparison of EST expression patterns among various target tissues. Central to this research was the in-house development of gene expression profiling strategies based on array screening. Comparative gene expression analyses between tissue-types and developmental stages using membrane-based macroarrays identified a significant number of differentially regulated genes (Carson et al., 2002a, b). These included genes associated with cell wall metabolism, various regulatory and signal transduction processes, as well as a suite of stress-induced genes.

This information, when analysed in concert to data from biochemical and physiological studies, allowed the construction and analysis of custom cDNA macroarrays. Such arrays, sometimes referred to as boutique arrays, were designed using specific ESTs known to encode gene products associated with sucrose metabolism and transport (Watt et al., 2005).

Expression profiling of these ESTs revealed information about key genes and pathways regulating sucrose accumulation. Such array-based gene expression profiling approaches gained considerable momentum after the development of the Affymetrix® Sugarcane Genome GeneChip (Affymetrix chip); an important innovation driven by Casu et al. (2006) in Australia. Using this resource, researchers at SASRI have examined the role of sugar sensing and signalling in mediating
the source-sink relationship in sugarcane (McCormick et al., 2006). That work revealed a potentially central role of trehalose metabolism in the sink-mediated modulation of photosynthetic activity (McCormick et al., 2008). Work is currently in progress to unravel further the relationship that may exist between the capacity of the sugarcane plant to modulate sucrose production in the leaf according to the demand for the sugar by the stalk. In this regard, a combination of Suppression Subtractive Hybridisation (SSH) and ultra-high throughput DNA sequencing, based on 454-technology, is proving pivotal.

**Genetic resources: isolating gene promoters**

Gene promoters are an essential component of any genetic engineering toolkit, as they are required to regulate transgene expression to an appropriate level and to target expression to the desired site within the plant. The unavailability in the public domain of suitable promoters to drive high-level tissue- or organ-specific transgene expression in South African sugarcane germplasm prompted SASRI to establish a promoter isolation research programme. The overall strategy used in this endeavour has three components, viz.: (1) identification of transcripts displaying a suitable tissue-specific expression pattern; (2) identification and isolation of the corresponding promoter region from genomic DNA; and (3) functional assessment of the promoter in planta. In this regard, SASRI has sought to isolate functional promoters for targeting transgene expression to the leaf, culm or root.

Identification of tissue-specific transcripts has relied on the macroarray and the SSH technologies that were developed and deployed in SASRI’s early EST research. More recently, the Affymetrix chip technology has also been used to good effect in detecting differentially expressed genes to serve as a basis for promoter discovery. However, further validation of the differential gene expression patterns, detected by these technologies, is a vital step prior to promoter isolation. To this end, SASRI researchers have used two validation protocols, viz. (1) virtual confirmation of laboratory observations using the numerous online tools and data available at the National Centre for Biotechnology Information; and (2) experimental confirmation using either northern hybridisation analysis or quantitative PCR (qPCR), with the latter being the current method-of-choice.

Initial promoter isolation approaches at SASRI used the nucleotide sequences of well-characterised differentially expressed genes to retrieve the corresponding promoter region from the sugarcane genome. Such retrieval was based on the screening of sugarcane genomic libraries, which were either in the form of Bacterial Artificial Chromosome (BAC) or bacteriophage libraries.

Numerous conceptual and practical challenges arose during the screening of such libraries, primarily as a result of the complex, polyploid nature of the sugarcane genome. These challenges included accounting for the potential presence in the genome of multiple pseudogenes with associated non-functional promoter sequences, in addition to allelic promoter variants with different levels of activity.

Of additional concern was the propensity for gene silencing in sugarcane observed at SASRI and also reported in the literature (Hansom et al., 1999, Mudge et al., 2009). Hence, to-date, the maize Ubi-1 promoter (Christensen and Quail, 1996) remains the most widely used plant-derived promoter for sugarcane transformation, primarily due to the difficulties encountered by many research groups in isolating promoters that are capable of stable and high-level transgene expression (Brumbley et al., 2008). To reduce the risk of promoter silencing by transcriptional gene silencing (TGS) events, a strategy has been implemented at SASRI to isolate tissue-specific promoters from close *Saccharum* relatives, viz. *Sorghum bicolor* and *Zea mays*, for use in sugarcane. Availability of the sorghum genome sequence (Paterson et al., 2009) has made this approach particularly efficient, in that promoter regions are easily targeted for PCR-mediated amplification by means of sequence-specific oligonucleotide primers.
As transient expression assays do not necessarily depict in planta promoter expression characteristics, the functionality of promoters isolated at SASRI was assessed in numerous plants regenerated from multiple transgenic events. The rapid in vitro propagation and genetic transformation protocols developed greatly assisted in the generation of the large numbers of transgenic plants required for promoter functional testing. Results obtained to-date indicate that overcoming the phenomenon of TGS remains a challenge. As a result, SASRI researchers are currently exploring ways to alleviate promoter methylation, which is a recognised cause of transgene silencing. A construct, pKOMet, is being used to alter the expression of the endogenous sugarcane DNA methyltransferase, while the efficacy of a construct bearing a viral suppressor of gene silencing, pUbi P1/HcPro is also under evaluation. The availability of tissue-specific promoters to drive high-level transgene expression will be an extremely valuable tool in SASRI’s genetic engineering research.

Establishing Proof-of-Concept: examples from SASRI’s research portfolio

Proof-of-Concept for transgenesis was first generated at SASRI using herbicide resistance conferred by the pat gene from Streptomyces viridochromogenes against the herbicidal compound glufosinate ammonium (Leibbrandt and Snyman, 2003) (Table 1). Gene constructs were delivered by microprojectile bombardment and selection was facilitated by the nptII gene using G418 or paromomycin as selection agents (Snyman, 2004). Gene expression of both the gene of interest and the selectable marker was driven by the maize ubiquitin promoter. Subsequent field trials with selected herbicide resistant lines established that the pat transgene was stably inherited and expressed over multiple ratoons (Leibbrandt and Snyman, 2003). Since that initial study, two additional Proof-of-Concept projects, focusing on the delivery to elite South African sugarcane germplasm of input and resistance traits, have been successfully completed, viz. (1) increased resistance to the sugarcane stem borer, Eldana saccharina, through expression of the Cry1A(c) δ-endotoxin gene from Bacillus thuringiensis and (2) tolerance of the herbicide, glyphosate, through expression of a transgene derived from Agrobacterium sp. strain CP4 encoding the enzyme 5-enolpyruvyl-shikimate-3-phosphate synthase (Table 1).

Technologies to modify the expression of genes encoding key enzymes of carbohydrate metabolism in sugarcane have generated insights into the complex biochemical, metabolic and physiological processes underlying sucrose accumulation. This research area at SASRI has benefited from a strong collaboration with the IPB at Stellenbosch University, as well as from data generated from the early EST and gene expression experiments. For example, the gene encoding UDP-glucose dehydrogenase (UDPG-DH) was shown to be preferentially expressed in the immature culm (Carson et al., 2002a). Using this information as a starting point, research has been conducted to down-regulate UDPG-DH activity using antisense and RNAi technologies (Bekker, 2007) (Table 1). It was hypothesised that assimilated carbon would be directed away from cell wall synthesis and towards sucrose synthesis. Internodes from transgenic lines grown under glasshouse conditions demonstrated an increase in sucrose content that was correlated with a decrease in UDPG-DH activity. Currently, several other lines with modified levels of key enzymes of sucrose metabolism, which demonstrated desirable phenotypes in cell suspension culture and under glasshouse conditions, are under analysis in field trials (Table 1).

Future directions

The application of genetic engineering technology at SASRI has yielded several invaluable outcomes, including Proof-of-Concept for the delivery of beneficial input and resistance traits, as well as insights into the regulation of sucrose accumulation.

As the prospect of commercial production of transgenic sugarcane becomes increasingly less distant, SASRI management and researchers have begun to focus their efforts on issues that will ultimately facilitate the realisation of that goal. Such issues include refinement of
transformation technologies and addressing, as far as is possible, the socio-political, freedom-to-operate and regulatory issues surrounding genetic engineering with a commercial intent.

Refinements to the genetic engineering toolkit currently underway at SASRI encompass the development of: (1) transformation protocols that offer an alternative to biolistics; (2) benign selection methodologies for transformation events; and (3) novel approaches to isolate promoters which are not susceptible to TGS.

**Table 1**—Novel input traits, resistance traits and modified sucrose metabolism conferred via transgenesis to South African sugarcane germplasm. Also reflected are the nature and source of transgenes and the extent to which transgenic lines have been characterised to-date.

* Field trials conducted under permit from the South African National Department of Agriculture, Directorate: Biosafety, in accordance with the GMO Act 15 of 1997.

In parallel to these practical issues, researchers are beginning to draw on the potential offered by ultra-high throughput technologies, such as those for nucleotide sequencing and metabolite profiling, for potential application to gene discovery and demonstration of substantive equivalence of transgenic lines to wild-type. SASRI’s genetic engineering research is conducted in
a favourable environment, in that the South African sugar industry is supportive and the national regulatory framework is well-established. Given this context, the expertise held by SASRI and the availability of an established repertoire of technologies, the future for sugarcane genetic engineering research in South Africa holds considerable promise.

MOTS CLÉS: Micro-Propagation In Vitro, Transformation Génétique, Promoteurs des Gènes, Canne à Sucre.

Résumé

DURANT LES 15 dernières années, les technologies de l’ADN recombiné et de la culture in vitro ont été utilisées au South African Sugar Research Institute (SASRI) pour la transformation génétique de la canne à sucre. Cette recherche avait un double but : établir la preuve de principe concernant le transfert de nouveaux traits de production et de résistance à la canne à sucre, et examiner le mécanisme génétique responsable de l’accumulation de saccharose. Pour atteindre ces objectifs, il a été nécessaire de développer en laboratoire les techniques essentielles, y compris, l’isolation des transgènes et promoteurs appropriés, l’optimisation des technologies du génie génétique et de la culture de tissus. Concernant la culture de tissus, l’accent a été mis sur les stratégies qui minimisent le potentiel de variation somaclonale, tout en maximisant l’efficacité de la transformation du germoplasme, la sélection, la régénération et l’acclimatation. L’isolation des promoteurs pour une forte expression du transgène ciblée, et l’identification des séquences d’ADN qui ont le potentiel de développer le phénotype recherché, ont fortement évoluées de par les avancées dans la découverte des gènes et leur expression. Les approches initiales dépendaient de l’analyse des banques d’étiquettes de séquences exprimées (EST) produites à partir des tissus de canne à sucre de différents stades de développement ou qui ont été soumis à des stress biotiques et abiotiques. Des améliorations ultérieures des technologies d’hybridation soustractive d’ADN (e.g. hybridation soustractive et suppressive) et de l’analyse de l’expression génique (e.g. Affymetrix® Sugarcane Genome Genechip) ont apporté des moyens nouveaux et puissants pour la découverte de gènes et de promoteurs. Les avancées dans la culture in vitro, la découverte de gènes et l’expression de transgènes, qui ont formé la base du programme de génie génétique au SASRI, sont revues ici. Les opportunités et les défis dans ce domaine de recherche, grâce à la disponibilité de séquençage d’ADN à ultra haut débit (e.g. le Système 454 de Séquençage) pour l’analyse du transcriptome, et les technologies pour établir un profil rapide et précis des métabolomes de la canne à sucre sont aussi discutés.
INVESTIGACIÓN EN ÁFRICA DEL SUR SOBRE INGENIERÍA GENÉTICA DE LA CAÑA DE AZÚCAR: DEL DESCUBRIMIENTO GENÉTICO A LA EXPRESIÓN TRANSGÉNICA

PALABRAS CLAVE: Micro-Propagación \textit{In Vitro}, Transformación Genética, Promotores Genéticos, Caña de Azúcar.

Resumen

DURANTE los últimos 15 años, las tecnologías de ADN recombinante y de cultivo \textit{in vitro} han sido utilizadas en combinación en el Instituto de Investigación en Caña de Azúcar de África del Sur (SASRI, por sus siglas en Inglés) para innovar genéticamente a la caña de azúcar. El propósito de tal investigación es doble, \textit{viz.} establecer pruebas contundentes de la incorporación de nuevos caracteres y de aquellos de resistencia, e investigar la base genética de la acumulación de sacarosa. Tales objetivos han sido sustentados por el desarrollo interno de recursos genéticos cruciales, incluidos el aislamiento de transgenes y elementos de promoción genética adecuados, y la optimización de las tecnologías de transformación y en el cultivo de tejidos. Con respecto de lo último, se ha enfatizado en el desarrollo de estrategias en el cultivo de tejido para minimizar el potencial de variación somaclonal, a la par de maximizar la eficiencia en la transformación de germoplasma, la selección, la regeneración y la aclimatación. El aislamiento de promotores para impulsar un alto nivel y el destino de la expresión transgénica, así como la identificación de secuencias de ADN para asegurar la obtención del genotipo deseado, han sido fuertemente impulsados por avances tecnológicos en el descubrimiento y expresión genéticos. Los esfuerzos iniciales dependían del análisis de las bibliotecas de Etiquetas de Secuencias Expresadas (EST, por sus siglas en Inglés) derivadas de tejidos de caña de azúcar en distintos estados de desarrollo o sometidas a agentes selectos de estrés abiótico y biótico. Mejoras subsecuentes en tecnologías de hibridación substractiva (p.e., supresión de hibridación substractiva) y en el análisis de la expresión genética (p.e., \textit{Chip} Affymetrix\textsuperscript{\textregistered} de Genes de la Caña de Azúcar) han provisto de nuevos y poderosos medios para el descubrimiento de genes y promotores. Aquí se revisan los avances en el cultivo de tejidos, el descubrimiento de genes y la investigación en la expresión transgénica, los cuales han significado el fundamento del programa de ingeniería genética en el SASRI. Asimismo, se debaten las oportunidades y retos en las áreas de investigación aquí expuestas debido a la disponibilidad en la secuenciación de alto procesamiento del ADN (p.e., el sistema de secuenciación 454) o el análisis en el transcriptomo y en tecnologías para la definición rápida y precisa del perfil de los metabolomas de la caña de azúcar.
IDENTIFICATION OF MICROSATELLITE MARKERS ASSOCIATED WITH YIELD COMPONENTS AND QUALITY PARAMETERS IN SUGARCANE

KEYWORDS: QTL, Molecular Markers, Yield Components, Quality Parameters.

Abstract

MARKER assisted selection depends on the identification of tightly linked association between marker and the trait of interest. In the present work, functional (EST-SSRs) and genomic (gSSRs) microsatellite markers were used to detect putative QTLs for sugarcane yield components (stalk number, diameter and height) and as well as for quality parameters (Brix, Pol and fibre) in plant cane. The mapping population (200 individuals) was derived from a bi-parental cross (IACSP95-3018 x IACSP93-3046) from the IAC Sugarcane Breeding Program. As the map is under construction, single marker trait association analysis based on the likelihood ratio test was undertaken to detect the QTLs. Of the 215 single dose markers evaluated (1:1 and 3:1), 90 (42%) were associated with putative QTLs involving 43 microsatellite primers (18 gSSRs and 25 EST-SSRs). For the yield components, 41 marker/trait associations were found: 20 for height, 6 for diameter and 15 for stalk number. An EST-SSRs marker with homology to non-phototropic hypocotyls 4 (NPH4) protein was associated with a putative QTL with positive effect for diameter as also with a negative effect for stalk number. In relation to the quality parameters, 18 marker trait associations were found for Brix, 19 for Pol, and 12 for fibre. For fibre, 58% of the QTLs detected showed a negative effect on this trait. Some markers associated with QTLs with a negative effect for fibre showed a positive effect for Pol, reflecting the negative correlation generally observed between these traits.

Introduction

The identification of molecular markers tightly linked to agronomic traits of breeders’ interest is an important step to make possible the implementation of marker assisted selection in a breeding program (Morgante and Salamini, 2003; Charcosset and Moreau, 2004).

Besides this practical application, molecular markers are also suitable to study the genetic architecture of agronomic traits, especially the complex ones (quantitative traits) that can be resolved into single Mendelian components.

Sugarcane is an important cash crop with a complex genome that, certainly, will benefit from molecular marker technology, as most of its agronomic traits have a multigenic and/or multi-allelic nature. Several QTLs have been detected for basic yield components such as plant weight,
stalk number, stalk diameter and also for Brix and suckering through molecular mapping involving sugarcane bi-parental crosses (Hoarau et al. 2002; Jordan et al. 2004; Reffay et al., 2005; Aitken et al., 2008). The identification of genomic regions responsible for a phenotype of a trait probably will be accelerated by the utilisation of molecular markers derived from expressed sequence tags (ESTs). This type of marker can provide the direct mapping of genes while, at the same time, they themselves may be responsible for the trait of interest (Cato et al., 2001).

EST databases, such as the Sugarcane EST (SUCEST), have been used in the development of molecular markers for mapping (Oliveira et al., 2007) and QTL detection (Pinto et al., 2009) in sugarcane. Microsatellites, as co-dominant markers, have a great potential to allow the comparison among sugarcane maps from different mapping populations. Nowadays, several microsatellites derived from ESTs (EST-SSRs) are available for sugarcane (Oliveira et al., 2009) and together with the genomic ones (Cordeiro et al., 2000) will extend the access to the sugarcane genome, especially to the expressed ones.

In the present work, functional (EST-SSRs) and genomic (gSSRs) microsatellite markers were used to detect putative QTLs for sugarcane yield components (stalk number, diameter and height) as also for quality parameters (Brix, Pol and fibre) in plant cane. As the map is under construction, single marker trait association analysis based on the likelihood ratio test was undertaken to detect putative QTLs at $P < 0.05$.

**Material and methods**

**Mapping population and field data**

The mapping population was composed of 200 individuals derived from a bi-parental cross between the elite clone IACSP95-3018 (female parent) and the variety IACSP93-3046 (male parent) from the IAC Sugarcane Breeding Program. The progeny were planted in July 2005 at IAC Sugarcane Station in Ribeirão Preto in an augmented randomised block design, with five replications and including varieties SP81-3250 and RB835486 as controls.

Yield components (stalk number, stalk diameter and stalk height) as well as Brix and Pol (Pol value; gram of sucrose /kg/100g of fresh cane) and fibre percent were collected for each genotype at harvest in plant cane in August 2006. Stalk number was counted in one metre plot. Stalk diameter was measured in a sample of 5 stalks in the middle of the internode (one third of the stalk height from the base to the top).

The same sample was also used for the stalk height measurement conducted with a tape measure. The phenotypic data of each clone was adjusted for differences among blocks by the SAS statistical package (SAS Institute Inc., NC, USA).

**Microsatellite analysis**

Total genomic DNA was extracted from 300 mg of powdered lyophilised young leaf tissues using a CTAB-method (Hoisington et al., 1994) modified for sugarcane. PCR reactions were performed in a 20 µL final volume containing 40 ng of template DNA, 0.2 µM of each forward and reverse primer, 100 µM of each dNTP, 2.0 mM MgCl₂, 10mM Tris-HCl, 50 mM KCl, and 0.5 Unit Taq DNA polymerase. Reactions were amplified as follows: 94°C for 3 min; followed by 30 cycles of 94°C for 1 min; annealing temperature specific for each primer for 1 min; extension of 72°C for 1 min and a final elongation step at 72°C for 2 min. Amplification products were separated by electrophoresis on 6% denatured polyacrylamide gels and using a 25-bp ladder as size standard and silver-staining according to Creste et al. (2002).

**Single-marker trait association analyses**

Marker segregation types were identified in a chi-square test for deviations from the expected segregation ratios of 1:1 and 3:1 (markers in single-dose in only one of the parents and markers in single-dose in both parents, respectively) with Bonferroni correction to control type I error for multiple tests. Markers were identified by the name of the SSRs plus a number according
to the fragment size (molecular weight) followed by a letter to denote parent polymorphism origin: D1 for marker present on ISCSP95-3018, D2 marker present on IACSP93-3046 and C for marker present in both parents.

Associations between the 215 single dose markers evaluated and QTL for yield components and quality parameters were done by comparing, through a likelihood ratio, the full regression model \( Y_j = \mu + bx + \epsilon_j \) assuming a lack of association between marker and QTL \((b = 0)\) (QTL search). The criteria adopted to declare putative marker-trait associations were p-values smaller than 0.05 and 0.01 (not correcting for multiple tests). The 215 single dose markers were derived from 43 microsatellite primers, of which, 18 genomic and 25 functional were chosen at random.

**Results and discussion**

The genetic map of the population used in the present work is under construction and therefore the number of single dose markers available until now is insufficient for a QTL mapping analysis. Thus, a single marker trait association analysis based on the likelihood ratio test (Liu, 1998) was undertaken to give previous information of putative QTL associations without the need of a genetic map. Moreover, this approach allowed maker trait association for all single dose markers obtained to be investigated.

**Single-marker trait associations**

Ninety marker trait associations \((P < 0.05)\) were found for the phenotypic measures obtained on plant cane of which 14 \((15%)\) were found at 1\% \((P < 0.01)\) significance level and 11 \((121%)\) at 0.5\% \((P < 0.005)\) significance level. These 90 putative marker trait associations represented 42\% of the total single dose markers evaluated in the single-marker analysis.

The number of associations detected \((90)\) exceeded the average number of statistical false positive association that might exist due to statistical chance. A statistical average of 64 potential false positive associations due to statistical chance is assumed at \(P<0.05\) \((0.05 \times 215 \text{ markers} \times 6 \text{ traits})\).

**Putative QTLs for yield components**

The range of the progeny phenotypic values ranged from 5 to 30 for stalk number (average of 14.14 ± 4.04), from 1.77 to 3.43 cm for stalk diameter (average of 2.71 ± 0.32 cm) and 0.93 to 3.29 m for stalk height (average of 2.36 ± 0.39 m).

For the phenotypic evaluations related to the yield components (height, diameter and stalk number), 41 marker associations were found: 20 \((17.8\%)\) for height, 6 \((5\%)\) for diameter and 15 \((13\%)\) for stalk number. Of the total number of markers associated with height, 6 \((30\%)\) showed a negative effect on this trait. SCA17.1C marker was associated either for height or diameter, with negative effect on both traits.

For stalk number, 8 \((53\%)\) markers showed negative effect contributing to reduction in tillering. Cir32.5D2 marker derived from IACSP93-3046 \((D2)\) parent had a high positive effect on stalk number \((7.48 \text{ stalks})\). SCB130.1D1 marker was associated with a putative QTL with positive effect \((0.13 \text{ cm})\) for diameter and negative \((-1.40 \text{ stalks})\) for stalk number (Table 1) reflecting the negative correlation usually observed between diameter and stalk number. Moreover, SCB130.1D1 marker is derived from an EST with homology to a hypocotyl protein.

**Putative QTLs for cane quality parameters**

For the quality parameters 18 \((20\%)\) single dose markers were found associated with putative QTLs for Brix, 19 \((21\%)\) for Pol and 12 \((13.3\%)\) for fibre. Of the markers associated with Brix putative QTLs, 11 were also found associated with Pol with similar effect values and direction \((i.e. \text{ increase or decrease in the effect})\).

In relation to fibre, 58\% of the putative QTLs identified had a negative effect on this trait. The SCB27.3C marker was associated with a QTL with negative effect for fibre \((\text{reduction of} -0.91\% \text{ in fibre})\) and also to a QTL with positive effect \((\text{increase of} 0.49 \text{ Pol}%)\) for Pol.

*Significance level at 5% (P<0.05). ** Significance level at 1% (P<0.01). *** Significance level at 0.5% (P<0.005). D1: Single dose in IACSP95-3018. D2: Single dose in IACSP93-3046. C: Single dose in both parents. In parenthesis number of marker trait associations detected at (P<0.01) and (P<0.005), respectively.
The same trend was observed for SCA48.1D2 marker that was not only associated with a QTL with a positive effect for Brix and Pol but also with a QTL with negative effect for stalk number.

**Biochemical relationship between marker homology and putative QTL detected**

The utilisation of molecular markers derived from ESTs allowed the investigation of the biochemical relationship between the role of the gene used as marker and the respective associated agronomic trait.

In our study, the relationship was investigated *a posteriori* as the EST-SSRs were chosen at random. Some of the putative QTL detected were associated with markers, which could be related with the phenotype evaluated.

For example, marker SCB58.7D1 having homology to Myb-like protein was associated with fibre. Some MYB genes have been shown to be involved in the control of phenylpropanoid metabolism involved in lignin production.

Marker SB130.1D1 associated with stalk diameter, stalk number and Brix has homology with a non-phototropic hypocotyl protein (NPH4) that encodes the auxin-regulated transcriptional activator ARF7 (AUXIN RESPONSE FACTOR 7), which is conditionally required for the modulation of differential growth of aerial tissues in *Arabidopsis* (Harper *et al.*, 2000).

MOTS-CLÉS: QTL, Marqueurs Moléculaires, Composantes de Rendement, Paramètres de Qualité.

Résumé
La sélection assistée par marqueurs dépend d’une étroite association entre le marqueur et le caractère à l’étude. Des marqueurs fonctionnels (EST-SSRs) et génomiques (gSSRs) ont été utilisés dans cette étude pour déterminer d’éventuels QTLS associés aux composantes de rendement (nombre de tiges, diamètre et hauteur) et aux paramètres de qualité (Brix, Pol et fibre) chez la canne vierge. Une descendance de 200 individus issue d’un croisement bi-parental (IACSP95-3018 x IACSP93-3046) provenant du IAC Sugarcane Breeding Program a été utilisée pour l’étude cartographique. Étant donné que la carte génétique n’a pas encore été réalisée, une association de marqueurs à caractère simple (single marker trait association), basée sur le test du rapport de vraisemblance (likelihood ratio test), a été utilisée pour déterminer les QTLS. Des 215 marqueurs simplex (ratio 1:1 et 3:1) identifiés à l’aide de 43 amorces microsatellites (18 gSSRs et 25 EST-

PALABRAS CLAVE: QTL, Marcadores Moleculares, Componentes de Rendimiento, Parámetros de Calidad.

Resumen

LA SELECCIÓN asistida por marcadores depende de la identificación de una fuerte asociación de ligamiento entre marcadores y carácter de interés. En el presente trabajo, marcadores funcionales (EST-SSRs) y genómicos (gSSRs) fueron usados para detectar QTLs putativos para componentes de rendimiento de la caña de azúcar (número de tallos, diámetro y altura), así como para parámetros de calidad (Brix, Pol y fibra) en planta de caña de azúcar. La población a cartografiar (de 200 individuos) fue derivada de una cruza bi-parental (IACSP95-3018 × IACSP93-3046) del Programa de Fitomejoramiento de Caña de Azúcar del IAC. Ya que el mapa se encuentra bajo construcción, un análisis de asociación entre carácter y marcadores únicos fue efectuado para detectar los QTLs, basado en una prueba de probabilidad. De los 215 marcadores de una sola dosis (1:1 y 3:1), 90 (42%) fueron asociados con QTLs putativos involucrando 43 iniciadores microsatélite (18 gSSRs y 25 EST-SSRs). Para los componentes de rendimiento, 41 asociaciones fueron encontradas entre marcadores y carácter: 20 para altura, 6 para diámetro y 15 para número de tallos. Un marcador EST-SSR con homología a la proteína 4 (NPH) del hipocotilo no fototrópico fue asociada con un QTL putativo de efecto positivo para el diámetro, así como con un efecto negativo para el número de tallos. En relación con los parámetros de calidad, 18 asociaciones entre marcadores y caracteres fueron encontrados para el Brix, 19 para el Pol y 12 para la fibra. Para la fibra, 58% de los QTLs detectados mostraron un efecto negativo en este carácter. Algunos marcadores asociados con un efecto negativo para la fibra mostraron un efecto positivo para Pol, reflejando una correlación negativa generalmente observada entre ambos caracteres.
COMPARISON OF AFLP, TRAP AND SSRs IN THE ESTIMATION OF GENETIC RELATIONSHIPS IN SUGARCANE

KEYWORDS: Molecular Markers, Genetic Distance, Sugarcane.

Abstract
The sugarcane Breeding Program of the Instituto Agronômico de Campinas has been using routinely different types of molecular markers for the characterisation of their breeding clones and varieties. In the present work, we compared the genetic relationships among 82 sugarcane clones/varieties using three types of molecular markers: AFLP, TRAP and Microsatellites (SSRs). Five AFLP selective primer combinations, 10 SSRs and four TRAP fixed primers, designed from candidate genes involved in the drought tolerance response metabolism, were used in combination with three arbitrary primers. The pair-wise genetic similarity based on the Jaccard’s coefficient, the dendrogram and matrix comparison were done using NTSYS Software. A total of 410 polymorphic markers were obtained: 145 AFLPs, 103 SSRs, and 160 TRAPs. Although the average genetic similarity estimates based on AFLP (0.675) and TRAP (0.655) were closer to each other than to SSRs (0.522), the correlation between TRAP and SSRs was higher (r= 0.24). The coefficient of variation was lower for AFLP and TRAP (~6.55%) than for SSRs (13%). These results indicate that the choice of molecular markers should be considered carefully, based on the purpose of the application in the breeding program, as it is not possible to select a marker system that fits all the requirements for germplasm characterisation.

Introduction
Molecular markers are essential tools in breeding programs. One of their applications is to allow the estimation of the genetic distance (GD) among elite genotypes. Genetic distance estimation revealed by molecular markers should be prioritised for crops like sugarcane, with narrow genetic base, unknown ancestors, and with no accurate or even non-existing pedigree records (Farooq and Azam, 2002). In sugarcane breeding, the choice of parents is based on agronomic traits and pedigree records, using bi-parental crosses or polycrosses among elite genotypes.

However, the lack of genealogy data, as well as errors in the identification of some genotypes has resulted in inaccurate estimation of genetic distance among sugarcane genotypes based on pedigree data. It is accepted that crosses between unrelated genotypes would maximise the number of segregating alleles resulting in a large genetic variance of the progeny (Cox et al., 1985; Messmer et al., 1993), thus increasing the probability of selecting rare and superior genotypes (Becelare et al., 2005). The genetic variability within sugarcane germplasm has been estimated using different molecular markers, including random (Lima et al., 2002, Aitken et al., 2006) and functional marker systems (Pinto et al., 2006; Alwala et al., 2006).
Molecular markers are used routinely at the Instituto Agronômico de Campinas as an additional tool to assess the genetic variability among genotypes used as parents. They are also used to fingerprint commercial and pre-commercial clones and to monitor for genetic identity in germplasm collections and in commercial fields. The objectives of this study were to evaluate the usefulness of microsatellite (SSR), amplified fragment length polymorphism (AFLP) and target region amplification polymorphism (TRAP) markers in the estimation of the genetic similarities (GS) in a specific set of sugarcane genotypes and to compare the GD values among them.

Material and methods

Plant material and DNA extraction

A total of 82 genotypes, comprising commercial and pre-commercial clones, were used. These represented a set of specific genotypes issued from the ‘Centro de Cana’ sugarcane breeding program, that are being evaluated in the field under the Brazilian ‘cerrado’ (savanna) conditions for drought response. From each genotype, total DNA was extracted from a fresh meristem cylinder (Ali et al., 1999).

Primers used

TRAP markers were obtained from four fixed primers designed from candidate genes involved in the drought tolerance response metabolism (Aquaporin – Aqua primer; late embryogenesis abundant protein – LEA primer; dehydration binding factor – DBF primer; and dehydration responsive binding elements – DREB primer) in combination with three arbitrary primers (referred to as arb1, arb2 and arb3 primers) provided by Li and Quiros (2001). TRAP PCR reactions were performed according Alwala et al. (2006).

AFLP analysis was carried out using five primer combinations (E-ACT/M-CAT, E-ACG/M-CTT, E-ACG/M-CTC, E-ACT/M-CAG, E-AGA/M-CTG), according Vos et al. (1995). A total of 10 SSRs (6 genomic and 4 derived from expressed sequence tags) were chosen based on the sugarcane functional map (Oliveira et al., 2007). The primer sequences and amplification conditions of genomic SSR and EST-SSRs were obtained, respectively, from Pan (2006) and Oliveira et al. (2009). The polymorphisms were detected in polyacrylamide gels by silver staining (Creste et al., 2001).

Data analysis

Amplified fragments were scored for presence (1) or absence (0) in all 82 genotypes. The genetic similarities among all genotypes were calculated according to Jaccard’s similarity coefficient using NTSYS-PC version 2.0j (Exeter Software, Setauket, NY, USA). The polymorphic information content (PIC) for allelic diversity at a given locus was measured. As PIC for dominant markers ranges from 0 to 0.5 and for co-dominant markers from 0 to 1.0, the PIC values obtained for AFLP and TRAP were converted in PIC % to allow comparison among the different marker types.

Results and discussion

The genetic polymorphism of 82 sugarcane genotypes was assessed by TRAP, AFLP and SSR markers. The data obtained for each marker type, in terms of total number of markers analysed, number of polymorphic markers; percent of polymorphism and PIC value are summarised in Table 1.

Target region amplification polymorphisms (TRAP)

The 12 TRAP primer combinations produced a total of 225 fragments, of which 160 (71.11%) were polymorphic. The total number of bands amplified by individual primer combinations ranged from 14 (DREB/Arb3 and LEA/Arb1) to 27 (Aquaporin + Arb3), an average of 18.75 bands per primer combination, and 13.30 polymorphic bands per primer combination. The highest number of polymorphic fragments was observed with primer combination DBF/Arb1 (18 fragments) and the lowest with DBF/Arb2 (9 fragments).
Table 1—Marker type, number of markers analysed, polymorphic markers, percentage of polymorphism, PIC values and PIC% obtained in a sample of 82 sugarcane genotypes evaluated by SSR, AFLP and TRAP markers.

The average of 13.30 polymorphic bands per primer combination was lower than that (29.38 polymorphic bands) derived with 18 TRAP primer combinations on a broad set of accessions composed of sugarcane hybrids, *Erianthus*, *Miscanthus* and *Saccharum* species as reported by Alwala *et al.* (2006). Different genotypes were evaluated in our research compared to the one conducted by Alwala *et al.* (2006), and thus the different numbers of polymorphic bands observed are probably due to differences in the genetic background of the accession group analysed. In fact, the large number of different accession types evaluated by Alwala *et al.* (2006) was wider than those of our study composed exclusively of commercial and semi-commercial varieties. The DBF/Arb 2 combination gave the lowest PIC value (0.16) while ACQUA/Arb1 combination gave the highest value (0.40). The average GS obtained among the genotypes was 0.65 with the lowest similarity value observed between IACSP03-8140 and IACSP03-8189 (0.46) and highest between IACSP03-8136 and IACSP03-8125 (0.84). The GS estimated with the 160 TRAP derived markers gave a coefficient of variation (CV) of 6.50%.
Amplification fragment length polymorphism – AFLP

The five AFLP primer combinations screened produced a total of 182 bands of which 145 (79.67%) were polymorphic. The total number of bands per primer combination ranged from 31 (E-ACG + M-CAT) to 45 (E-ACG + M-CTG) with an average of 36.4 bands. The PIC values ranged from 0.23 (E-ACT + M-CTG) to 0.32 (E-ACT + M-CAT and E-ACG + M-CTT). The average GS was 0.67 with the lowest value observed between IACSP93-2094 and IACSP03-8136 (0.38) and the highest between IACSP03-8077 and IACSP03-8145 (0.88), considering a CV of 6.5%. The average GS observed among the 82 sugarcane genotypes was lower than that of 47% (CV of 4.29%) reported by Lima et al. (2001) on 83 sugarcane varieties from different Brazilian breeding programs.

Microsatellites (SSRs)

The 10 microsatellite primers used yielded a total of 103 alleles (markers) with an average of 10.3 alleles per locus ranging from 5 (Cir51, Cir56) to 15 (1047HA). The PIC values ranged from 0.68 (Cir 51) to 0.90 (SCB100) with an average value of 0.82 (Table 1). These values were higher than those reported for 15 sugarcane commercial varieties from Coimbatore assessed with 168 SSRs (Singh et al., 2008).

The average GS among the 82 sugarcane genotypes was 0.51 with the lowest pair wise genetic similarity value observed between IAC97-2028 and IACSP03-8164 (0.28) and the highest value observed between IACSP97-7077 and IACSP97-2023 (0.87) considering a CV of 13.0%. The average GS value observed here was smaller (68.3%) than that reported among 20 sugarcane varieties assessed with SSRs (Selvi et al., 2008).

Comparison among different marker types

As expected, the results obtained with the different molecular markers used in this research were different, since each marker system allowed us to assess the genetic variability of the 82 sugarcane genotypes at different genomic regions.

In general, the polymorphism observed in this study reflects the nature of each type of marker (AFLP, TRAP, and SSRs). The PIC value adjusted for percentage (PIC%) varied according to the respective marker type: from 0.32 (DBF/ A2) to 0.80 (ACQUA/ A1) for TRAP, 0.46 (E-AGA + M-CTG) to 0.64 (E-ACT + M-CAT and E-ACG + M-CTT) for AFLP, and from 0.684 (CIR51) to 0.896 (SCB100) for SSR.

The highest PIC% values were observed with SSR markers, probably due to the nature of this marker, which usually shows high mutation rates when compared to other types of molecular markers (Jarne and Lagoda, 1996).

The estimates of the correlation between the genetic similarity matrices and its significance (t test) were generally low: \( r = 0.12 (t = 1.53 \text{ ns}, p = 0.937) \) for AFLP vs TRAP, \( r = 0.011 \) \( (t = 0.16 \text{ ns}, p = 0.565) \) for AFLP vs SSRs, and \( r = 0.24 \) \( (t = 3.62 \text{ ns}, p = 0.999) \) for TRAP vs SSRs.

This situation was expected, since each marker system reflects the polymorphism in different portions of the genome (i.e. repetitive regions, or genome wide or target genes). The highest correlation value was observed between TRAP and SSRs and this could be partially attributed to the fact that among the 10 SSRs screened, 4 were derived from expressed sequence tags (EST-SSRs) sampling a functional region of the genome.

The range of variation of GS values was smaller for TRAP (0.45–0.84) than for AFLP (0.38 –0.88) and SSR (0.28–0.87) (Figure 1). The TRAP markers used are derived from candidates genes related to drought tolerance in sugarcane. Drought tolerance has been considered as an important trait in sugarcane breeding, and probably these genes have been under a higher selection pressure than those assessed by SSR and AFLP markers. So, there is a lower genetic variability for this trait in the pool of the genotypes sampled in comparison with those revealed by the repetitive or random markers.
The highest range in the GS distribution was generated with microsatellite data. In sugarcane, SSR markers have been considered as the most efficient marker for its characterisation, due to their reproducibility and high polymorphisms (Pinto et al., 2006) and also because they are ideal to establish relationships and for fingerprinting. In this study, the SSR makers used allowed the identification of several alleles including those that are unique to a variety or clone contributing to an increase in the range in the genetic diversity in the pool of genotypes assessed.

![Frequency distribution of TRAP, AFLP and SSR-based genetic similarity values for all the 82 genotypes evaluated (3321 genotypes combinations).](image)

According to Alwala et al. (2006), AFLP markers may be more robust for detecting polymorphisms among closely related genotypes, as they are more likely to sample different segments throughout the genome. However, it has been suggested that the choice of the marker (random or functional) for germplasm characterisation is dependent on the aim of the study. If the study is focused on the evolution or historical processes, random markers are suitable (Tiendiren et al., 2002).

For the assessment of variation in wild relatives or for establishing GS between genotypes for breeding purposes, it is more valuable to have information on the variability of specific genes that potentially affect important traits in breeding. The variation in expressed or regulatory sequences might reflect the past influences of selections, which could be different for each gene.

For instance, the characteristics that enable a sugarcane variety to show superior performance in a specific environment may depend on a limited set of genes, and the variation in genes will probably not be the same as in a group of genes involved in the expression of an independent characteristic.

Therefore the variation in these genes will most probably not be detected using random markers (Tienderen et al., 2002). In fact, the importance of accessing polymorphisms that account for the phenotypic variation (i.e. in target genes) in genetic breeding has contributed to the increase in the use of single nucleotide polymorphism (SNP) marker technology for sugarcane characterisation (Cordeiro et al., 2006).

Thus, it is important to choose a marker system related to the objective of the research. Using different markers is also an interesting approach since it provides different and complementary information on genotypes.

**MOTS-CLÉS: Marqueur Moléculaire, Distance Génétique, Canne à Sucre.**

**Résumé**

Le programme d’amélioration variétale de ‘Instituto Agronômico de Campinas’ fait l’usage routinier de différents types de marqueurs moléculaires pour la caractérisation des clones et variétés. Dans cette étude, nous avons comparé la parenté génomique parmi 82 clones/variétés de canne à sucre en utilisant trois types de marqueurs moléculaires: AFLP, TRAP et microsatellites (SSRs). Cinq combinaisons d’amorce sélective pour AFLP, 10 amorces SSRs et 4 marqueurs TRAP développés à partir des données des gènes candidats impliqués dans le métabolisme pour la résistance à la sécheresse ont été utilisées en combinaison avec trois amorces arbitraires. Les correspondances génétiques, basées sur la méthode du coefficient de Jaccard, du dendrogramme en classification ascendante et hiérarchique et la matrice de comparaison, ont été faites selon le logiciel NTSYS. Un total de 410 marqueurs polymorphes a été obtenu notamment 145 marqueurs AFLP, 103 SSRs et 160 marqueurs TRAP. Quoique l’estimation moyenne de la similarité génétique basée sur les marqueurs AFLP (0,675) et marqueurs TRAP (0,655) était plus près l’un de l’autre en comparaison avec les marqueurs SSRs (0,522), la corrélation entre les marqueurs TRAP et SSRs était plus élevée (r = 0.24). Le coefficient de variation était inférieur entre les marqueurs AFLP et TRAP (~6.55%) en comparaison avec les SSRs(13%). Ces résultats indiquent que le choix de marqueurs devrait être soigneusement considéré. En sus, le choix doit être basé sur l’objectif de l’application des marqueurs dans le programme d’amélioration variétale car il n’est pas possible d’adopter un système de marqueur pour tous les besoins pour la caractérisation du germoplasme.
COMPARACIÓN DE MARCADORES AFLP, TRAP Y SSRs EN LA EVALUACIÓN DE RELACIONES GENÉTICAS DE CAÑA DE AZÚCAR

PALABRAS CLAVE: Marcadores Moleculares, Diatancia Genética, Caña de Azúcar.

Resumen

El PROGRAMA de Fitomejoramiento de la Caña de Azúcar de Campinas ha utilizado de manera rutinaria diferentes tipos de marcadores moleculares para la caracterización de sus clonas mejoradas y variedades. En el presente trabajo, comparamos las relaciones genéticas entre 82 clonas/variedades de caña de azúcar usando tres tipos de marcadores moleculares: AFLP, TRAP y Microsatélites (SSR). Cinco combinaciones de iniciadores selectivos AFLP, diez SSR y cuatro iniciadores fijos TRAP fueron diseñados a partir de genes candidatos involucrados en el metabolismo de respuesta en la tolerancia a la sequía, usándoseles en combinación con tres iniciadores arbitrarios. La similitud genética basada en el coeficiente de Jaccard, el dendrograma y la comparación de matriz fueron calculados usando el programa de cómputo NTSYS. Se obtuvieron un total de 410 marcadores polimórficos: 145 AFLPs, 103 SSRs y 160 TRAP. Pese a que el promedio de los cálculos de similitud genética se sustentaron en la relación entre los marcadores AFLP (0.675) y TRAP (0.655), más cercana entre ellos que en relación a los SSRs (0.522), la correlación entre TRAP y SSR fue mayor ($r = 0.24$). El coeficiente de variación fue menor para AFLP y TRAP ($~6.55\%$) que para los SSR (13%). Estos resultados indican que la elección de marcadores moleculares debe conducirse juiciosamente dependiendo del propósito para aplicarles en un programa de fitomejoramiento, ya que no es posible seleccionar un sistema de marcadores que cumpla con todos los requerimientos en la caracterización de germoplasma.
A REVIEW OF EXISTING REGULATIONS FOR GM CROPS
AND PROGRESS MADE ON GM SUGARCANE
RESEARCH IN CHINA

By

KEYWORDS: Regulations, GM Crops, GM Sugarcane, China.

Abstract
In China, legislation is in place and a system has been established for the safety assessment of genetically modified organisms (GMOs). The Ministry of Agriculture is responsible for the regulation of genetically modified (GM) crops and a Biosafety Committee has been authorised to handle the safety evaluation for such crops. A set of regulations for GM crops has also been promulgated. Good progress has been made in GMO development in the laboratories, but so far no GM sugarcane has reached commercial testing. A number of standard protocols for the detection of GM crops and their derived products have been developed and one for detecting GM sugarcane is currently being formulated.

Introduction
China is one of the countries that grows genetically modified (GM) crops in the world. There are five GM crops presently cultivated in China namely tomato, pepper, poplar, papaya and cotton (Wang et al., 2007). In 2006, GM cotton was the leading crop being grown over 3.5 million hectares and covering up two thirds of the total cotton planting area. With the fast adoption of GM crops, China is also developing biosafety measures to ensure their safe use. A system has been established for the assessment of GM crops and legislation is also in place for their control. The Ministry of Agriculture is responsible for the regulation of GM crops and for agricultural products derived from them. A Biosafety Committee, to oversee agricultural GMOs, is authorised to handle the safety evaluation for all greenhouse experiments, environmental impacts, release, and commercial production. A set of regulations for GM crops, animals and microbes has also been promulgated. In this paper, a review of the various biosafety measures in place in China as well as progress achieved in the development of GM sugarcane is reported.

Regulations for GM crops in China
China has issued a set of regulations for GM crops, animals and microbes. In 1993, the first regulation for the administration of genetic engineering was promulgated by the State Scientific and Technological Commission. Thereafter, more regulations were formulated and five major ones for agriculture were further promulgated by the Chinese State Council (Anon., 2001) and Ministry of Agriculture (Anon., 2002).

The State Council, well ahead of the entry into force of the Cartagena Protocol on Biosafety in 2003, promulgated a primary regulation entitled ‘Regulations on Administration of Agricultural Genetically Modified Organisms Safety’ in May 2001 (Anon., 2001). This regulation caters for the control of GM plants, animals and microbes with the objectives to protect human health and the
environment. The regulation which contains 56 articles also aims to strengthen control on genetic engineering research and development (R&D), as well as production, processing and trading of GM agricultural products, including plants, animals and microbes. It calls for mandatory assessment of the safety of all GM products being developed as well as for labelling of such products. Research institutions are required to have facilities and techniques to ensure the safety of their research on GMOs. Research institutions developing GMOs, upon completion of experiments, need to apply for a Safety Certificate from the State Agriculture Administration Department (SAAD) for their final product. An individual engaged in the production and processing of GM products must also have the approval from the SAAD or from the provincial level. Products listed and authorised in the GM Product Catalog in China must be properly labelled before they are marketed. The SAAD is also responsible for approving the import of GMOs and GM products while the Entry-Exit Inspection and Quarantine Bureaus are responsible for their export. The SAAD also has the power to ban any production, processing or trading of GM product that is found to be a hazard to human health, and the environment.

**Procedures in safety assessment of GM sugarcane**

Article 2 of the ‘Regulations on Administration of Agricultural Genetically Modified Organisms Safety’ developed by the State Council describes the procedures for the assessment of GM crops related to research, restricted field-testing, medium-scale field-testing and productive testing. Restricted field-testing concerns small-scale tests conducted within a controlled system or under controlled conditions. For GM sugarcane, such experiments can be conducted in a contained greenhouse. Medium-scale field-testing can be carried out under natural environmental conditions with appropriate safety measures. The field should be fenced and, in the case of GM sugarcane being tested, no other sugarcane plantations should be present within a distance of 300 metres for non-flowering varieties and 500 metres for flowering varieties, the isolation distance being based on other crop species (Anon., 2002). Productive testing consists of large-scale tests prior to commercial production and application. When an experiment has passed one testing stage and requires testing in the next stage, a new application must be made to the SAAD. If the tests pass the safety evaluations conducted by the Biosafety Committee and a Safety Certificate is obtained, the SAAD may give its approval. Research on GMOs in China conducted by Chinese-foreign contractual cooperation or joint capital or sole foreign capital must have the approval from the competent Agricultural Administrative Department of the State Council.

Four additional regulations, based on the primary regulation by the State Council, concerning safety assessment (Anon., 2002), labelling, processing, and import and export of agricultural products have also been promulgated by the Ministry of Agriculture.

**Gene cloning for genetic modification of sugarcane**

Apart from the genes obtained from abroad for sugarcane transformation including the galanthus nivalis agglutinin (GNA) gene from the snowdrop lily (Chen et al., 2004a) and Hsi pro-1 gene (Chen et al., 2004b) for pest resistance, as well as the leafy (Li et al., 2003) gene for plant flowering, Chinese scientists have cloned a few genes. In 2000, a trehalose synthase gene (Tsase) was cloned using RT-PCR based on the sequence of a trehalose synthase gene from the Basidiomycete, Grifola frondosa, and the sequence of 2199 bp containing a start codon and a stop codon was transformed into sugarcane (Zhang et al., 2000). A few genes were cloned from the coat protein gene and the N1b coding region of Sugarcane mosaic virus (ScMV), namely ScMV-CP-E (Jiang et al., 2006), ScMV-HC-Pro (Liu, 2008), SrMVP1 and Nib (Yao et al., 2006a). ScMV-CP-E
is a gene from ScMV-CP and a specific inhibitor to strain E of ScMV. The ScMV-HC-Pro and SrMVP1 genes are factors in RNA-mediated silencing in viruses. The *Nib* gene contains the consensus motif GDD box to resist the virus. The templates to clone the above genes and their pathways are different but they all aim at inhibiting expression of ScMV. In addition, a gene from *Sugarcane yellow leaf virus* coat-protein (ScYLV-CP) was cloned and a ScYLV-CP prokaryotic expression vector was constructed to evaluate the gene’s function (Huang et al., 2007). Furthermore, a full-length cDNA library was constructed from a water-stressed plant of *Erianthus arundinaceus* in order to isolate genes for drought tolerance (Liu and Zhang 2008; Cai et al., 2009). For the improvement of sugarcane, the gene BADH (encoding betaine aldehyde dehydrogenase) for drought tolerance (Yu, 2004), and a new promoter Prd29A (Wu et al., 2008) were cloned from *Arabidopsis thaliana*. A gene coding for sucrose phosphate synthase (He et al., 2007) was also cloned from sugarcane and the sequence was analysed. Another gene, resveratrol synthase (RS) from grape was transferred into sugarcane for value-added products (Xu et al., 2008b). RS is one of the key enzymes in resveratrol biosynthesis, which catalyses one molecule of coumaroyl CoA and three molecules of malonyl CoA to form one molecule of resveratrol.

**Leading method in sugarcane gene transformation**

At the start, sugarcane transformation was mediated by *Agrobacterium tumefaciens* strain LBA4404 (Chen et al., 1996). Another strain EHA105 was found suitable for gene transfer into sugarcane (Zhang et al., 2006). Thereafter, particle bombardment, a direct DNA transforming system suitable for the transformation of monocots, has been used for transformation of sugarcane. This system can transfer minimal gene expression cassettes (promoter, open reading frame, terminator) into plant genomes and also generates safer transformants, in addition to multiple genes delivery. Direct gene transfer now prevails over *Agrobacterium tumefaciens* and is a major approach for gene transfer into sugarcane calli (Chen and Chen, 2004). Almost all existing GM sugarcane lines so far developed in China are as a result of particle bombardment except for one event (Zhang et al., 2000). However, some disadvantages of using the particle bombardment system have been observed. A large population of GM sugarcane plants needs to be screened in order to identify a desirable line, resulting in huge screening costs. Hence, the use of *Agrobacterium tumefaciens* for gene transfer into sugarcane is being reevaluated.

**Progress on GM sugarcane research**

China has made good progress at the laboratory level on the development of GM sugarcane. The gene *Tsase* was transformed into sugarcane by *Agrobacterium tumefaciens* strain EHA105 in 2000 (Zhang et al., 2000). This gene produces trehalose, a healthy sugar that could be a substitute for sucrose. Three transgenic plants were confirmed by PCR and Dot-Southern blot analysis and are in the stage of restricted field-testing. The transgenic plants are also promising drought-tolerant clones.

Insect pests can cause significant yield losses in sugarcane. In 2004, genes of *GNA* for aphid-resistance and *Hs1 pro-1* for nematode-resistance were introduced into sugarcane calli via particle bombardment and transgenic plants were obtained and tested in the greenhouse. Sugarcane transgenic lines with cry1A(c) gene were obtained in 2008 following particle bombardment and an application has been made for restricted field testing (Xu et al., 2008a). The cloning of the coat protein genes of *Sugarcane mosaic virus* (ScMV) was initiated in 2004 and several groups were involved (Yao et al., 2004, 2006; Guo et al., 2008). More than four genes including ScMV-CP-E, ScMV-HC-Pro, SrMVP1, and *Nib* have been cloned and transformed in variety Badila and hybrid
clones. A few GM plants with SCMV-CP-E are now ready for productive testing. A cloned BADH gene for drought tolerance and a new promoter Prd29A from *Arabidopsis thaliana* were transferred into sugarcane callus tissue by particle bombardment. A number of experiments are currently being performed at laboratory and field level for the development of GM sugarcane.

**Standards for detection of GM sugarcane**

A number of standards have been promulgated in China for the detection of GM crops including maize, rapeseed, soybean, potato, cotton, tobacco, tomato and rice and their derived products. These standards provide guidelines for detecting the GM component and for the biosafety assessment of the GM crops and their derivates. However, no standard for detection of GM sugarcane has been developed so far. The Ministry of Agriculture is presently working on a Standard for the detection of GM sugarcane and its derived products.

**Conclusion**

The development of GMOs has progressed extensively in the laboratory in China. Emphasis is also on biosafety measures to ensure the safe use of the GMOs due to the increasing demand from farmers to exploit such crops. It is expected that GM sugarcane will be one of the leading GM crops in the future in view of its specific characteristics for adaptation to less productive lands and due to its non flowering nature in mainland China, thus representing low biosafety issues.

phcemail@126.com

MOTS-CLÉS: Règlements, Plantes Génétiquement Modifiées, Canne à Sucre Transgénique, Chine.

Résumé
LA LÉGISLATION étant en place, un système a été établi en Chine pour évaluer les risques associés avec les organismes génétiquement modifiés (OGMs). Il incombe au Ministère de l’Agriculture de réglementer les plantes génétiquement modifiées (GM) et un Comité pour la biosécurité est autorisé à évaluer les risques associés avec les plantes GM. Un nombre de règlements pour les plantes GM a été promulgué. Ainsi, des progrès conséquents ont été accomplis dans la production des OGMs au laboratoire, mais jusqu’ici aucune canne transgénique n’a atteint l’étape d’évaluation commerciale. Un certain nombre de protocoles standard pour la détection des OGMs et leurs produits dérivés ont été développés. En sus, un protocole est actuellement en préparation pour la canne transgénique.

UNA REVISIÓN DE REGULACIONES ACTUALES PARA LOS CULTIVOS GM Y AVANCES EN LA INVESTIGACIÓN DE CAÑA DE AZÚCAR EN CHINA

PALABRAS CLAVE: Regulaciones, Cultivos GM, Caña de Azúcar GM, China

Resumen
EN CHINA, existen un marco legal y un sistema establecido para la evaluación de seguridad de organismos genéticamente modificados (OGMs). El Ministerio de Agricultura es responsable de la regulación de cultivos genéticamente modificados (GM) y un Comité de Bioseguridad ha sido autorizado para conducir la evaluación de seguridad para tales cultivos. Asimismo, un conjunto de regulaciones para los cultivos GM ha sido promulgado. Un buen avance ha sido conseguido en el desarrollo de GMO en los laboratorios, pero al momento ninguna caña de azúcar GM ha alcanzado una evaluación comercial. Se ha desarrollado un número de protocolos estándar para la detección de cultivos GM y de sus productos derivados, y actualmente existe uno definiéndose para la detección de caña de azúcar GM.

Abstract
GLOBAL investments in developing genetically modified (GM) sugarcane (\textit{Saccharum} spp. hybrids) to enhance its agronomic performance generate novel bioproducts, and bio-industries based on the crop's attributes for high biomass production are increasing. As for all GM crops, GM sugarcane will have to go through regulatory systems prior to commercial release, which will encompass environmental safety assessments. However, sexual reproduction for the vegetatively propagated crop has not been studied except to improve breeding. Consequently, knowledge of sexual reproduction in a commercial production setting is lacking and, thus, the baseline to determine possible environmental effects of a GM sugarcane is non-existent. We have initiated research in Australia to close this historical and global knowledge gap for sugarcane to provide baseline information for determining any potential environmental risks and, if necessary, for developing risk management strategies for the deployment of GM sugarcane. A proposed research framework developed and refined for identifying and addressing risks arising from potential sexual reproductive avenues of non-intentional gene escape from a GM sugarcane crop is described. We have engaged Australian regulatory authorities frequently during the development of the framework and the subsequent research to address the important issues for which they consider there is insufficient information. The principles and approaches described in the research framework would be equally applicable for assessing potential issues for the deployment of GM sugarcane in other agro-environments and for future developments of novel GM grass crops.

Introduction
Increasingly, global investments are aimed at the development of GM sugarcane (\textit{Saccharum} spp. hybrid) germplasm. Traits to improve the sugarcane business agronomically and those that will expand the crop's scope of agro-industrial end-uses are being targeted. During the development and prior to the release of GM sugarcane, regulatory systems in many jurisdictions will encompass rigorous, science-based environmental safety assessments. Initially, the potential routes of transgene escape and establishment (within and outside cultivation) for the environment
receiving the GM sugarcane require identification. Future evaluations of environmental effects of individual transgenes can then be conducted and compared from such generic baseline.

Relative to the abundance of agronomical and environmental studies on factors affecting growth and development of the vegetatively-propagated crop, sugarcane sexual reproduction has been globally and historically ignored except by breeders. Kock (2007) highlighted the lack of any sugarcane-derived data in a presentation on biosafety regulation of GM crops as no data for cane existed in the scientific literature at that time. Such a situation was noted by Bonnett et al. (2007) in the context of a potential introduction of GM sugarcane, which would initially be addressed by conducting studies for an understanding of the crop’s sexual reproduction. Sugarcane seed holds no caloric or economic importance in the harvested product. In most other crops, flowering is a pre-requisite to obtaining the harvestable product, seeds. In sugarcane, flowering is not required to obtain the next filial generation nor economic yield. Consequently, there are no studies on the reproduction of sugarcane in the field let alone gene dispersal via pollen or seed. For other grass crops, where the production of seed for planting material needs to be of high genetic purity and quality, the isolation distances of genotypes have been determined. Further, the absence of flowering of sugarcane in some areas has been used to assert sugarcane is a ‘secure biofactory’ (Wang et al., 2005); indeed, an untested assumption in many sugarcane growing regions. Finally, while sugarcane is unlikely to pose any new risk not evaluated for other transgenic crops, the necessary data are not available for sugarcane. Hence, a comprehensive understanding of the sexual reproductive biology and ecology of sugarcane is required to provide baseline information for the decision-making process of regulatory authorities to manage the safe release of GM sugarcane.

Elements in risk assessments

Within regulatory systems, the assessment of environmental risks for the approval and management of GM crops involves (Craig et al., 2008): a) the identification of potential environmental effects or perceived hazards that would arise from its release; b) an evaluation of the potential consequences; and, c) the determination of the probability (likelihood) of their occurrence.

Identifying potential environmental effects or hazards is generally based on biological features of the modified species/crop, and is dependent on the ecological context in which it is proposed for release. The general focus is on the potential for: a) unintentional escape of the GM organisms that would, if unmanaged, elicit a detrimental effect to the environment; and, b) transfer of the transgene(s), and thus those trait(s), to sexually compatible species (or to non-GM cultivars from GM crops) that would affect their fitness, alter their role in various environmental niches or facilitate the introgression to other non-targeted genetic pools.

Determining the likelihood of an environmental effect or hazard to occur would define the level of exposure to the environment. Once effects or hazards have been identified for a target environment, the competent authority within regulatory systems would assess any consequence of the particular transgenes in relation to any such hazard. While the evaluation of the consequences (for that effect or hazard to occur) is a process largely dependent on the specificity of the genes/traits modified, it is possible to generate a generic research framework to identify the effect or hazard component of risk assessment.

Development of a research framework

A conceptual framework to identify the environmental effect or hazard component of environmental risk is shown in Figure 1. The generic inquiries start with the most basic sexual reproductive process, flowering, and ends with seed germination and establishment of new plants in the target environment(s). Depending on the answers to the questions sequentially asked, the researcher is directed to more research. Should the process under study give rise to no potential effect or hazard, the information gathering can cease. For any particular transgene, a risk analysis would encompass additional analyses to verify if any biological parameter changed as a result of genetic improvement and, thus, if there are potential effects or hazards to be addressed. A risk
analysis would then be prepared by the competent authority based on the data, methods, reproducibility, likelihood and relevance of the effect, with a subsequent preparation of a risk management strategy to mitigate or manage any risk.

Fig. 1—A generic framework for the identification of potential environmental effects or hazards within a risk assessment, resulting from the sexual reproduction of sugarcane in commercial fields.

An important feature of the process of developing and refining this research framework has been regular engagement with Australian regulatory agencies during the planning and conduct of the research. This has ensured that their most important questions are being addressed, allowing us to modify both the strategy and experimental approaches as a consequence of feedback. With the publication of results as a final objective, this would allow: (i) the work to be available to a wider audience including regulators and technology developers; and, (ii) other researchers to apply it to their agro-environments of interest, and to identify any omission for their particular situation in order for them to design experiments that would fill those knowledge gaps. The subsequent sections summarise the results we have found when developing and applying the framework to sugarcane growing regions in Australia.

Does sugarcane flower in the target environment(s)?

Flowering varies greatly between years and locations (Berding et al., 2004). In some instances, such observations have led to the location of breeding facilities in areas of highest flowering. They have also led, in areas of no or low flowering, to the notion that sugarcane is an ideal GM crop because it is vegetatively propagated and does not flower. However, prior to the release of GM crops, a determination of whether flowering occurs is crucial and, if it does, if any viable seed is produced. As sugarcane is grown over a range of latitudes and altitudes (even in one country), multiple environments should be monitored. In Australia, sugarcane is grown from
latitude 16ºS in the north to 29ºS in the south, with flowering varying across seasons and cropping regions (Cox et al., 2000). Our approach has been to monitor the flowering of sugarcane in commercial fields in several regions in north Queensland over several years; multiple sites within each region were monitored at monthly intervals. Flowering occurred to some degree in all regions in all years studied, with the peaks of flowering for cropping seasons 2007 and 2008 in the Mulgrave and Herbert River regions shown in Table 1. Additionally, we also have quantified the extent of flowering in other sugarcane growing regions at higher latitudes. Flowering, as expected, was less frequent and less intense.

Are there any sexually compatible species to sugarcane?

Sugarcane and its closest relatives are not native in many sugarcane growing countries. A good source of information for identifying species and genera present in such different countries and regions are botanical flora and herbarium specimens. Internationally published flora compendia and taxonomical atlases are other valuable sources. In some instances, details of the occurrence and locations of plants related to sugarcane can be found in work describing the collection of germplasm for breeding purposes either indigenous (e.g., Nagatomi and Degi, 2007) or endo-exogenous (viz., regional or world germplasm repositories: Sugarcane Breeding Institute Collection, Coimbatore, India; Sugarcane Development Program, Canal Point, USA).

From breeding literature, we identified a list of species that were demonstrated to produce fertile hybrids with commercial sugarcane (Bonnett et al., 2008). When comparing these with related species and genera present in such different countries and regions are botanical flora and herbarium specimens. Internationally published flora compendia and taxonomical atlases are other valuable sources. In some instances, details of the occurrence and locations of plants related to sugarcane can be found in work describing the collection of germplasm for breeding purposes either indigenous (e.g., Nagatomi and Degi, 2007) or endo-exogenous (viz., regional or world germplasm repositories: Sugarcane Breeding Institute Collection, Coimbatore, India; Sugarcane Development Program, Canal Point, USA).

From breeding literature, we identified a list of species that were demonstrated to produce fertile hybrids with commercial sugarcane (Bonnett et al., 2008). When comparing these with related species and genera present in the likely target environments of Australia for the future introduction of GM sugarcane, we identified that Saccharum spontaneum L. is the most likely species which could spontaneously hybridise with commercial sugarcane. A wild relative (and one of the progenitors) of modern sugarcane cultivars, S. spontaneum has established as naturalised populations in close proximity to commercial sugarcane in five recently recorded locations in north Queensland (Bonnett et al., 2008), in addition to one remote location on the Daly River in the Northern Territory, where no sugarcane is commercially grown. While the north Queensland populations were identified from herbarium samples and local knowledge, we determined their extent by conducting land and river surveys. For the Northern Territory location, there were entries of S. spontaneum at the Queensland Herbarium. In countries where the progenitors and relatives of sugarcane occur sympatrically with sugarcane, the most important question is whether their flowering is synchronous with commercial sugarcane. A risk assessment, thus, would focus more on the consequence of the gene being transferred rather than the likelihood of transfer per se.

Is flowering sympatric with sexually compatible species?
Flowering times and seed production of commercial crops and of the naturalised populations of *S. spontaneum* were assessed as components of the regional monitoring previously described. The monthly observations indicated that there was synchronous flowering at some locations (Olivares-Villegas *et al.*, 2008). From an analysis of seed collected from the crop and the non-domesticated species (Table 2), we demonstrated that in some instances of synchronous flowering (Table 1), both were sexually fertile and produced viable seed. Thus, in those locations there appears to be an opportunity for hybridisation between commercial sugarcane cultivars and *S. spontaneum*. Consequently, managed experiments have been conducted to determine the ability of some of the naturalised populations of *S. spontaneum* to accept pollen from commercial sugarcane.

Hybrid incidence is being assessed via non-radioactive molecular markers.

### Is flowering sympatric between sugarcane cultivars?

As sympatric, synchronous sexual fertility is mostly observed in commercial cultivars across the monitored regions (Olivares-Villegas *et al.*, 2008, Table 1), we have been evaluating the potential hybridisation among sugarcane cultivars under field conditions. Distance of pollen dispersal and studies on non-intentional, inter-cultivar hybridisation have also been conducted to determine the limits of gene transfer via the microgametophyte to other *Saccharum* spp. hybrids. Such information would establish a comparative baseline for gene escape during testing phases of GM cane crops, which may be dependent on the transformed germplasm and transgene involved.

### Is fertile seed produced?

Transgene dispersal and establishment outside of cultivation via seed is one of the main environmental risk issues within the regulatory assessment for the prospective release of GM crops. While sugarcane is a vegetatively-propagated crop, under certain conditions it can produce seed — the basis of sugarcane breeding programs. As previously noted, our monitoring of north Queensland regions included seed collection not only of *S. spontaneum*, but also of sugarcane cultivars. As flowering is not indicative of the plant's ability to produce fertile seed, we tested the seed viability. Initial observations of variable seed fertility in opportunistic collections (Bonnett *et al.*, 2007) led to systematic assessments, where sub-samples of collected seed were subjected to *in vitro* germination tests. Viable seed was produced to some extent in some regions in each year when tested under the optimum germination temperature of 36°C (constant). The highest germinations of seed for 2007 and 2008 in the Mulgrave and Herbert regions are shown in Table 2. While the data is mostly lower than the average seed germination from breeders' crosses for sugarcane (*viz.*, 39 seedlings per gram of fuzz), seed germinates; thus, a risk assessment would have to consider its impact on the target...
environment. However, flowering may not always lead to viable seed set, either due to mega- or microgametophyte infertility resulting from genetic aberration and thermosensitivity.

**Can seed germinate and establish in the target environment(s)?**

Seed germination under *in vitro* ideal conditions is not indicative of seed’s ability to germinate *in situ* (viz., under the environmental conditions and niches to which the seed would be exposed). Although there is an information void on sugarcane seed longevity under field conditions and its response to environmental variables, there are some instances where there have been observations of in-field seedling establishment from germinated sugarcane seed, by sugarcane industry personnel. Albeit infrequent, there is potential for these plants to survive until sexual maturity, a fact yet to be verified as those observations were not systematically continued (to see if seedlings progressed to mature sugarcane plants). Currently, we are conducting studies on the potential of seeds and seedlings to germinate and establish, respectively, in various target environments where germination has been observed in the past, and their development (through time) is being followed.

We have also determined the response of sugarcane seed to temperature upon testing both seed produced by breeders and that collected from commercial fields under conditions of non-limiting moisture. We found that the optimum germination occurred between 30–36°C, with a 60% reduction at 24°C and a further reduction of 50% at 18°C, while there was some seed germinating at 15°C and, none was observed at 10°C (Powell et al., in preparation). Thus, temperature *per se* might not prevent germination of viable seed in sugarcane growing regions of Australia. As temperature is not the sole factor that determines germination in the environment, experiments are underway to understand the effects of various moisture stresses on sugarcane seed germination.

**Further research to support decision making on environmental issues by regulators**

Evolution of increased weediness is a potential, significant environmental consequence of non-intentional gene flow from cultivated plants to wild relatives (Ellstrand et al., 1999). Plant ecologists and population geneticists have studied such gene flow in the context of conventionally-improved crops to anticipate possible risks of transgenic crops. The most discussed resulting effects from crop-to-wild hybridisation is increased fitness through introgression, the evolution of increased weediness or invasiveness in wild relatives, the evolution of pests that are resistant to new strategies for their control, and the impacts on non-target species in associated ecosystems (Dale et al., 2002).

In sugarcane, the centuries-old agricultural practice has been to select against weedy traits in the vegetatively propagated crop, but there are wild relatives of sugarcane that are weeds (Anon., 2008). In particular, some genotypes/accessions of *S. spontaneum* are aggressive weeds in regions of southeast Asia, Indonesia, the Philippines and, recently, in Panama (Holm et al., 1997; Hammond, 1999); whether environmentally influenced or not, those accessions have particular allele combinations that could explain their resistance to environmental stresses, seed dispersal, vigorous tillering and fast developing rhizomatous root system. In Australia, the naturalised populations of *S. spontaneum* have not become as invasive, but such potential could be latent. Current studies are being conducted to understand those biological and ecological features that could explain the invasiveness of the weedy accession in Panama. A non-intentional elicitation of weediness through the modification of certain traits, such as those conferring abiotic stress tolerance, might potentially become an important issue to monitor in future developments of GM cane.

**Conclusions**

We have described a research framework for identifying and addressing risks related to potential avenues of non-intentional gene escape from a GM sugarcane crop, providing information that would aid decisions for GM cane management. While the framework was conceived for the cropping context of sugarcane growing in Australia and for assisting decision-making within its
regulatory system, it is applicable to other cane-growing industries across the world, particularly where those jurisdictions have legislation based on science-based evaluations (e.g., following legislation adherent to international standards). In addition to its application to other sugarcane agro-environments, the approaches also could be applied to other grass crops potentially useful for biofuel or bioproducts applications where sexual reproduction is not a pre-requisite for economic yield and so may be relatively unknown. The intent of this research was not to address the specific effects of particular genes, but to provide information about generic elements when potentially introducing a GM sugarcane into the environment. The research should, however, address decisions for the development and managed deployment of GM sugarcane.

Acknowledgments

The research was supported by the Australian Cooperative Research Centre Sugar Industry Innovation through Biotechnology (CRC SIIIB). The authors are deeply grateful to the many field and laboratory collaborators within the sugarcane industry across production regions, who contributed at various phases of the many components of the research herein summarised. Bryan Simon (DEEDI) provided access and assistance with herbarium samples. The authors acknowledge the kind collaboration of sugarcane growers of Australia for allowing the conduct of experiments on their farms.

Résumé

Les investissements à travers le monde sont en progression pour le développement de la canne à sucre (hybrides de Saccharum spp.) génétiquement modifiée (GM) dans le but d’améliorer sa performance agronomique pour générer de nouveaux bioproduits et pour l’utiliser comme bio-industrie grâce à sa production de biomasse élevée. Comme pour toutes les cultures GM, la canne GM aura à se conformer à des systèmes réglementaires, comprenant des évaluations de biosécurité à l’environnement avant son exploitation industrielle. Cependant, la reproduction sexuée de cette culture qui est propagée de manière végétative, n’a pas encore été étudiée, sauf pour les besoins d’amélioration génétique. Conséquemment, une connaissance dans un milieu de production industrielle n’est pas disponible et cela justifie l’obtention des données de base pour évaluer des éventuels effets environnementaux de la canne GM. Nous avons initié une recherche en Australie pour combler cette lacune historique et mondiale pour la canne à sucre. Cette étude consistait à obtenir des informations de base pour déterminer les éventuels risques à l’environnement, et si nécessaire, développer des stratégies de gestion appropriées pour l’exploitation de la canne à sucre GM. Un cadre de recherche développé et raffiné pour identifier et adresser les risques découlant des avenues potentielles de la reproduction sexuée liée à des fuites non-intentionnées des gènes de la canne GM est rapporté. Nous avons engagé les autorités régulatrices australiennes pendant le développement de ce cadre et pour la recherche subséquente pour adresser les aspects importants pour lesquels elles considéraient ne pas détenir suffisamment d’information. Les principes et les approches décrits dans ce cadre de recherche s’appliqueraient aussi pour évaluer les questions potentielles pour l’exploitation de la canne GM dans d’autres agro-environnements et pour le développement futur des nouvelles cultures herbacées génétiquement modifiées.

PALABRAS CLAVE: Caña de Azúcar, Modificación Genética, Biotecnología, Regulación, Liberación, Reproducción Sexual.

Resumen
Inversiones mundiales están en incremento para desarrollar caña de azúcar (híbridos de Saccharum spp.) genéticamente modificada (GM) a fin de aumentar su desempeño agronómico, generar novedosos bioproductos y explotar bioindustrias sustentadas en los atributos del cultivo para producir gran biomasa. Al igual que para todos los cultivos GM y previo a su liberación comercial, la caña de azúcar GM tendrá que cursar sistemas de regulación entre cuyas evaluaciones a conducir se encuentra la seguridad ambiental. Sin embargo, para el cultivo propagado vegetativamente, su reproducción sexual no ha sido estudiada excepto para progresar el fitomejoramiento. En consecuencia, falta la comprensión de la reproducción sexual en un contexto de producción comercial y, por tanto, resulta inexistente el referente para determinar posibles efectos ambientales de una caña de azúcar GM. Iniciamos investigaciones en Australia para cerrar esta brecha histórica y mundial a fin de proveer información referencial para determinar cualesquier riesgos potenciales al ambiente y, de ser necesario, para desarrollar estrategias de manejo de riesgo en la liberación de caña de azúcar GM. Proponemos y describimos una infraestructura de investigación desarrollada y afinada para identificar y atender riesgos derivados de las potenciales avenidas reproductivas sexuales de escape génico no intencional desde un cultivo de caña de azúcar GM. Hemos involucrado frecuentemente a las autoridades regulatorias Australianas durante el desarrollo de la infraestructura e investigación subsecuente a fin de atender las cuestiones más importantes para los cuales consideraron que no existe información suficiente. Los principios y enfoques descritos en la infraestructura de investigación son aplicables, igualmente, a la evaluación de asuntos potenciales en la liberación de caña de azúcar GM en otros agro-ambientes y para desarrollos futuros de cultivos de pastos GM.
FUNCTIONAL GENOMICS APPROACHES FOR THE STUDY OF WATER STRESS IN SUGARCANE

KEYWORDS: Water Restriction, Differential Expression, Stress Response, Drought Tolerance.

Abstract

The aim of this study was to evaluate gene expression in leaf roll tissues of sugarcane plantlets subjected to water restriction under greenhouse controlled conditions using two functional genomics approaches: EST library analysis and differential gene expression by a cDNA macroarray analysis. Sugarcane plantlets of variety SP80-3280 were submitted to water restriction for 17 days and leaf rolls were collected on days 1, 5, 9, 13 and 17 after initiation of the water restriction treatment. Two cDNA libraries were constructed using mRNA isolated from tissues collected at day 9 (LR9 library) and day 17 (LR17 library) and, after sequencing, the generated ESTs were analysed using bioinformatics tools. The results from the EST library analysis showed that transcripts for all the enzymes of the octadecanoid pathway leading to jasmonic acid (JA) biosynthesis were present during both periods, indicating that water-deficit-stress-induced expression of genes was involved in JA production. Transcripts for the antioxidant enzymes catalase, ascorbate peroxidase, polyphenol oxidase and superoxide dismutase were present. A macroarray containing 1202 spotted genes in duplicate were hybridised with cDNAs prepared from mRNA isolated from leaf rolls. An analysis of differentially expressed genes showed that only 147 genes presented differential expression, being induced or repressed. As observed in the cDNA libraries studies, genes coding enzymes of the octadecanoid pathway were induced. Similarly, genes coding antioxidant enzymes (two catalase isoforms, one monohydroascorbate reductase, two ascorbate peroxidase isoforms), indicating the tissue was under oxidative stress.

Introduction

Water deficit is one of the most important environmental stress factors limiting growth and productivity of agronomically important crops (Neill and Burnett, 1999). The changes in metabolism and development induced by stress can frequently be attributed to alterations in the level of gene expression (Taiz and Zeiger, 2004).

A relatively rapid way to obtain information about gene expression is the partial sequencing of cDNAs. Digital analysis of gene expression can be achieved by producing tags, e.g. ESTs, to expressed genes and then inferring transcript abundance from the frequency of these tags (Lee et al., 1995).

The DNA macroarrays enable the identification of activated or deactivated metabolic routes, in addition to the depiction of the hundreds of interactions that occur, at the transcriptional level, in response to several physiological events (Nepomuceno et al., 2001).
Material and methods

Leaf rolls were collected from 48-day-old sugarcane plants (var. SP80-3280) after 9 and 17 days of water restriction. Two leaf roll cDNA libraries, LR3 (9-day water restriction) and LR4 (17-day water restriction), were constructed from mRNA.

Total RNA was isolated using the acidphenol-guanidine-thiocyanate protocol (Chomczynski and Sacchi, 1987). Extraction of mRNA was performed with Oligotex mRNA Mini kit (Qiagen, CA, USA).

Sequencing of cDNA inserts was performed from the 5’ end using the BigDyeTM Terminator Cycle Sequencing v2.0 (PE Biosystems, CA, USA) and the reactions were subjected to automated sequencing in a 3700 DNA Analyser (PE Applied Biosystems).

Macroarray experiments were based on ESTs from the LR9 and LR17 libraries, in which 12 ESTs most highly expressed were arrayed on the membrane together with 34 ESTs classified as no hits and 250 ESTs associated with stress.

The remaining 905 ESTs selected for the array belonged to stress-related metabolic pathways that were identified in the Sugarcane Expressed Sequence Tag (SUCEST) project (Vettore et al., 2003) resulting in a membrane with a total of 1202 ESTs. The membranes were created at Centro Brasileiro de Estocagem de Clones (HTTP://www.bcccenter.fcav.unesp.br).

Results and discussion

A total of 4252 ESTs of good quality (minimum of 140 bases with Phred quality ≥ 20) were obtained for the two libraries under water stress conditions, with 1934 from the LR9 library and 2318 from the LR17 library.

All had the 5’ extremity sequenced and 387 clones also had the 3’ extremity sequenced, with 237 from the LR9 library and 150 from the LR17 library. The mean size of the inserts (ESTs) was 835 bp for the LR9 library and 502 bp for the LR17 library (data not shown).

In the LR9 library, 8 ESTs (0.414%) coding for lypoxygenase (LOX) were observed while, in the LR17 library, 35 ESTs (1.510%) showed significant similarity to this gene. An analysis of the 43 ESTs for LOX present in the LR9 and LR17 libraries showed that they were distributed in 6 clusters (Table 1).

Clone analysis revealed the presence of four ESTs for catalase (CAT; three in LR9 and one in LR17), three for ascorbate peroxidase (APX; one in LR9 and two in LR17), five for polyphenol oxidase (PPO; all in LR9) and two for superoxide dismutase (SOD; all in LR17) (Table 2).

To protect cells and subcellular compartments from the harmful effects of ROS, plants synthesise a suite of antioxidant enzymes, among which CAT, SOD, APX and PPO are the most important (Mittler, 2002; Soares and Machado, 2007).

The data generated by the macroarrays analysis indicated that 147 ESTs exhibited differential expression during the water stress period evaluated. As observed in the cDNA libraries, genes coding enzymes of the octadecanoid pathway were induced. Similarly, genes coding antioxidant enzymes (two catalase isoforms, and two ascorbate peroxidase isoforms) indicated a state of oxidative stress. According to Kumari et al. (2006) the possibility that \( \text{H}_2\text{O}_2 \) oxidative stress produced in response to water deficit, with the direct participation of JA itself, and the stress induced on account of the functioning of the octadecanoid pathway (\( \beta \)-oxidation stage in the peroxisomes/glyoxysomes) can contribute to the activation of genes coding Bowman-Birk (BBI) protease inhibitors.

These two mechanisms could be acting concomitantly during the induction of defensive mechanisms to counter the negative effects of water-deficit stress (Ferro, 2008).

The profiling of the EST clones from the LR9 and LR17 libraries, and the analysis of their expression with macroarrays indicated that the octadecanoid pathway or oxylipin pathway was activated by water stress, appearing more active as the severity of stress increased. During activation of this pathway, JA and \( \text{H}_2\text{O}_2 \) are produced which then lead to induction of antioxidant enzymes, signaling pathway genes and defence gene expression (Figure 1).

MOTS CLÉS: Stress Hydrique, Expression Différentielle, Réponse au Stress, Tolérance à la Sécheresse.

Résumé

L’OBJECTIF de cette étude consistait à évaluer l’expression génique dans des tissus de feuilles enroulées issues des plantules de canne à sucre sous des conditions contrôlées de serre. Deux approches de génomique fonctionnelle furent utilisées: l’analyse des banques des marqueurs de séquence exprimée (ESTs) et l’expression différentielle de gènes par l’analyse de macroarray d’ADNc. Des plantules de canne à sucre de la variété SP80-3280 furent soumises à une restriction hydrique pendant 17 jours et les feuilles enroulées furent prélevées au bout de 1, 5, 9, 13, et 17 jours après l’initiation du stress hydrique. Deux banques d’ADNc ont été construites en utilisant l’ARNm isolé des tissus prélevés au 9ème (banque LR9) et 17ème jour (banque LR17) et, après le séquençage, les ESTs générés furent analysés en utilisant des outils bioinformatiques. Les résultats des analyses de banques d’EST ont montré que les transcripts pour toutes les enzymes de la voie octadécanoïde de la biosynthèse de l’acide jasmonique étaient présents durant les deux périodes, indiquant que l’expression de gènes induits par un stress hydrique était impliquée dans la production de l’acide jasmonique. Des transcripts pour les enzymes antioxydants suivants: la catalase, l’ascorbate peroxidase, la polyphénol oxidase et la superoxyde dismutase étaient présents. Un microarray contenant 1202 gènes spottés en double ont été hybridés avec les ADNc préparés avec de l’ARNm isolé des feuilles enroulées. Une analyse des gènes exprimés différentiellement a montré que seulement 147 gènes présentaient des expressions différentielles, étant induits ou réprimés. Comme observé dans des études des banques d’ADNc, des gènes codant pour des enzymes de la voie octadécanoïde furent induits. Parallèlement, des gènes codant pour les enzymes antioxydants (deux isoformes de la catalase, une réductase monohydroascorbate, deux isoformes de l’ascorbate peroxydase), furent induits indiquant que le tissu était sous le stress oxydatif.

Resumen

EL OBJETIVO de este estudio fue evaluar la expresión de genes en tejidos foliares de plántulas sometidas a restricción hídrica bajo condiciones controladas en invernadero usando dos enfoques de genómica funcional: el análisis de librerías EST y el análisis de la expresión génica diferencial en una macrocolección de cADN. Las plántulas de caña de azúcar de la variedad SP80-3280 fueron sometidas a restricción hídrica por 17 días y rollos de hojas fueron colectados 1, 5, 9, 13 y 17 días posteriores al tratamiento de restricción hídrica. Las dos librerías de cADN fueron construidas usando mARN aislado de tejidos colectados en los días 9 (librería LR9) y 17 (librería LR17) y, luego de su secuenciación, los ESTs generados fueron analizados usando herramientas de la bioinformática. Los resultados del análisis de la librería de EST mostró que los transcriptos para todos los enzimas de la ruta octadecanoide conducente a la biosíntesis de ácido jasmónico (JA) se encontraban presentes durante ambos períodos, indicando que la expresión génica inducida por el estrés hídrico está involucrada en la producción de JA. Entre los transcriptos presentes se encontraron aquellos para los enzimas antioxidantes de la catalasa, la peroxidasa del ascorbato, la oxidasa polifenólica y la dismutasa superóxido. Una macrocolección conteniendo 1202 genes contados en duplicado fueron sujetos a una hibridación con los cADN preparados a partir de mARN aislados de los rollos de hojas. Un análisis de los genes expresados diferencialmente mostró que sólo 147 genes presentaron expresión diferencial, ya inducida ya reprimida. Tal y como se observó en los estudios de librerías de cADN, se indujeron los genes que codifican para los enzimas de la ruta octadeconoide. De manera similar, se hallaron los genes que codifican a los enzimas antioxidantes (dos isoformas de la catalasa, una reductasa del monohidroascorbato, dos isoformas del peróxido ascorbato), indicando que el tejido estaba bajo estrés oxidativo.
PLANT EXPRESSED CELLULASES FOR THE PRODUCTION OF BIOFUELS

Abstract

SYNGENTA has pioneered the concept of plant expressed enzymes for biofuel production, and is continuing to develop crops tailored for next generation biofuel production by expressing optimised enzymes in planta for the conversion of cellulose to fermentable sugars. Agricultural waste streams such as corn stover, corn cobs and sugarcane bagasse are attractive potential feed stocks for advanced second generation biofuels due to their comparatively low cost, abundance and availability. A sugarcane mill processing 7 million t/y will generate close to 2 million t/y of wet bagasse. Given that about one quarter of this material is cellulose, then more than 12 000 t/y of enzymes are needed at current enzyme loadings to convert the cellulose to fermentable sugar. Producing this much enzyme by microbial fermentation requires twelve 100 000 L/d fermentors operating at 100 g enzyme/L ferment for a year. In an alternative approach, Syngenta has demonstrated the production of several classes of cellulases in maize and shown that they are nearly as active as their microbially produced counterparts. Furthermore, maize- expressed cellulases were tested on pre-treated sugarcane bagasse. To make sugarcane production and delivery of cellulases a reality, Syngenta recently formed the Syngenta Center for Sugar cane Biofuel Development (SCSBD) in collaboration with the Queensland University of Technology, Brisbane, Australia to develop efficient sugarcane transformation technologies. By providing technologies like these, Syngenta is helping to make second generation biofuels economically viable, while reducing agricultural waste and increasing the value realised from a hectare of land.

Introduction

Many governments have passed legislation promoting biofuel production. For example, the European Union has specified that 5.75% of its overall transport fuel should come from renewable sources by 2010, and that this level should rise to 10% by 2020, while the United States passed the Energy Independence and Security Act (EISA) in December of 2007 that sets a target of 136 billion L of ethanol by 2025 with 80 billion L coming primarily from cellulosic ethanol.

Initiatives like these, along with Brazil’s ethanol mandate have driven fuel ethanol production from 30 billion L in 2000 to over 65 billion L in 2008 (Renewable fuels association, 2009; Berg, 2001). With steep projected growth in the bioethanol markets, Syngenta has pioneered the concept of plant-expressed enzymes to make converting plant materials to fermentable sugars more efficient and cost effective.

Advanced traits are needed for ‘second generation’ biofuels. Cellulosic ethanol (ethanol from cellulose) is viewed as truly ‘renewable’ but is currently expensive due to high capital and
enzyme costs. One analysis of industry data showed that enzymes cost $0.59/L cellulosic ethanol (Bon and Ferrara, 2007). Even with a selling price of $1.00/L ethanol, this cost is too high for successful commercialisation. By comparison, enzyme costs for the corn dry-grind process were about forty times cheaper, estimated at $0.014/L ethanol (Galbe et al., 2007).

The main reason for the higher cost is that more enzyme (25 kg/t) is required to convert cellulose to ethanol than is required for starch to ethanol processes (1.9 kg/t) (Somerville, 2007; McAloon et al., 2000). Reducing the cost of the enzyme is critical to making this a practical technology. Syngenta estimates that the enzyme cost can be reduced to under $0.02/L ethanol by producing the enzymes in planta.

In this scenario, the main cost component would be separation of the enzymes from the biomass if an enzyme unfriendly process (e.g. acid/steam hydrolysis) is used, though other process models might include ammonia-fibre-explosion (AFEX), or an enzymatic pre-treatment process.

Efficient conversion of cellulose to fermentable sugars typically requires four fungal enzymes: two cellobiohydrolases (CBHI and CBHII), endoglucanase (EG), and beta-glucosidase. Here we report on the expression of the cellobiohydrolase enzymes in Zea mays.

Results

Gene cassettes were made to target accumulation of CBHI or CBHIII to the cytoplasm, endoplasmic reticulum (ER), or apoplast and transformed into maize. Studies evaluated subcellular targeting in both seed, and vegetative tissues.

Figure 1 shows the results for individual T1 transformants expressing CBHI in seed. Subcellular targeting of CBHI was found to affect both the numbers of transformants showing activity and the level of activity seen. Targeting the protein to the ER produced more plants with high activity levels than did cytoplasmic, or apoplastic targeting.

![Fig. 1—Relative activity levels of Trichoderma reesei CBHI from transgenic maize seed. Expression was sub-cellularly targeted to cytoplasm, apoplast or ER. Each bar represents relative activity from a single transgenic event. Relative activity (arbitrary units) was determined by extracting protein from 25 ground T1 maize seed and measuring activity of 1 mg of total soluble protein (TSP) on p-nitrophenyl-β-D-lactopyranoside, a chromogenic soluble substrate. Fungal controls were made by dosing 200 mg ground wild type flour with 0, 181, or 362 g/g of purified Trichoderma reesei CBH I protein purchased from Megazyme (Megazyme, International, Ireland) prior to protein extraction.]
Mature maize leaves were collected from two high activity T2 events and the protein levels were determined. Results shown in Figure 2 indicate that 7%–10% of total soluble protein (TSP) in the T2 generation was CBHI.

![Figure 2](image)

**Fig. 2**—Estimated fraction of TSP that was CBHI (Syngenta proprietary) in T2 maize leaves. Two events are shown: orange bars are for event A and blue bars are for event B. The first two bars for each event are T2 siblings from the same T1 parent, while the second two bars are T2 siblings from a different T1 parent for the same event. Both events were ER targeted and vegetatively expressed CBHI. Activity of 1 mg of TSP on 4-methylumbelliferyl-β-D-lactoside was measured and the percentage of active CBHI was calculated by dividing the rate of the reaction by the specific activity of the same microbially expressed protein to give the amount of active CBHI. This was divided by the total amount of TSP and expressed as a percent. Error bars represent standard deviations of extraction replicates n = 4 (one biological sample).

To ensure that the plant-made enzymes are as effective as their microbial counterparts, the plant-produced enzymes were tested in head to head reactions in enzyme cocktails on pre-treated sugarcane bagasse.

For CBHI, enzyme cocktails were prepared containing EG, CBHII and either a plant produced or microbially produced version of CBHI loaded on an equal mg protein basis and then used to digest pre-treated sugarcane bagasse (acid/steam pre-treatment process). The results shown in Figure 3 indicate that, in a cocktail, the purified plant produced CBHI performed as well as the purified microbial protein.

For CBHI, the test was repeated with the plant produced version of the protein loaded on an equal activity basis on a soluble, fluorescent substrate 4-methylumbelliferyl-β-D-lactoside (MUL) with similar results. Similar tests were done for CBHII with CBHII loaded on an equal activity on phosphoric acid swollen cellulose (PASC); however, CBHI was left out of the cocktail so that the difference between the plant and microbial versions of CBHII could be more clearly seen.

Based on the PASC results, plant produced CBHII was loaded at 90% that of purified microbial CBHII (on a mass basis) due to its higher specific activity on PASC.

The results in Figure 4 indicate that the plant produced CBHII had 64%–77% the activity of the microbial version on pre-treated cane bagasse at this loading.
Fig. 3—Performance of a purified, seed expressed, ER targeted *Trichoderma reesei* CBHI on acid/steam pre-treated sugarcane bagasse. Results are expressed as a percentage of the performance of a purified, microbially produced CBHI (Syngenta proprietary). All reactions contained CBHII and an EG. Samples of the reactions were taken after incubating at 40°C with agitation at 300 rpm for zero h, 16 h and 72 h and the percent hydrolysis was determined. Enzyme loadings were 12 mg of each enzyme per gram cellulose except for the negative control where CBHI was omitted. All reactions were done in triplicate. Error bars are standard error (n = 3).

Fig. 4—Performance of purified, vegetatively expressed, ER targeted, CBHII on acid/steam pre-treated sugarcane bagasse. Results are expressed as a percentage of the performance of a purified, microbially produced version of the same enzyme. EG and the microbially produced CBHII were used at 7 mg/g cellulose, while the purified plant CBHII loadings were matched based on activity on PASC. Plant produced CBHII was used at 6.4 mg/g cellulose based on its higher PASC (specific) activity. Samples of the reactions were taken after incubating at 40°C with agitation at 300 rpm for zero h, 15 h, 25 h, 48 h and 72 h and the percent hydrolysis was determined. All reactions were done in triplicate. Error bars are standard error (n = 3).
Discussion and conclusions

The work presented here shows that it is possible to produce cellubiohydrolases at high levels (7–10% of TSP) in plants, and that these CBH enzymes have good activity against pre-treated sugarcane bagasse. If the expression levels obtained in maize can be achieved in sugarcane, it will be possible to use cane itself to produce enough enzyme for converting the cellulose in bagasse to ethanol.

A cane mill processing 7 million t/y of cane produces about 980 000 t/y of dry bagasse. Since only about half of dry bagasse is cellulose, the current enzyme requirements are close to 12 000 t/y of enzyme.

Preliminary data from maize suggests that we can meet this requirement and produce enough extra enzyme to account for the small performance differences seen in the plant produced enzyme. This is important information for a process model because these plant produced CBH enzymes were tested on pre-treated cane bagasse that is believed to be an important target for the cellulosic ethanol industry.

While the enzymes used in this study were produced in maize, the Syngenta Center for Sugarcane Biofuel Development at Queensland University of Technology, Brisbane, Australia, is developing efficient cane transformation technologies focusing on cane produced cellulases (Sainz and Dale, 2009).

By showing that these enzymes can be produced at relevant levels and are active on important substrates, Syngenta is contributing to making this new technology a reality which might lead to the creation of new products for the SC industry.

MOTS CLÉS: Cellulases, Expression dans la Plante,
Biocarburants, Éthanol, Bagasse.

Résumé
SYNGENTA a été le pionnier dans la conception de la production des biocarburants dans les plantes qui expriment des enzymes. Elle continue à développer de nouvelles générations de plantes pour la production des biocarburants en exprimant des enzymes in planta pour la transformation de la cellulose en sucres fermentescibles. Les déchets agricoles, composés de tiges et d’épis de maïs ainsi que la bagasse de la canne à sucre, sont considérés comme d’éventuelles sources attrayantes pour la production des biocarburants de deuxième génération en raison de leur coût relativement faible, leur abondance et leur disponibilité. Une usine qui peut transformer 7 millions tonnes de canne par an peut générer près de 2 millions tonnes de bagasse fraîche. Etant donné que près d'un quart de cette matière est composée de la cellulose, plus de 12 000 tonnes d'enzymes par an sont nécessaires pour transformer la cellulose en sucres fermentescibles. La production de cette quantité d’enzyme par la fermentation microbienne nécessite douze fermenteurs avec une capacité de 100 000 L par jour et fonctionnant à 100 g d’enzyme/L de ferment durant toute l’année. Syngenta a démontré la possibilité de produire différents types de cellulases dans le maïs et elles sont aussi actives que leurs homologues microbiennes. De plus, les cellulases exprimées chez le maïs ont été testées sur de la bagasse pré-traitée de la canne à sucre. Dans le but de développer des technologies efficaces pour la production et la transformation de la canne à sucre et de rendre possible la production de la cellulase, Syngenta a récemment créé le ‘Syngenta Center for Sugarcane Biofuel Development’ (SCSBD), en partenariat avec l’Université de Technologie de Queensland, en Brisbane, Australie. Avec de telles technologies, Syngenta contribue à faire de la deuxième génération de biocarburants une opération économiquement viable, tout en réduisant les déchets agricoles et en augmentant les bénéfices obtenus à partir d'un hectare de terre.
EXPRESIÓN DE CELULASES EN PLANTAS PARA LA PRODUCCIÓN DE BIOCOMBUSTIBLES

Resumen

SYNGENTA ha sido pionera en el concepto de la expresión de enzimas en plantas para producir biocombustibles, y continúa el desarrollo de cultivos diseñados para la siguiente generación de biocombustibles al expresar enzimas optimizadas in planta para la conversión de celulosa en azúcares fermentables. Los flujos de residuos agrícolas como el rastrojo de maíz, las mazorcas de maíz y el bagazo de la caña de azúcar son atractivas materias primas con potencial en la segunda generación avanzada de biocombustibles debido a su costo comparativamente bajo, abundancia y disponibilidad. Un molino de caña de azúcar procesando 7 millones t/a generará cerca de 2 millones t/a de bagazo húmedo. Dado que cerca de un cuarto del material es celulosa, entonces más de 12 000 t/a de enzimos serían necesarios, a niveles actuales de producción, para convertir celulosa en azúcar fermentable. La producción de tanto enzimo por fermentación microbiológica requeriría 100 000 L/d de fermentadores operando a una capacidad de 100 g de enzimo/L de fermento durante un año. En un enfoque alternativo, Syngenta ha demostrado la producción de diversas clases de celulasas en el maíz y mostró que son casi tan activas como sus contrapartes producidas de manera microbiana. Además, las celulasas expresadas en maíz fueron evaluadas en bagazo de caña de azúcar tratadas previamente. Para hacer realidad la producción de caña de azúcar y la entrega de enzimos, Syngenta recientemente formó el Centro Syngenta para el Desarrollo de Biocombustibles de la Caña de Azúcar (SCSBD, por sus siglas en Inglés), en colaboración con la Universidad de Tecnología de Queensland, Brisbane, Australia, a fin de desarrollar tecnologías eficientes de transformación de caña de azúcar. Al proveer de tales tecnologías, Syngenta está ayudando a hacer económicamente viables los biocombustibles de segunda generación, mientras reduce el desecho agrícola e incrementa el valor derivado de un hectárea de tierra.
ISOLATION AND CHARACTERISATION OF A GENE ENCODING THE \( \Delta^1 \)-PYRROLINE-5-CARBOXYLATE SYNTHETASE IN SUGARCANE (\textit{Saccharum} spp HYBRID VAR. ROC22)

KEYWORDS: Sugarcane, \( \Delta^1 \)-Pyroline-5-Carboxylate Synthetase (P5CS) Gene, Proline, Water Stress.

Abstract

SUGARCANE variety ROC22 was used as the experimental material. Water stress treatment was performed on 4 to 5-leaf stage plants with a 25% polyethylene glycol (PEG) 6000 solution. A cDNA sequence for the ScP5CS sugarcane gene was isolated by homologous cloning. The sequence contained 2151 bp and an open reading frame of 716 amino acids (GenBank accession number EU005373). Comparing the sequence of ScP5CS with that of sugarcane P5CS reported in GenBank, the nucleotide sequence (EF155655) showed high identity (98%), but the deduced amino acid was only 92% identical. The deduced protein contained a putative ATP-binding site, putative leucine domains, a Glu-5-kinase domain, a putative NADPH-binding domain, a conserved GSA-DH domain and a feedback inhibition site. Besides, there were differences in the Glu-5-kinase domain from the reported deduced amino acid sequence of P5CS (ABM30223), but less for the P5CSs from rice (\textit{Oryza sativa}) and wheat (\textit{Triticum aestivum}). So we believe this gene to be a new gene of sugarcane P5CS.

Introduction

Proline is accumulated under drought and salinity stress in a number of plant species and it is thought to play an important role in plant cells for adaptation to water stress. Proline is synthesised via two routes from either glutamate (Glu) or ornithine (Orn) in eukaryotes, specifically in higher plants and its accumulation is mainly from Glu (Delauney and Verma, 1993).

High-level expression of \( \Delta^1 \)-pyrroline-5-carboxylate synthetase (P5CS), a bifunctional enzyme that catalyses the first and second reactions of proline biosynthesis, which exhibit both \( \gamma \)-GK and GSA dehydrogenase activities, has been reported to increase salinity stress tolerance in transgenic tobacco plants (Kishor \textit{et al}., 1995).

In \textit{Vigna aconitifolia} and \textit{Arabidopsis}, the first two steps of proline biosynthesis from Glu are catalysed by P5CS (Hu \textit{et al}., 1992; Savouré \textit{et al}., 1995; Yoshiha \textit{et al}., 1995).

Several genes encoding the enzymes in the route of proline biosynthesis have been identified in a number of plant species, namely \textit{Arabidopsis thaliana}, petunias, \textit{Triticum aestivum} L. and \textit{Oryza sativa} L. Functional analysis showed that all have been reported to be up regulated in response to water deprivation and/or salinity (Hare and Cress, 1997; Hare \textit{et al}., 1998; Yamada \textit{et al}., 2005; Ma, 2005; Igarashi \textit{et al}., 1997). The genes encoding P5CS have been cloned from
Arabidopsis thaliana, rice (Oryza sativa), wheat (Triticum aestivum), alfalfa (Medicago sativa), tomato (Lycopersicon esculentum), lettuce (Lactuca sativa), soybean (Glycine max.), radish (Raphanus sativus), grape (Vitis vinifera), and moth bean (Vigna aconitifolia).

In this paper, we report on the isolation and structure of the ScP5CS gene in sugarcane as well as the features of the encoded polypeptide.

Materials and methods

Plant growth and salt-stress treatment

Seed cane of sugarcane variety ROC22 was germinated and grown in the laboratory. Water stress treatment was performed when the plants had developed 4–5 leaves. The plants were treated with a 25% polyethylene glycol (PEG) 6000 solution. Control plants were treated with deionised water. Leaf samples were taken for RNA extraction 18–24 h after treatment.

Cloning and sequencing of P5CS cDNA from sugarcane leaves

Total RNA was extracted from young leaves from both treated and control plants. PCR amplification was conducted using the procedures described by Wang and Fang (2002). The P5CS cDNA fragment was amplified from the total pool of cDNA, using gene specific primers designed with reference to the known P5CS gene sequences (GenBank accession number: EF155655, AY574031, D49714, AY888045, DQ864376).

The cDNA for PCR was synthesised in a standard first strand reaction using 0.5–5 µg of total RNA from leaves with 20 units of avian myeloblastosis virus reverse (AMV) transcriptase (Takara). The cDNA was subjected to 35 cycles of amplification in a 25 µL reaction mixture containing 0.4 µM of each primer, 0.2 mM each of dATP, dTTP, dGTP, and dCTP, 10×PCR Buffer (MgCl₂ plus) and 1.25 units of Taq DNA polymerase.

Each amplification cycle consisted of 3 min at 94°C, then 1 min of denaturation at 94°C, 40 s of annealing at 53°C, and 90 s of extension at 72°C, with a final extension for 10 min at 72°C. The PCR products (10 µL) were size fractionated by electrophoresis through 1% agarose gels and extracted from the gels. The amplified cDNA was cloned and sequenced, and named ScP5CS.

Sequence analysis

The analyses of DNA and protein sequences were performed using DNAMAN Software package and BLAST program of the NCBI. Homology alignment was performed using the Clustalx 1.83 and ClustalW program.

Results

Isolation, sequencing, and characterisation of sugarcane ScP5CS cDNA

The complete nucleotide sequence of a P5CS cDNA clone, ScP5CS, was cloned. The sequence of 2151 bp contained a single major open reading frame encoding a polypeptide of 77762.0 Da for a putative protein of 716 amino acids with a calculated isoelectric point of 6.29 (GenBank accession number EU005373).

Translation would be initiated from the first ATG codon, at the 5’ end of the coding strand. Comparing the sequence of ScP5CS with that of sugarcane P5CS reported in GenBank revealed sequence similarity of 98%, although the deduced amino acid was only 92% similar. However, the isolated cDNA showed 85% and 84% overall sequence similarity to those of rice (Oryza sativa) and wheat (Triticum aestivum) respectively.

Interestingly, the putative ATP-binding site, putative leucine domains, Glu-5-kinase domain, putative NADPH-binding domain, conserved GSA-DH domain and feedback inhibition site were present in each of the enzymatic domains of sugarcane ScP5CS (Chiang et al., 1995; Ma, 2005; Hu et al., 1999). There were more differences in Glu-5-kinase domain from the deduced amino acid of the reported sugarcane P5CS (ABM30223), but less for the P5CSs from rice (Oryza sativa) and wheat (Triticum aestivum) (Figure 1).
Fig. 1—Sequence alignment of the predicted ScP5CS amino acid sequence of sugarcane with the P5CS protein sequences of graminaceous plants, AAS89034, BAA19916 (Oryza sativa); AAX35536, BAD97364
Sugarcane ScP5CS contains domains homologous to *E. coli* proA and proBA proteins

The ScP5CS clones efficiently complemented *E. coli* proA and proBA, but not proC, the predicted two domains showed high homology to the *E. coli* proBA and proA proteins, and the recombinant ScP5CS protein showed GSA-dependent γ-GK enzyme activity. High homology was also observed to the bacterial and yeast γ-glutamyl kinase at the N-terminus and to the bacterial γ-glutamyl phosphate reductase at the C-terminus of the ScP5CS protein. Searching in GenBank resulted in the conserved domain of the deduced amino acid sequences of sugarcane ScP5CS, which is shown in Figure 2.

**Discussion**

In this study, the cDNA and corresponding gene of ScP5CS encoding the Δ¹-pyrroline-5-carboxylate synthetase from sugarcane variety ROC 22 was successfully isolated and the features of the encoded polypeptide characterised. Comparing the sequence of ScP5CS with that of sugarcane P5CS reported in GenBank, the nucleotide acid sequences showed high identity (98%), but the deduced amino acid homology was only 92%. The alignment of ScP5CS with all the presently available similar proteins in GenBank revealed two enzymatic domains corresponding to bacterial and yeast γ-glutamyl kinase and to bacterial γ-glutamyl phosphate reductase. The two residues in the positions 125 and 128, which were aspartate (Asp, D) and phenylalanine (Phe, F) respectively, were conserved in sugarcane ScP5CS and other plants. Site-directed mutagenesis could indicate whether they are implicated in the feedback inhibition by proline.

Amino acid sequence analysis revealed the identical sequences between the ScP5CS and graminaceous plants. There were more differences in Glu-5-kinase domain from the deduced amino acid of the reported sugarcane P5CS (ABM30223), but less for the P5CSs from rice (*Oryza sativa*) and wheat (*Triticum aestivum*). Different molecular structures would lead to different functions for the ScP5CSs. Presently, further functional analysis of this gene is being studied. Characterisation of events underlying P5CS gene expression is currently under investigation, which could provide insights into the role of proline and stress-related changes in gene expression in abiotic stress tolerance of sugarcane.

Résumé

Cet article décrit l’isolement et la caractérisation d’un gène codant pour la $\Delta^1$ pyrroline 5 carboxylate synthétase chez la canne à sucre (Saccharum spp. var. hybride ROC22). Des plantules au stade de quatre à cinq feuilles sont soumises à un stress hydrique via l’application d’une solution de 25% polyéthylène glycol (PEG). La séquence ADNc correspondant au gène ScP5CS de la canne à sucre a été isolée par clonage homologue. Cette séquence de 2151 pb, qui contient un ORF (Open Reading Frame) codant 716 acides aminés (numéro d’accession Genbank: EU005373), partage un fort pourcentage d’identité (98%) avec les séquences du gène P5CS (EF155655) chez la canne à sucre. Cependant, le pourcentage d’identité en acides aminés n’est que de 92%. La protéine déduite possède un site putatif de fixation au NADPH, des domaines leucine conservés, un domaine Glu5-kinase, un domaine GSA-DH ainsi qu’un site de rétro-inhibition. Des différences ont été observées au niveau du domaine Glu-5 kinase de ScP5CS avec les séquences en acides aminés de P5CS (ABM30223). Cependant ces différences sont moins importantes qu’avec les séquences du riz (Oryza sativa) et du blé (Triticum aestivum). Le gène isolé correspondrait donc à un nouveau gène P5CS chez la canne à sucre.
AISLAMIENTO Y CARACTERIZACIÓN DE UN GEN QUE CODIFICA LA \(\Delta^1\)-PIRROLINA-5-CARBOXILATO SINTETASA EN CAÑA DE AZÚCAR (HÍBRIDO DE SACCARUM SPP VAR. ROC22)

PALABRAS CLAVES: Caña de Azúcar, Gene \(\Delta^1\)-Pirrolina-5-Carboxilato Sintetasa (P5CS), Prolina, Estrés Hídrico.

Resumen

La variedad de caña ROC22 fue utilizada como el material experimental en el presente estudio. Plantas de dicha variedad que tenían de 4 y 5 hojas fueron sometidas a estrés hídrico aplicándoles una solución de Polietilenglicol (PEG) 6000 al 25%. La secuencia de cADN que codifica para el gen de caña ScP5CS fue aislada por clonación homologa. La secuencia del gen estaba compuesta de 2151 pb con un marco de lectura abierto de 716 aminoácidos. (Acceso en GenBank número EU005373). Al comparar la secuencia de ScP5CS con la secuencia del gen de caña de azúcar P5CS registrado en GenBank, mostró que la secuencia nucleotídica (EF155655) tenía una identidad del 98%, pero la secuencia a nivel de aminoácido fue solo idéntica en un 92%. La proteína contiene un sitio de unión a ATP, un dominio de leucina, un dominio para Glu-5-quinasa, un dominio de unión NADPH, un dominio conservado de GSA-DH y un sitio de reacción inhibición. Adicionalmente, se encontraron diferencias a nivel de la secuencia para el dominio Glu-5-quinasa comparadas con las registradas para la secuencia de aminoácidos de P5CS (ABM30223), y menos diferencias al compararlas con la secuencia del gen P5CSs de arroz (Oryza sativa) y trigo (Triticum aestivum). Por lo tanto creemos que este gen es un nuevo gen de P5CS en caña de azúcar.
AN IN VITRO INDUCED MUTAGENESIS PROTOCOL FOR THE PRODUCTION OF SUGARCANE TOLERANT TO IMIDAZOLINONE HERBICIDES

KEYWORDS: Ethyl Methanesulfonate, Imazapyr, Somatic Embryogenesis.

Abstract

THE MAIN objective of this study was to establish a protocol for the production of imidazolinone-tolerant sugarcane genotypes through in vitro induced mutagenesis. The approach involved using the chemical mutagen ethyl methanesulfonate (EMS) to induce a single target-site mutation in the acetolactate synthase gene, and testing the tolerance of regenerated plants with the herbicide Arsenal (250 g/L imazapyr). The initial work determined the mutagenic (8 mM and 16 mM EMS for 4h) and in vitro screening conditions (LD$_{50}$ = 0.042 µM, LD$_{90}$ = 0.08 µM imazapyr in the medium) for 6–10 week-old somatic embryogenic calli of the N12 sugarcane cultivar, and the screening treatment for ex-vitro control plants (spraying with Arsenal in the greenhouse). As the culture conditions (which included 2,4-D) alone did not cause a significant production of somaclones, the mutagenic agent was essential to increase the chance of producing herbicide tolerant plantlets. The EMS and imazapyr treatments were then applied in combination and the calli were exposed to increasing levels (0.042–0.16 µM) of herbicide. Putative tolerant plants have been obtained but their regeneration was slower than the control; after acclimatisation they will be sprayed with Arsenal (102 g a.i./ha; 0.39 M). For all treatments, callus mass, number of green, albino and abnormal plantlets, and biomass of acclimatised plants were recorded, and amplified fragment length polymorphism analyses were performed on the regenerated plants.

Introduction

Imidazolinone herbicides (e.g imazapyr) control weeds by inhibiting acetolactate synthase (ALS), which is involved in the biosynthesis of essential branched-chain amino acids. Any of several single target-site (dominant) mutations (Tan et al., 2005), in five conserved regions on the enzyme (Webster and Masson, 2001), reduce target site sensitivity (Yu et al., 2003), thereby conferring resistance to the herbicide. Such mutations occur during in vitro morphogenesis caused by culture conditions (e.g. auxins) resulting in somaclonal variant cells, which can then be regenerated into variant plants.

An example in sugarcane is the generation of cell lines, which yielded plants with a five-fold tolerance to glyphosate (Zambrano et al., 2003). This approach can be further enhanced by mutagenic agents (e.g. EMS) (Van Harten, 1998). To-date, efforts in the production of herbicide tolerant sugarcane genotypes have focused on genetic engineering but in vitro mutagenesis may offer a potential alternative to recombinant DNA technologies. This study aimed at assessing such an option.
Materials and methods

The somatic embryogenesis protocol of Snyman (2004) was followed using immature leaf rolls of *Saccharum* spp. hybrid var. N12: 1) calli were induced on MS, 20 g sucrose, 8 g agar and 3 mg 2,4-D per L (6–10 weeks); 2) embryo germination was on the same medium devoid of 2,4-D (6–8 weeks); 3) plantlets were established on ½ MS, 5 g sucrose and 8 g agar per L (4 weeks); and 4) plants were acclimatised in a misting chamber (1 min every 6 h) for 3 days, before transfer to a polytunnel. All cultures were subcultured onto fresh media fortnightly.

Calli (0.2 g) were exposed to 10 mL of ethyl methanesulfonate (EMS) (0–96.6 mM) for 4 h, rinsed and placed on callus medium. Imazapyr (Sigma-Aldrich; Pestanal®) was prepared as 5 M in 10 mM potassium phosphate (pH 7.5), and required aliquots were added to the media. Imazapyr concentrations in the media were 0–0.1 µM for callus and 0–20 µM for established plantlets.

Various mutagen and herbicide concentrations were tested in combination, and with step-wise increases of imazapyr. *Ex-vitro* plants were sprayed with 9.25–262.5 g a.i./ha; 0.036–1 M) Arsenal (BASF; 250 g/L imazapyr) after acclimatisation. Measurements included callus and plantlet biomass, % plant regeneration and survival, and Amplified Fragment Length Polymorphism (AFLP) analyses.

Results and discussion

The strategy employed in this study was to induce somaclonal variation in embryogenic callus cells (with and without mutagen exposure), followed by *in vitro* selection of imazapyr tolerant cells and then further screening of the putative tolerant plants regenerated from them.

The indirect somatic embryogenesis protocol used here resulted in a relatively low frequency of somaclonal variants, as previously reported for a direct method (Watt *et al*., 2009).

The results (including AFLPs) obtained from the control (0 EMS, 0 imazapyr) (±7% abnormal plants) and herbicide-only selection indicated that 2,4-D did not induce much somaclonal variation. This confirmed the premise that a mutagen was essential to increase the frequency of new cell lines in culture. The chemical mutagen EMS was therefore employed as it causes high frequency of gene mutations and low frequency of chromosomal aberrations (Van Harten, 1998).

Each step of the protocol was first established, with conclusions based on biomass, plantlet regeneration and AFLP analyses. From the EMS-only treatment (i.e. no imazapyr in the medium), 8 mM and 16 mM EMS were selected for further studies.

The LD$_{50}$ and LD$_{90}$ for % plantlet inhibition by imazapyr were 0.042 µM and 0.08 µM, respectively. The spraying treatment deemed suitable for screening *ex-vitro* plants in the greenhouse was 102 g a.i./ha (0.39 M) Arsenal.

Table 1 shows an example of the results obtained for some of the tested combinations of the mutagenic (16 mM EMS) and *in vitro* selection treatments. The indirect somatic embryogenesis protocol (control) routinely yields approximately 400–500 plantlets/g fresh mass; predictably, plantlet yield decreased and regeneration time increased with increasing stringency of EMS and imazapyr regimes.

All of the potentially imazapyr-tolerant subclones, including those treated with 8 mM EMS (results not shown) are being further screened and assessed. The tolerant genotypes will also to be evaluated in the field to determine phenotypic effects and the level of whole plant tolerance to the herbicide.

In sugarcane, glyphosate- (Zambrano *et al*., 2003) and red rot- tolerant plants (Singh *et al*., 2008) have been obtained by selection of mutant lines, which arose randomly in response to culture media pressure.
Table 1—Plantlet regeneration after mutagenic treatment with 16 mM EMS and selection on various imazapyr regimes. The standard protocol (no EMS, no imazapyr) yielded 488±99.3 and 35±9.4 plants/g callus fresh mass normal and abnormal (albino and visually chimaeric) plants, respectively. n = 5, mean ± SE.

Résumé

L’OBJECTIF principal de cette étude était d’établir un protocole pour la production de génotypes de canne à sucre tolérants à l’imidazolinone à travers la mutagénèse induite \textit{in vitro}. L’approche consistait en une utilisation d’un mutagène chimique, l’éthylméthane sulfonate (EMS), pour induire une mutagénèse dirigée dans le gène acétolactate synthase, suivi d’une évaluation de la tolérance des plantes régénérées à l’herbicide Arsenal (250 g/L imazapyr). Une étude initiale a établi la concentration du mutagène (8 mM et 14 mM EMS pendant 4 h), les conditions de sélection \textit{in vitro} (LD50 = 0.042 µM, LD90 = 0.08 µM imazapyr dans le milieu) pour le développement des cals embryogènes somatiques âgés de 6 à 10 semaines de la variété N12 et pour une évaluation des plantes témoins en serre (avec un traitement à l’herbicide Arsenal). Comme les conditions de culture (qui incluaient le 2,4-D) à elles seules n’ont pas produit un nombre significatif de somaclones, l’agent mutagène était essentiel pour augmenter la chance d’obtenir des plantules tolérantes à l’herbicide. Les traitements EMS et imazapyr ont ensuite été appliqués simultanément et les cals exposés à des taux croissants (0.042 – 0.16 µM) d’herbicide. Des plantes tolérantes putatives ont été obtenues mais leur régénération était plus lente que celle du témoin. Après une acclimatation, les plantes seront pulvérisées avec de l’Arsenal (102 g a.i/ha ; 0.39 M). Pour chaque traitement, le poids du cal, le nombre de plantules vertes, albinos et anormales ainsi que la biomasse des plantes acclimatées ont été notés. PALABRAS CLAVE: Etil Metanosulfonato, Imazapyr,
Embriogénesis Somática.

Resumen
EL OBJETIVO principal de este estudio fue establecer un protocolo para la producción de genotipos de caña de azúcar tolerantes a la imidazolínona mediante la inducción in vitro de una mutagénesis. El enfoque involucró el uso del mutágeno químico denominado etil metanosulfonato (EMS), el cual induce una mutación en un sitio específico del gen sintasa de acetolactato, y en la evaluación de plantas regeneradas tolerantes al herbicida Arsenal (250 g/L de imazapyr). El trabajo inicial permitió definir las condiciones mutagénicas (8 mM y 16 mM EMS por 4h) de criba in vitro (LD₅₀ = 0.042 µM, LD₉₀ = 0.08 µM de imazapyr en el medio de cultivo) para callos embriogénicos (de alrededor de 6 a 10 semanas) del cultivar de caña de azúcar N12, y de una metodología de criba ex vitro para las plantas control (con aspersión del herbicida Arsenal en el invernadero). Debido a que las condiciones de cultivo (incluyendo el 2,4-D) no ocasionaron por sí mismas una producción significativa de somaclonas, se consideró al agente mutagénico como crucial en el incremento de la producción de plántulas tolerantes al herbicida. Posteriormente, los tratamientos de EMS e imazapyr fueron aplicados en conjunto, sometiendo a los callos a diferentes niveles de herbicida (0.042 – 0.16 µM). Si bien se obtuvieron supuestas plantas tolerantes, su regeneración fue más lenta que el control; luego de una aclimatación se les roció con Arsenal (102 g a.i./ha; 0.39 M). En todos los tratamientos, se registraron masas de callo, número de plántulas normales, anormales y albinas, y la biomasa de plantas aclimatizadas. Asimismo, se condujeron análisis del polimorfismo en fragmento amplificado (AFLP, por sus siglas en Inglés) en aquellas plantas regeneradas.
THE EFFECT OF ORANGE RUST (Puccinia kuehnii) ON SUGAR YIELD IN SIX SUGAR CANE VARIETIES IN GUATEMALA

KEYWORDS: Orange rust, Puccinia Kuehnii, Sugarcane, Yield Effects.

Abstract
A REPLICATED field trial was conducted to estimate the effect of orange rust (caused by Puccinia kuehnii) on yield in six sugarcane varieties in a plant cane crop in Guatemala. CP72-2086 is the leading variety in Guatemala constituting 57% of the crop in the 2007–08 harvest season. The other varieties (CG96-135, SP79-2233, CP88-1508, CP89-2143 and PR75-2002) showed symptoms of orange rust in September 2007 when the disease first appeared. The experimental design of the field trial was a split plot in a complete randomised block design where the main plot was variety and the sub plot fungicide treatment (treated with the fungicide Alto® (Cyproconazole) at a dose of 500 mL per ha) or untreated. The susceptible variety SP79-2233 was planted on each side of the trial and around individual plots as a natural P. kuehnii inoculum source. Orange rust severity in fungicide treated and untreated plots was recorded monthly from three to nine months crop age. Cane yield components (plant height, stalk diameter and stalk population) and cane weight per plot were used to estimate cane yield in tonnes of cane per hectare (TCH); sucrose concentration (Pol % cane) was also assessed at harvest. Yield losses were estimated using a regression of orange rust severity on yield (tonnes sugar per ha, TSH) for the variety CP72-2086. Data suggest that orange rust may reduce sugarcane yields in five of the six varieties. Losses in CP72-2086 were 7.67% (TCH), 8.61% (Pol % C) and 15.78% (TSH), with the regression equation y = 20.3 – 0.2×. The highest orange rust severity occurred at five to six months crop age in all varieties and symptoms were observed through to plant maturity.

Introduction
Until the year 2000, orange rust, caused by Puccinia kuehnii was of little economic importance worldwide but, in that year, an Australian epidemic caused losses estimated to be worth between 150 and 210 million Australian dollars (Braithwaite, 2005). The variety Q124 was the most widely planted in Queensland, occupying 45% of the total area, and it became susceptible to the disease. The orange rust epidemic was, in economic terms, the most important disease epidemic in the history of the Australian sugarcane industry (Braithwaite, 2005).

Pre-2007, orange rust was found only in countries such as Papua New Guinea, Indonesia, Philippines and Australia (south east Asia, Oceania areas) (Magarey et al., 2005). In June 2007, the disease was detected in Palm Beach County, Florida, USA, on the varieties CP80-1743 and CP72-2086 (Comstock et al., 2008) and this constituted the first report of the disease in the western Hemisphere. The variety CP72-2086 is the most important in Guatemala.
Orange rust was detected for the first time in Guatemala on September 7, 2007 (Ovalle et al., 2008) in a commercial field of the variety CP72-2086. This variety occupied 66% of the total area (210 000 ha) during the 2006–2007 harvest season.

As a first step to confirm the diagnosis, infected leaf samples were sent to the USDA-APHIS Systematic Mycology and Microbiology Laboratory in Beltsville, Maryland, for molecular and morphological examination.

The rust pathogen was confirmed as *P. kuehnii* in November 2007. The potential impact of orange rust on Guatemalan sugarcane crops was unknown at this time.

The purpose of this research was to determine the effect of orange rust on sugar yield in six commercial varieties that had shown disease symptoms.

**Materials and methods**

**Tested varieties**

The varieties evaluated were: CP72-2086, SP79-2233, CP88-1508, PR75-2002, CG96-135 and CP89-2143. The first four are major varieties in Guatemala and the last two are minor commercial varieties.

**Planting and handling in the field**

The experimental design of the field trial was a split plot in a complete randomised block design. The main plot was the variety and the sub plot was either treated or untreated with fungicide (Alto® 10 SL fungicide (Cyproconazole) used at a dosage of 500 mL per ha (Staier et al., 2003)). Applications began when the crop was two months of age, when pustules were first observed, and continued at 10 day intervals (nine applications) concluding when the crop was five months of age.

Small plots were five rows, 10 metres long and 1.5 m apart. The variety SP79-2233 (the most susceptible at the time) was planted in inoculum spreader rows, adjacent to each main plot and around the whole trial site. Crops was fertilised at recommended commercial rates (40.8, 60.9, 0.0 kg/ha NPK)

**Disease severity with time**

Orange rust disease severity was recorded at monthly intervals, from three to nine months crop age. Severity assessments were made on the top third of the seventh fully expanded leaf. One rating for each of the three central rows from each small plot (three leaves per plot), and one rating from each of the inoculum spreader rows were taken.

Each rating was identified by row to be able to match specific yield of each row with disease severity in that row (18 values for each variety). This enabled yield losses to be correlated with disease severity.

**Harvest**

The varieties were harvested at eleven months crop age (February, 2009) independent of optimum variety maturity and without ripener application.

Rows from each plot were harvested and weighed individually to estimate cane yield. Eighteen yield measurements were obtained for each variety (3 rows, 3 reps, treated / untreated) and were analysed using regression techniques.

At harvest five stalk samples from each small plot were analysed for sucrose concentration (Pol % cane).

**Measured variables**

The measured variables were cane weight per row to estimate cane yield in tonnes per hectare (TCH) and sugar concentration (Pol % cane) to estimate the derived parameter sugar yield in tonnes of sugar per hectare (TSH).

Cane yield components (stalk length, stalk diameter and stalk number/metre) were also recorded.
Data analysis

Analysis of variance was undertaken for TCH, Pol % cane, TSH, stalk length, stalk diameter and stalk population. For TCH, TSH, Pol % cane and cane yield components, “t” tests were undertaken to compare treatment x variety effects (CP72-2086, CG96-135 and SP79-2233).

Results and discussion

Figure 1 shows the severity of orange rust in inoculum spreader rows during crop growth. Relatively high disease severity occurred during the whole evaluation period. This suggests there was a high infection pressure on the test varieties within the trial.

The data suggest 25 percent leaf area was the maximum average severity observed from five to eight months age; however, in individual rows, up to 40 percent leaf area affected was recorded.

![Infection (%) on +7 leaf vs Age (Months after planting)](image)

Fig. 1—Severity of orange rust in spreader rows of the variety SP79-2233.

Despite the high infection pressure, fungicide application maintained lower disease severity (near zero) compared with plots without fungicide. When fungicide applications ceased (after five months crop age) disease levels rose in formerly treated plots (Figure 2).

The increase in rust severity in the fungicide treated plot may have reduced the differences between the two treatments.

The percent leaf area infected in these test appears to be less than occurred in the Australian epidemic where up to 70% of the third fully expanded leaf was affected (Magarey et al., 2001). Magarey et al. (2003) mentioned losses as high as 40% in central Queensland in the 2000 crop.

The authors suggest that the variation could be related to local weather and agronomic conditions at the sites and the same could be occurring with the Guatemalan test. Besides, differences in variety resistance should be considered.

Orange rust affected biomass (TCH) production in five out of six tested varieties, based on the difference in cane yield in plots with and without fungicide application (Table 1). However, the analysis of variance did not show significant treatment differences (Table 2).

The biggest effect of orange rust was in the variety CG96-135 with average losses of 18.09 TCH (12.25%). CG 96-135 had the largest variance value and, therefore, the biggest experimental data error. This variance caused no significant treatment differences in this variety.
The variety CP72-2086 showed a 7.67% decrease in cane yield (significant using a “t” test). Biomass differences for the rest of the varieties were not significant.

The smallest effect was seen with CP88-1508 where yield differences were 0.07 tonnes (0.05% of losses). PR75-2002 did not show a decrease in tonnage despite a higher orange rust incidence than CP89-2143 (Figures 3 and 5).

Average TCH in fungicide vs. non-treated plots was 140.78 and 136.52. Average losses associated with orange rust were 3.02%.

With five varieties there was a decrease in sugar content (Pol % cane) associated with orange rust (no fungicide application) (Table 3). The variety exhibiting the biggest decrease (8.61 percent) was CP72-2086 (significant “t” test). The exception was the variety CG96-135, which showed 12.97 percent more sugar in non-fungicide plots (also significant with the “t” test). There were no significant differences in Pol % cane for the six tested varieties.

Table 3—Orange rust effect on sugar concentration (Pol % cane) in six commercial varieties with and without fungicide application in the plant cane crop, 2008–2009 harvest season, Amazonas farm, Santa Ana Mill, Guatemala.

The effect of fungicide application on the derived tonnes sugar per hectare is shown in Figure 3. Statistical analysis showed there were significant differences (10% level) in TSH for six varieties, with yields averaging 20.5 (fungicide) and 19.5 (no fungicide). However, for individual varieties, the biggest effect of orange rust on yield was with CP72-2086, where losses of 15.78% (TSH) were associated with orange rust; smaller losses were recorded with CP89-2143 and SP79-2233. It is important to take into account that fungicide application was only to five months crop
age, due to application difficulties in older crops. Figure 2 illustrates that, beyond five months, orange rust still occurred reaching more than 10% severity in CP72-2086 in nine-month old crops. The difference in TSH in the variety CP72-2086 was statistically significant (“t” test). The variety CG96-135 showed the smallest fungicide effect as it had a higher sucrose concentration in untreated plots (Table 3); the reason for this is unknown. This particular result should be further investigated in subsequent crop harvests to confirm the effect of orange rust on Pol % cane in this variety.

It is very important to note that the results above are from a field trial planted in an environment conducive to \textit{P. kuehnii}. In addition, orange rust spreader rows were planted with the purpose of promoting rust infection. To more realistically estimate sugar losses in commercial fields of CP72-2086, orange rust severity needs to be quantified in these specific fields and related to yield losses using the regression equation of Figure 4.
Statistical analysis showed no significant differences in cane yield components (stalk population, stalk length and stalk diameter). However, for stalk population, a difference was seen with the variety SP79-2233 (data not shown).

Disease severity over time in test varieties is shown in the Figure 5. In general, the maximum severity was recorded in crops of five to six months of age; after that severity tended to decrease.

Contrary to brown rust (*P. melanocephala*), orange rust infection continued to occur up to nine months crop age.

The variety with the highest disease severity throughout the season was SP79-2233, with 26.7 percent leaf area affected (on the +7 leaf) being the maximum level recorded. CP72-2086 (12.3 percent leaf area at five months of age) had the second highest level of disease.

![Graph showing orange rust severity with time in six commercial varieties.](image)

Fig. 5—Orange rust severity with time in six commercial varieties in the plant crop, 2008–2009 harvest season, Amazonas farm, Santa Ana Mill, Guatemala.

Conclusions

- Orange rust caused significant yield losses in the variety CP72-2086, the major commercial variety in Guatemala.
- Orange rust caused non-significant yield losses in four other varieties.
- Orange rust reached its highest severity at five and six months crop age in all of the tested varieties.
- Orange rust infection occurred in mature (up to nine months) crops.

Acknowledgements

The authors give thanks to the Field General Manager of Santa Ana Mill, Ing. Javier Fernández, to Sub Field General Manager, Ing. Juan Luis Ponce and to the Field Technicians Mr. Emilio Rosales and Mr. Abner López.

Also thanks to Ing. Ovidio Pérez and Ing. Adlai Meneses for the statistical analysis of data, both of CENGICAÑA senior staff and to Lic. Wendy de Cano and staff for the juice analysis at the CENGICAÑA’S Agronomic Laboratory.

Special thanks go to Dr. Jack Comstock, Research Plant Pathologist, USDA-ARS, Canal Point Experiment Station, for his exhaustive revision of the manuscript.

Résumé
Un essai à répétitions a été établi au champ pour estimer l’effet de la rouille orangée (causée par *Puccinia kuehnii*) sur le rendement en canne vierge de six variétés de la canne à sucre au Guatemala. La variété CP72-2086 est la variété principale au Guatemala et constituait 57% de la surface cultivée pendant la campagne 2007-08. Les autres variétés (CG96-135, SP79-2233, CP88-1508, CP89-2143 et PR75-2002) ont présenté des symptômes de la rouille orangée en septembre 2007 lors de l’apparition de la maladie. Le dispositif expérimental était un traitement à parcelles subdivisées en bloc de Fisher, le facteur principal étant la variété alors que le facteur secondaire était le traitement au fongicide (application d’Alto®, cyproconazole, à une dose de 500 mLha⁻¹) ou la parcelle non-traitée. La variété sensible SP79-2233 était plantée aux deux côtés de l’essai de même qu’autour de chaque parcelle comme source d’infection naturelle de *P. kuehnii*. La sévérité de la rouille orangée dans les parcelles traitées et non-traitées était évaluée tous les mois du troisième au neuvième mois du stade de poussée. La hauteur, le diamètre et la population de la tige de même que le poids de canne par parcelle étaient utilisés pour estimer le rendement à l’hectare (TCH). La concentration de saccharose (Pol % cane) était aussi recueillie à la récolte. Les pertes en rendement étaient estimées en adoptant une régression de sévérité de la rouille orangée en fonction du rendement (tonnes sucre à l’hectare, TSH) pour la variété CP72-2086. Les données indiquent
EFECTO DE LA ROYANA NARANJA (*Puccinia kuehnii*) EN EL RENDIMIENTO DE AZÚCAR EN SEIS VARIEDADES DE CAÑA DE AZÚCAR EN GUATEMALA

Resumen

SE EFECTUÓ un experimento de campo para estimar el efecto de la roya naranja (causada por *Puccinia kuehnii*) sobre el rendimiento de azúcar en seis variedades en caña planta en Guatemala.

La variedad CP72-2086 es la más importante en Guatemala y ocupó el 57% del área sembrada en la zafra 2007-08. Las otras variedades evaluadas (CG96-135, SP79-2233, CP88-1508, CP89-2143 y PR75-2002) son variedades comerciales que mostraron síntomas de roya naranja en septiembre de 2007 cuando la enfermedad se presentó en Guatemala. En el experimento de campo se utilizó un diseño experimental en Bloques completos al azar con arreglo en parcelas divididas, en donde la parcela grande fue variedad y la sub parcela fue tratamiento con fungicida (aplicaciones del fungicida Alto® (Cyproconazole) en dosis de 500 ml por hectárea) y sin aplicaciones. En cada lado del experimento y alrededor de las parcelas individuales se sembró la variedad susceptible SP79-2233 como fuente de inóculo natural de *P. kuehnii*. Se registró mensualmente la severidad de la roya naranja en las parcelas con y sin tratamiento con fungicida desde los tres hasta los nueve meses de edad del cultivo. Se utilizó los componentes de rendimiento de caña (altura de planta, diámetro de tallos y población) y el peso de caña por parcela para estimar el rendimiento de caña por hectárea (TCH), también se evaluó la concentración de azúcar (Pol % caña) al momento de la cosecha. Las pérdidas en rendimiento de azúcar se estimaron haciendo análisis de regresión entre severidad de roya naranja y rendimiento (toneladas de azúcar por hectárea, TAH) para la variedad CP72-2086. La información sugiere que la roya naranja puede reducir los rendimientos de azúcar en cinco de las seis variedades evaluadas. Las pérdidas en la variedad CP72-2086 fueron 7.67% (TCH), 8.61% (Pol % caña) y 15.78% (TAH), y la ecuación de regresión es y = 20.3 − 0.2x. La severidad mayor de roya naranja ocurrió entre cinco y seis meses de edad del cultivo en todas las variedades y se observaron síntomas de la enfermedad hasta la madurez de la planta.
ADVANCES AND CHALLENGES IN SUGARCANE BIOTECHNOLOGY AND PLANT PATHOLOGY: A REVIEW OF THE IX PLANT PATHOLOGY WORKSHOP AND VI MOLECULAR BIOLOGY WORKSHOP

KEYWORDS: Diseases, Plant Resistance, Genetic Mapping, Molecular Characterisation, Transgenics.

Abstract

For the second time, the International Society of Sugar Cane Technologists (ISSCT) pathology and molecular biology workshops were jointly held, from 23–27 June 2008 in Cali, Colombia. The meeting was hosted by CENICAÑA and organised by Jorge I. Victoria and Jershon López-Gerena. The response of participants was positive with 44 delegates representing 15 countries attending. Thirty seven oral presentations and ten posters covering a wide range of topics including molecular characterisation of yeasts, insect pests and pathogens, genetic transformation of sugarcane, molecular markers, genetic mapping, pathogen variability, disease diagnosis, plant resistance and disease epidemiology among others were presented. The workshop also provided the opportunity to listen to three plenary talks on biofuel production, transgenics and nutritional improvements in food crops through genomics. A special session was devoted to orange rust, a newly introduced disease in Florida and in Central America. Following the technical sessions, site visits were organised during two days to sugar mills, commercial fields, plots with transgenic sugarcane, and laboratories at CENICAÑA. The experience of having joint-section meetings proved very useful with excellent interaction among participants.

Introduction

The ISSCT IX Pathology Workshop and VI Molecular Biology Workshop were organised jointly in 2008. The workshops were hosted by the Colombian Sugarcane Research Centre (CENICAÑA) from 23–27 June 2008 at the Radisson Royal Hotel in Cali, Colombia. It was organised by Drs Jorge I. Victoria and Jershon López-Gerena. The Workshops were well attended by 44 participants, with 39 of them coming from overseas – Argentina (4), Australia (4), Brazil (3), Ecuador (1), France (3), Guadeloupe (2), Guatemala (2), India (2), Mauritius (2), Nicaragua (2), Panama (1), South Africa (2), USA (9), Venezuela (1) and Zimbabwe (1) – and 5 from Colombia.
Apart from three plenary talks on biofuel production in Colombia, transgenics and the role of genomics to improve nutrition in food crops, 37 verbal and 10 poster presentations were made during 11 sessions. The topics covered during the workshop were diverse. Site visits were organised during two days to sugar mills, commercial fields, plots with transgenic sugarcane, and laboratories at CENICAÑA.

**Molecular characterisation of yeasts, insect pests and pathogens**

In Colombia, ethanol production within the sugar industry is rapidly expanding, and is being driven primarily by price regulation and tax incentives from government. Although production is based on technology imported from India, efforts are being made on several fronts to adapt the technology to suit local conditions. Research focused on the isolation of wild yeast strains that have the potential to out-perform commercial yeasts. Biochemical and molecular characterisation of 18 isolates revealed that 10 of them were *Saccharomyces* and were capable of fermentative respiration to produce ethanol. All of the ethanol-producing isolates could tolerate ethanol concentrations of 12% (v/v) and were at least as efficient as commercial strains.

The Colombian sugar industry has a long and proud history of successful biocontrol of sugarcane pests and the insect vectors of pathogens. A strategy was reported to reduce the negative impact of the yellow sugarcane aphid (*Sipha flava*), which reportedly reduces sugar yield (tonnes sucrose/ha) by up to 52%. Currently, the effects of this pest are minimised by insecticide application, host plant resistance and natural predation. Attempts at biocontrol have been made through the introduction of commercially reared North American lacewings (*Chrysoperla* spp.), but release results were erratic and difficult to interpret. Consequently, researchers at CENICAÑA are searching for local lacewings that may serve as more effective biocontrol agents of the aphid. Molecular technologies were used for the analysis of the lacewing phylogeny and 11 chrysopid morphotypes have been found. These findings will serve as the foundation for the development of a biocontrol mechanism against the yellow sugarcane aphid.

A molecular and morphological diversity study based on the sequence of the mitochondrial cytochrome oxidase gene, *COII*, from 108 borer specimens collected along the Cauca Valley, in Colombia, was carried out in 2005 to determine possible new races of the three borer species in the region: *Diatraea saccharalis*, *D. indigenella*, and *Blastobasis gramineae* that may explain recent borer population increases in the region. *D. saccharalis* was found to be the main species behind the outbreak, and there were no new races that explained the recent borer outbreak, according to genetic differentiation indices based on PCR-RFLP and sequence of a *COII* gene fragment. Changes in climate or agricultural practices may explain the outbreak. A survey in 2006 indicated that the borer population has decreased after control practices were further implemented.

**Genetically modified sugarcane**

In Argentina, regulatory framework governing the commercial release of genetically modified (GM) crops encompasses both food safety and environmental issues. Concern exists over the potential of GM crops becoming weeds or crossing with wild species that have the potential to become weeds. As *Saccharum spontaneum* exists as naturalised populations in Argentina, consideration of the potential for transgene spread from GM *Saccharum* spp. hybrid crops is essential. The low temperatures (10–12ºC) experienced in Argentina in the period prior to anther opening (June and July) were believed sufficient to suppress male fertility. However, it was revealed that, during June to August 2006, fertile sugarcane pollen was detectable in the northern regions of the Argentinean industry (between S 23°16’ and S 24°50’), although prevalence decreased southwards, such that no fertile pollen was detected between S 26°30’ and S 27°55’. The unexpectedly high pollen fertility encountered in the northern regions was ascribed to unusually warm winter conditions. It is important to note that final interpretation of these observations and the impact that they may have on the assessment of the risk of transgene spread in Argentina will require assessment of pollen longevity, distance of dispersal and, ultimately, seed viability.
Many institutes involved in GM sugarcane research are seeking ways to simplify and speed-up the transformation process, as well as to reduce somaclonal variation that sometimes results from tissue culture. Efforts to reduce time in culture, viz. through imposition of a 1–2 week post-bombardment callus induction period where selection was restricted to the regeneration phase, resulted in plants with chimaeric phenotypes. Researchers at Chacra Experimental Agricola Station, in Argentina, proposed that insufficient selective growth of transgenic cells in the absence of a callus selection phase yields heterogeneous masses of both transformed cells that develop into chimaeric embryos, which regenerate under non-stringent geneticin selection protocols. That group aims to further refine minimal culture and selection requirements, which will reduce or eliminate chimaeras.

In Brazil an attempt was made to evaluate stress-inducible production of proline in transgenic sugarcane. Researchers expressed into sugarcane the heterologous P5CS gene (for proline biosynthesis) from the drought resistant bean, *Vigna angustifolia*, under the control of the synthetic stress-induced AIPC promoter. A series of transgenic events with 1–4 insertions was generated and, upon drought stress, the proline content was on average 2.5 times higher than in the controls, and this led to good drought tolerance. It was determined that the mode of action was not due to osmotic adjustment but, instead, related to a component of oxidative defence system.

In Australia, *Agrobacterium*-mediated and biolistic methods for transformation of sugarcane were compared. Several parameters were tested in transient assays to optimise *Agrobacterium*-mediated transformation of embryogenic callus of the variety Q117. *Agrobacterium* strains LBA4404 and AGL1, and a pCambia vector with GUS as the reporter gene under the control of the CaMV 35S promoter were used. Vacuum infiltration worked well for transient expression. Further optimisation was done with AGL1 and it was found that dilution of the *Agrobacterium* cultures to an O.D. of 0.4 was best as was a 4-day co-cultivation period on EM3 medium. However, no transgenic plant was regenerated, and constructs using the maize Ubi 1 promoter rather than the CaMV35S promoter were produced and generated over 200 plants. Most of the plants had only 1 or 2 insertion events. In a comparison between *Agrobacterium* and biolistic methods for expression levels, the biolistic approach led to much higher expression levels, but there was no correlation with copy number.

Molecular markers and genetic mapping

Microsatellite primers were used to DNA fingerprint varieties in Colombia and in USA, and DNA databases are being built. The intended use of these databases includes identification of mislabelled parental clones, as molecular descriptors for newly released varieties determine genetic relatedness of elite clones, assessing the quality of crosses, and identifying F1 hybrids from crosses with wild germplasm.

In South Africa, progress was reported to identify the key control steps in sucrose accumulation in sugarcane. Early work focused on changes in gene expression, biochemistry, and physiology occurring along internode maturation in one or a few varieties with different sucrose accumulation capacities. Gene expression studies moved to focus on key metabolic pathways identified by subtractive DNA libraries and boutique arrays. A small set of candidates was identified, and some of them studied on transgenic plants grown in the field. Currently, physiological evidence points to source-sink communication as crucial to sucrose metabolism, where feedback inhibition between sucrose concentration in the culm and leaf photosynthesis limits further accumulation of sucrose. New candidate genes will be tested via simple and stacked transgenic approaches to attempt unlocking the key to sucrose accumulation.

Also in South Africa, the potential of combining two relatively new PCR-based marker systems, Targeted Region Amplified Polymorphism (TRAP) and Motif-Directed Profiling (MDP) into a high-throughput hybrid system to generate polymorphic markers around targeted candidate gene sequences for smut resistance, was explored.
In Colombia, QTLs for sugar content and biomass components were identified in a population of 300 individuals from a cross between a high sugar content cultivar and a low sucrose cultivar.

In Mauritius, efforts were deployed to detect QTLs for yellow spot disease resistance. The foundation of the study was a bi-parental cross between a resistant and a susceptible parent, which generated 227 progeny with a segregation pattern for yellow spot infection suggestive of monogenic dominant inheritance (3:1). A genetic map of variety M 134/75 was constructed using 764 single-dose polymorphisms assigned to 102 linkage groups, each of which contained at least two markers in coupling. QTL analysis by means of QTL-CARTOGRAPHER v1.17d and MAPMAKER/QTL v1.1 identified a major QTL located on Linkage Group 87, flanked by an AFLP and SSR marker.

Work from CIRAD in France provided evidence of a major dominant gene *Brul*, conferring brown rust resistance, identified in cultivar R570 to confer resistance to eight isolates from Brazil, Colombia, Zimbabwe, USA (Florida), Réunion and Guadeloupe. The target haplotype map encompasses 15 markers that co-segregate with *Brul* and markers, and the physical map encompassing 16 BAC clones was discussed. The markers surrounding *Brul* in R570 were surveyed in nearly 400 international sugarcane cultivars and were also phenotyped for rust resistance in Réunion and Guadeloupe islands and found that *Brul* was present in most of the resistant cultivars. Only 7% of them did not display the *Brul* haplotype, and thus they represent alternative sources of resistance to the rust pathogen. The PCR marker in perfect linkage disequilibrium with *Brul* can also be used as a diagnostic for the presence of *Brul* in experimental sugarcane cultivars.

Preliminary results regarding tagging alleles involved in *X. albilineans* leaf infection resistance were reported by Hoarau and collaborators from CIRAD, Guadeloupe. The authors used a large unstructured population of 198 sugarcane clones that was recorded for severity of leaf symptoms, and 700 polymorphic AFLP markers. A set of six markers explained 31% of the total phenotypic variation in necrotic leaf symptom intensity. This first insight into *X. albilineans* leaf colonisation resistance needs to be continued with additional markers to further tag sugarcane alleles involved in this resistance.

**Leaf scald disease**

Results of a proteomics approach to study sugarcane’s reaction to infection by *Xanthomonas albilineans* were presented by researchers from Lousiana State University, USA. They used a differential protein expression analysis based on 2-dimensional electrophoresis using one resistant (Ho 95-988) and one susceptible (CP 89-846) sugarcane variety and compared protein profiles from infected and non-infected plants. Proteins that were differentially up and down-regulated in the susceptible and resistant varieties were found.

Leaf surface colonisation and stalk infection by *Xanthomonas albilineans* of sugarcane was determined in varieties grown under high rainfall conditions in Guadeloupe. The *X. albilineans* colonisation of sugarcane leaf surface after aerial spread of the pathogen varied according to the host cultivar. The stalks of two (out of 8) sugarcane varieties that exhibited the highest leaf surface populations were also the most infected by *X. albilineans*. Additionally, severity of leaf necrotic symptoms was correlated with intensity of leaf colonisation. It was also concluded that resistance of sugarcane to leaf scald appears to be controlled by several mechanisms, from leaf surface colonisation to stalk colonisation. It was noted that only a few reports of aerial spread of *X. albilineans* have been reported in Florida, USA, Guadeloupe and Mauritius and that possible recovery from stalk infection from one crop cycle to another could occur. The importance of high temperature on leaf scald symptom progress and severity was discussed.

**Viruses**

The first large-scale survey of the causal agent of sugarcane mosaic in Argentina and neighbouring regions was made. This survey was undertaken to determine the mosaic virus
population present in Argentina and to improve control of mosaic with transgenic plants. Five hundred and twenty two plants showing mosaic symptoms were analysed by RT-PCR, and leaves were sampled from 111 sites and 106 sugarcane varieties. The majority (95%) of samples from Argentina were infected by Sugarcane mosaic virus (SCMV). Sorghum mosaic virus (SrMV) was found in only 1.5% of the samples. SCMV was present in the 35 samples from Bolivia and Uruguay. Both SCMV and SrMV were detected in symptomatic plants from Paraguay, but only a few samples originated from this country. Some samples (4.4%) from Argentina tested negative for SCMV and SrMV and the virus present in these samples remains to be determined.

Mike Grisham described the virus strains causing sugarcane mosaic symptoms in Louisiana and Florida, USA. No SCMV was found in Louisiana and no SrMV in Florida. In Louisiana, strains of SrMV present were: SrMV-I, 66%, SrMV-H, 14% and SrMV-M 6%. In 7% of samples, RFLP analysis indicated that the strain was different from strains H, I and M. Furthermore, an unknown strain was present in 10% of samples showing mosaic symptoms, suggesting the presence of another virus causing mosaic in Louisiana. In Florida, only SCMV-E was observed in symptomatic samples. No Sugarcane streak mosaic virus (SCSMV) was detected in samples from both States. The results of this study showed that there has been a shift in the strain profile in Louisiana since 1990–1995, when SrMV-H was most abundant (90%), followed by SrMV-I (10%) and SrMV-M (3–5%). The difference in the strain distribution of Florida and Louisiana could not be explained. It was felt that there is a need to investigate the genetic diversity of SCMV internationally.

In Mauritius, a sensitive detection technique for Sugarcane yellow leaf virus (SCYLV) using real-time fluorescent Taqman® RT-PCR assay was developed. This was found to be 100x more sensitive than conventional RT-PCR. This method allowed the simultaneous detection of the virus and an internal sugarcane positive control. The internal positive control increases the reliability of the test by eliminating false negatives. Also, genetic diversity studies using a two-step RT-PCR showed the presence of the REU genotype of the virus, predominantly, as well as CUB and BRA-PER genotypes in the Mauritian sugarcane germplasm collection. Mixed infection of REU with either CUB or BRA-PER genotype was also present.

In Mauritius an island-wide survey for the presence of SCLYV in 22 commercial cultivars revealed that 58.8% of the over 3000 samples were infected with the virus. The incidence of infection ranged from zero in variety M 1176/77 to 100% in variety R 579. Severe symptoms were observed in varieties M 695/69, M 52/78, M 387/85, M 1186/86, M 1400/86, M 2004/88, M 703/89, M 2593/92, R 570, R 573, and R 575, but did not correlate closely with the presence of the virus. The presence of the aphid vector, Melanaphis sacchari was low and the spread of the virus was thought to be primarily by seed cane.

The incidence of SCYLV was compared in the two geographically close islands of Guadeloupe and Martinique. Infection was lower in Guadeloupe, although the vector population and cultivated varieties were the same. In Guadeloupe, the REU genotype predominated over BRA-PER. In Martinique, BRA-PER was more important and sometimes with mixed infection of REU. The differences observed between the two islands suggest the occurrence of local effects and interactions.

In Ecuador, from 2001 to 2005, the incidence of SCYLV increased dramatically. Yield trials using disease-free plants obtained via meristem culture had 20% more cane production and 36% more tonnes sucrose per hectare (TSH) than infected plants. Plants treated with insecticides increased yields compared to untreated plants. The best method of control was a combination of using virus-free plants derived from meristem culture along with systemic insecticides.

Studies at CIRAD indicated that, of the four different genotypes of SCYLV, diagnosis of the CUB genotype was the most difficult with the available primers. New primers were developed that allowed detection of all isolates of CUB genotype. The distribution of CUB isolates is being investigated using the newly developed primers.
Evidence was presented by research carried out in Australia that the causal agent of Ramu stunt disease is a virus. Viral preparations from infected leaves showed a 36-kDa protein to be consistently detected and isometric viral particles were observed from the infected cultivar Ragnar. Sequences of RNA with homology to viral RNA-dependent RNA polymerase have been cloned. A test that can detect a 1 kb RT-PCR product in leaf RNA extracts and the insect vector has been developed for the disease.

Phytoplasmas

In India, nucleotide sequence analysis of the 16SrRNA gene and the 16S/23S rDNA established that sugarcane grassy shoot (SCGS) phytoplasma is closely related to that of sugarcane white leaf (SCWL) disease. The two sugarcane phytoplasmas share a 97.5–98.8% homology with respect to their 16S rDNA sequences. SCGS phytoplasma was also found to belong to the rice yellow dwarf phytoplasma group. In contrast, sorghum grassy shoot phytoplasma was more distantly related to SCGS. Nested PCR was required to reliably detect SCGS. Resistance to the disease was found to be present among cultivated varieties.

The occurrence of sugarcane yellows phytoplasma (SCYP) associated with yellow leaf syndrome (YLS) exhibiting symptoms of sugarcane leaf yellows and yellowing of midribs was also reported in India. A phytoplasma characteristic ~0.840 kb rDNA PCR product was amplified from DNAs of all infected sugarcane leaf samples but not in healthy sugarcane plants tested using phytoplasma universal primer pairs P1/P7 and fU3/rU5. RFLP analysis of PCR products with Hae III and Hha I endonuclease generated fragment profiles that were identical for all the samples. The 16S rRNA sequence of the Indian SCYP isolate (EU170474) showed the closest identity (99%) with that of SCYP isolate in Cuba identified in Macroptilium lathyroides (AY725233) and other grasses like Cynodon dactylon (AB052871), Conyza canadensis (AY 725231) and Sorghum halapense (AY 725232), which belong to 16SrXII (Stolbur group). This was the first report of 16SrXII group phytoplasma affecting sugarcane in India.

Smut

With the introduction of sugarcane smut (Ustilago scitaminea) into Queensland in Australia in 2006, a smut-screening program started there, as it was clear that the disease could not be eradicated. The proportion of smut-resistant clones increased from 0.4% in 2000 to 52% in 2007. Spore traps were used to detect sugarcane smut spores in areas prior to the visual detection of the disease. Initially, smut spores were identified by visual inspection of the collection tapes. Because of dirt particles and other spores, visual confirmation was slow and difficult. A DNA extraction and PCR-based assay method was developed that allowed easy confirmation of the presence of smut spores.

In several sugarcane growing areas, smut was identified on the tape samples prior to the actual visual observation of smut whips in the same areas. The confirmation of the aerial spread of smut into areas where smut had not been observed helped to influence growers to shift to smut-resistant varieties.

Although smut spores are a major method of spread of smut over long distances, their survival is influenced by temperature and moisture. Studies showed that spores germinated under temperatures ranging from 12 to 36°C. Under moist conditions, smut spores survived only for short time periods (2–3 months) in the soil, sugarcane trash and in the laboratory. However, survival of smut spores under dry conditions is greatly extended. Smut spores will survive for up to 6 months on machinery and on cotton clothing, and these mechanisms could, in theory, spread the pathogen.

Rusts

The epidemiology of brown rust (Puccinia melanocephala) in Louisiana was discussed with major emphasis on yield losses, resistance and fungicidal control. The magnitude of demonstrated losses strongly suggested that the application of fungicides be explored. Strobilurin fungicides were found more effective than triazole fungicides in reducing rust severity and yield losses. However,
combinations of these two fungicide types were superior. Two applications of fungicides can provide better economic benefits against rust incidence and infection severity. However, further research is required for the time and mode of application of fungicides against rust infection for maximum economic benefit, and research is in progress. Until now, host resistance is the most desirable control method of brown rust in Louisiana, but adaptability of the pathogen and problems in regular replacement of commercial sugarcane varieties in sugarcane are the major hurdles.

In Colombia, brown rust severity has increased on resistant varieties (CC 85-92, CC 84-75, CC 93-3895, CC 92-2804 and CC 94-5827) during the last 2 years. No molecular variation in the rust pathogen was observed using ITS 1F/ITS4 primers and restriction enzymes (ALU I and Hinf I). More genomic regions in the rust pathogen are being evaluated. The reason for the increased severity of rust symptoms is unknown. Based on microscopic evaluation, only the brown rust pathogen was present. Based on the differences in rust symptom expression, it is assumed that a new race may be present.

Until 2007, orange rust (Puccinia kuehnii) had been observed only in Australia, Philippines, Indonesia and Papua New Guinea. In Australia it was considered as a minor disease until an epidemic occurred in 2000 and caused millions of Australian dollar losses to the sugar industry there. Then, in 2007, orange rust was confirmed in Florida (USA), Costa Rica, Guatemala, Nicaragua and Panama. In Guatemala, the presence of sugarcane orange rust (Puccinia kuehnii) was detected in September 2007. The disease was found to be widespread on CP 72-2086 with low severity of symptoms.

Concerns were expressed over the appearance of the disease in the American continent, and ways and means to counteract the disease were discussed including the replacement of susceptible commercial varieties and the identification of resistant parents for crosses.

New techniques

The usefulness of tools applied in precision agriculture to plant pathology was explained by the group of researchers from Louisiana, USA. The influence of environmental conditions and cultural practices on the incidence of brown rust was investigated. Infection was found to be positively correlated with soil properties, particularly the levels of phosphorus and sulfur. It was deduced that excess fertiliser applications could bring about a higher rust incidence and thereby negatively affect sucrose and cane yields. Remote sensing using a fibre optic spectrometer was utilised to determine leaf infection by SCMV or SrMV. Analysis of mild and severe SCMV leaf reflectance measurements were correctly classified in 75 and 68% of the cases, respectively. Leaves infected by SCYLV were correctly identified 77% of the time.

Conclusion

The workshop was very successful and the quality of work presented by participants was high. It is evident that a number of important and significant advances have been made recently both in the field of sugarcane pathology and biotechnology since the last workshops. The ISSCT sponsored workshops have played a major role in advancing the knowledge, cooperation and technology of sugarcane scientists. The attendees of the Workshop thank Drs Victoria and López-Gerena and CENICANA for hosting this excellent Workshop.

Résumé

LES ATELIERS de travail de Pathologie et de Biologie Moléculaire de l’International Society of Sugar Cane Technologists (ISSCT) ont été tenus conjointement pour la deuxième fois du 23-27 juin 2008 à Cali, Colombie. La réunion a été parrainée par le CENICAÑA et organisée par Jorge I. Victoria et Jershon López-Gerena. La participation fut très positive avec la présence de 44 délégués de 15 pays. Trente-sept présentations orales et dix posters, couvrant un large éventail de sujets, tels que la caractérisation moléculaire des levures, les ravageurs et les pathogènes, la transformation génétique de la canne, les marqueurs moléculaires, la cartographie génétique, la variabilité des pathogènes, le diagnostic des maladies, la résistance de la plante et l’épidémiologie des maladies ont été abordés. Trois discours sur la production des biocarburants, la transgénèse et le génomique de l’amélioration nutritionnelle des cultures vivrières furent prononcés pendant les sessions plénières. Une session spéciale a été consacrée à la rouille orangée, une maladie nouvellement apparue en Floride et en Amérique Centrale. Pendant deux jours, les participants eurent aussi l’occasion de visiter des sucreries, des champs industriels, des parcelles de canne transgéniques ainsi que les laboratoires de CENICAÑA. Cette réunion conjointe s’est avérée fruitueuse et elle a donné lieu à une excellente interaction entre les participants.

PALABRAS CLAVES: Enfermedades, Resistencia, Mapeo Genético, Caracterización Molecular, Transgénicos.

Resumen

POR SEGUNDA VEZ, la Sociedad Internacional de Tecnólogos de la Caña de Azúcar (ISSCT) se celebraron conjuntamente los talleres de Patología y de Biología Molecular, entre el 23–27 junio de 2008 en Cali, Colombia. La reunión fue organizada por CENICAÑA bajo la dirección de Jorge I. Victoria y Jershon López-Gerena. La respuesta de los participantes fue positiva, con 44 delegados en representación de 15 países asistentes. Treinta y siete presentaciones orales y diez carteles que cubrieron una amplia gama de temas, se presentaron, incluyendo la caracterización molecular de levaduras, insectos plagas y patógenos, la transformación genética de la caña de azúcar, marcadores moleculares, mapeo genético, la variabilidad del patógeno, el diagnóstico de enfermedades, resistencia de las plantas y la epidemiología de la enfermedad, entre otros. El taller también brindó la oportunidad de escuchar tres conferencias plenarias sobre la producción de biocombustibles, los transgénicos y las mejoras nutricionales en los cultivos de alimentos a través de la genómica. Una sesión especial fue dedicada a la roya de naranja, una enfermedad de reciente introducción en la Florida y en América Central. Tras las sesiones técnicas, se organizaron visitas durante dos días en los ingenios azucareros, los campos comerciales, terrenos con caña de azúcar transgénica, y los laboratorios de Cenicaña. La experiencia de tener reuniones y sesiones conjuntas nuevamente demostró ser muy útil por la excelente interacción entre los participantes.
SUGARCANE RUSTS IN FLORIDA

By

KEYWORDS: Sugarcane Brown Rust, Orange Rust, Puccinia melanocephala, P. kuehniii.

Abstract
SUGARCANE orange rust symptoms were first observed in Florida in June 2007 on cultivar CP 80-1743. The causal agent, Puccinia kuehniii, was subsequently verified morphologically and molecularly constituting the first confirmed report of sugarcane orange rust in the Western Hemisphere. Orange rust was distributed throughout the entire Florida sugarcane industry, primarily on cultivars CP 80-1743 and CP 72-2086. The objective of this research was to evaluate the reaction of the commercial cultivars to both sugarcane brown and orange rusts and to assess their effect on the CP-cultivar development program in Florida. The rust reactions of several widely grown commercial cultivars, newly released cultivars and clones in the selection program, parental clones and CP historical clones were determined in order to develop a suitable resistance strategy to address the new incursion of orange rust. Changes in the program to increase the level of rust-resistant progeny are detailed.

Introduction
Sugarcane brown and orange rusts are the two primary rust diseases of sugarcane (Magarey, 2000; Raid and Comstock, 2000). Both sugarcane rusts have had a significant impact on the Florida sugarcane industry. The development of sustained resistance to sugarcane brown rust caused by Puccinia melanocephala has not always been successful.

The brown rust pathogen, P. melanocephala, was unable to develop on a number of cultivars when they were released but they subsequently show severe symptoms. After several years of commercial production, brown rust developed on CP 70-1133, CP 72-1210 and CP 78-1247 rendering them unsuitable for further cropping. Additionally, CP 78-1628, a major cultivar on sand soils, has also become susceptible to brown rust since being released in 1991 (Tai et al., 1991).

During the clonal selection program, rust reactions were traditionally determined solely on natural infection of clones in field plots. Unfortunately, this can lead to inconsistent results due to variability in disease levels between locations resulting in an inadequate rust resistance evaluation. Another possible reason for the change in resistance rating may be pathogen variation.

There have been reports of pathogenic races of P. melanocephala in Florida (Shine et al., 2005) and P. kuehniii in Australia (Braithwaite, 2005). Some stages of the Canal Point cultivar development program are of necessity planted at a time of the year that does not favour rust infection in these canes (in the March through mid-May period when brown rust is most prevalent).

In June 2007, orange rust caused by P. kuehniii was detected in Florida (Comstock et al., 2008). Orange rust was initially recognised because of the unusual amount of rust seen in the previously rust-
resistant cultivar CP 80-1743. On close examination, the rust pustules were lighter and more orange in colour than brown rust pustules. Furthermore, the urediniospores had a prominent apical thickening instead of the uniform walls observed in *P. melanocephala*.

These morphological characteristics, together with molecular sequencing information, confirmed the pathogen as *Puccinia kuehnii*, the orange rust pathogen (Comstock *et al.*, 2008). Subsequently, orange rust was confirmed in Guatemala, Costa Rica, Nicaragua, El Salvador, Mexico and Panama (Ovalle *et al.*, 2008; Chavarría *et al.*, 2009; Flores *et al.*, 2009). In Florida, orange rust associated yield losses in crops of CP 80-1743 were estimated at 40% in 2008 (Richard Raid, Pers. Comm.).

This is similar to losses reported in the Central district of Australia in the 1999-series plant crop (Magarey *et al.*, 2008). Orange rust has reduced yields of CP 72-2086 in some locations in Central America where environmental conditions are conducive for disease development. This is particularly true in the southern region of Costa Rica and the lower elevations of Guatemala, both warm humid areas. Losses of 8% were estimated in Guatemala on CP 72-2086 (W. Ovalle, Pers. Comm.).

CP 80-1743 occupied 22.8% of the industry acreage in Florida in 2007 and up to 40% in some sections of the industry. Initial surveys indicated that orange rust was distributed throughout the entire industry (where CP 80-1743 or other susceptible clones were grown). Yield losses dictated the need to withdraw CP 80-1743 from production. Germplasm in the Canal Point (CP) Cultivar Development Program was impacted, as a large portion of parental clones were susceptible, as too were a portion of the clones in the selection program and these too had to be eliminated.

A whorl inoculation technique was recently developed and is being used to determine rust reactions in Florida (Sood *et al.*, 2009). This procedure allows individual plants to be inoculated in the field with specifically selected inoculum. When windblown inocula are limited, screens can be completed using stored spores. Large numbers of clones can be screened using limited labour. Ratings are applied based on the type and severity of pustule development.

The objectives of this paper are 1) to provide a brief history of the sugarcane orange rust outbreak in Florida, 2) present the impact of sugarcane orange rust on the commercial cultivars and parental clones, 3) to present resistance data on clones in the CP-Cultivar Development Program and compare the ratings of individual clones as they are advanced from one stage to the next.

**Materials and methods**

**Rust rating scales**

Both sugarcane brown and orange rusts were rated using two different rating scales depending on whether the plants were naturally infected in the field or were inoculated using a whorl inoculation technique under field conditions.

The natural infection scale is based on the presence and number of pustules using a 5 point scale as follows: 0 = no symptoms; 1 = one or a very few pustules; 2 = more than a few pustules; 3 = numerous pustules both on the lower leaves and to a lesser extent on the upper leaves and 4 = severe rust development with extensive coalescing of pustules and leaf necrosis due to rust. Ratings 0 and 1 are classified as resistant reactions, a rating of 2 is moderately susceptible and 3 and 4 are susceptible.

Field plot ratings require rust assessments on check varieties to validate the ratings. The artificial inoculation scale used to determine rust reactions after whorl inoculation is based entirely on pustule formation and presence and amount of sporulation occurring using the following scale: 1 = no visible symptoms; 2 = small yellow flecking with no sporulation and no pustule development; 3 = small pustules with limited urediniospore development (some sporulation); and 4 = pustules with abundant sporulation. Ratings 1 and 2 are resistant and ratings 3 and 4 are respectively, moderately susceptible and susceptible.
Whorl inoculation procedure

A whorl inoculation procedure was used to inoculate 3 to 6 month old field plants as previously described (Sood et al., 2009). Briefly, inoculations are made using an automatic pipetter by placing 0.5 to 1.0 mL urediniospore suspension (10^4 urediniospores per mL for *P. kuehnii* and 10^5 urediniospores per mL for *P. melanocephala*) into the spindle leaf whorl of individual stalks. Inoculated stalks are marked by cutting off one third of the leaf tips to identify what leaves to evaluate. Inoculations are made at 7:30 am to 9:00 am when the plants have dew on their leaves and prior to the peak temperature of the day. There were three inoculated plants in a single plot for Stage II clones, six inoculated plants for Stage III clones (3 plants in two plots) and 12 plants for Stage III increase and Stage IV clones (3 plants in 4 plots). Rust reaction ratings were made 4 weeks after inoculation using the whorl inoculation scale described above and the data were averaged.

Rust reactions based on natural infection

Rust reactions of both brown and orange rust (since 2007) reactions were based on natural infection using the 0 to 4 rating scale described above. The following germplasm was rated for their rust reactions: commercial cultivars, released cultivars (with < 1% of the acreage), clones in the program to increase seedcane for multiplication, clones in all stages of the selection program including Stage II (single location, unreplicated), Stage III (four locations), and Stage IV (10 locations), parental clones and 1060 domestic and foreign clones in the CP historical nursery. The number of ratings for each genotype varied from a single rating in the unreplicated plots to more than 6 for the replicated trials. The highest rating is designated the assigned reaction.

Rust reactions based on whorl inoculation

Clones in the following CP Series were tested using the whorl inoculation technique: CP 05 Series in 2008 (Stage III increase) and 2009 (Stage IV), CP 06 Series in 2008 (Stage III) and 2009 (Stage III increases) and CP 07 Series in 2008 (Stage II) and 2009 (Stage III). Data are summarised to indicate the percentage of resistant clones at each stage. Correlations of the ratings in these different stages were made using clones common to each of the above series.

Results and discussion

Rust in commercial sugarcane production

The rust ratings of the commercial cultivars grown in Florida are presented (Table 1). Cultivar CP 80-1743 was the most susceptible and withdrawal from commercial production is recommended. Its acreage decreased from 22.8% in 2007 to 19.6% in 2009 prior to harvest and planting. In 2007, many growers could not change their planting plans because the orange rust resistance reaction of available, alternative cultivars could not be finalised prior to planting. Since 2007, the acreage of CP 88-1762 and CP 89-2143 increased by 1.9 and 4.2% to 20.4 and 31.1% respectively. Growers are reluctant to further increase CP 89-2143 and CP 88-1762 because these two cultivars are grown primarily on organic soils and the proportion of their acreage in some areas is very high (approaching 40%). Orange rust has recently been observed on CP 88-1762 that had not previously exhibited symptoms, suggesting a change in *P. kuehnii* pathogenicity. This is a real concern because shifts in pathogenicity can severely affect commercial production, cultivar deployment, and restrict the progress in the cultivar development program.

CP 78-1628 was resistant to *P. melanocephala* when it was released and for several years afterward, but now is moderately susceptible to brown rust. In Florida, brown rust has a history of affecting previously resistant cultivars. Brown rust resistance in CP 70-1133 and CP 72-1210 appeared to ‘breakdown’ as the acreage expanded above 30% in Florida. Similarly brown rust resistance of LCP 85-384 ‘broke down’ after its acreage approached 85%, contributing to its recent decline in Louisiana.
(K. Gravois, pers. comm.). In Colombia, brown rust severity has increased on CC 85-92 and CC 84-75 that combined occupy 80% of the acreage (Angel et al., 2008). The occurrence of new pathogenic races of either *P. melanocephala* or *P. kuehnii* are a real threat to the Florida industry since races of brown rust have been previously reported (Shine et al., 2005).

Orange rust development in 2009 has been slower than in 2008 since there was a severe freeze in March of this year and most of the sugarcane foliage was ‘burnt’ back by the freezing temperatures, thereby reducing the amount of *P. kuehnii* inoculum. The rust epidemic was delayed 3 months compared to the previous year, and orange rust severity in September was at a level comparable to that in July in 2008. Disease ratings based on natural infection were therefore delayed in 2009.

### Table 1—Rust reaction ratings based on natural infection and acreage of the major commercial cultivars grown in Florida in 2009.

a In June 2007 when orange rust was detected CP 80-1743 occupied 22.8% of the commercial acreage.

b CP 88-1762 previously had no orange symptoms but, in August 2009, orange rust was observed in multiple grower fields and it is now classified moderately susceptible.

c Orange rust severity has been rated R3 in some locations in 2009.

Recently released cultivars, CP 00-1101 (Gilbert et al., 2008), CP 00-1446 (Comstock et al., 2009), CP 00-2180 (Glaz et al., 2009), CP 01-1372 (Edme et al., 2009) and CPCL 97-2730 (Milligan et al., 2009) are either resistant or moderately resistant to rust (Table 2) and are rapidly being increased in Florida; however, the percent acreage of each cultivar in the industry still remains slightly below 1%. CP 80-1743 is not being replanted and the demand for these recently released resistant cultivars has been higher than the available seed cane for planting. The successful economic use of fungicides to control orange rust has enabled cropping for the normal crop cycle period, even in susceptible cultivars and has opened new control options to consider.

### Rust reaction of parental clones

A high proportion of parental clones available for crossing in 2007 and 2008 were susceptible to orange rust (Table 3). The short time period since the orange rust incursion has limited significant changes in the resistance of parental populations. The proportion of resistant parental germplasm was
less than Australia where 70% of the germplasm was resistant (Magarey and Bull, 2009). Consequently, changes in the breeding population have been more difficult in Florida than Australia. Although resistant × resistant and resistant × susceptible crosses are desirable, some crosses of susceptible × susceptible were made because of flower availability at the time of crossing. Some resistant progeny will be produced in these crosses. A more restrictive use of susceptible parental clones is being implemented.

Table 3—Summary of orange rust reactions of parental clones used for crossing in the CP program for Florida based on ratings taken in 2007 and 2008.

*Prefix CL indicates clones developed entirely by the breeding program of US Sugar Corporation. CPCL prefix indicates clones derived from seed resulting from crosses made by the breeding program of US Sugar Corporation and selected by the CP program at the USDA-ARS Sugarcane Field Station. CP indicates clones developed entirely by the CP program.*

Of the 1060 clones in the CP historical nursery, 78 and 59% were classified as resistant to brown and orange rust, respectively. The nursery comprised primarily Florida (CP, CPCL, and CL), Louisiana (Ho, HoCP, L and LCP) and Texas (TCP) clones. Since the breeding and crossing programs for the US mainland sugar industries relies on these clones, the impact of orange rust is important.

**Effect of rust on the CP cultivar development program**

In 2007, the proportion of clones resistant \( R \leq 1.0 \) to both brown and orange rust that were advanced to Stage III (third clonal stage of selection) was 47.8% (Table 4). In 2008, 63.8% of the clones rated resistant \( R < 1 \) and advanced to Stage III (the first multi-location yield trial) were assigned a rating based on natural infection. Moreover, the mean rust rating of the entire population of Stage II clones decreased while the ratings of the check clones increased. The proportion of rust-resistant germplasm was less in Florida when orange rust was introduced than that in Australia in 2000, where 70% of the germplasm was resistant (Magarey and Bull, 2009). Guatemala also has a lower proportion of resistant germplasm in their selection program than Australia (W. Ovalle, pers. comm.). The lower proportion of resistant clones in the western hemisphere than Australia may be because, in Australia, \( P. kuehnii \) had been present for years and there probably was some selection for resistance in contrast to western hemisphere where the pathogen was newly introduced.

Table 4—Rust ratings of Stage II clones advanced to Stage III, 2007 versus 2008.

</tbody>
</table>
There are two trends concerning sugarcane brown and orange rusts in the CP cultivar development program: 1. a trend toward more resistance. In time a shift toward resistance is likely to be more dramatic as selection for rust resistance will be emphasised compared to other traits, and 2. a possible change in orange rust pathogenicity.

Pathogenic changes are evident since CP 88-1762 did not have orange rust symptoms in 2007 when the disease was detected. Growers and scientists made numerous observations of crops of these major cultivars and, if orange rust was infesting them in 2007, it had to be at an extremely low level. In 2009, orange rust pustules were observed on CP 88-1762 for the first time. Only pathogenicity and molecular characterisation will confirm if in fact there are distinct races of *P. kuehnii* present in Florida.

**Whorl inoculation ratings**

The proportion of rust resistant clones in the CP 05, CP 06 and CP 07 series are presented in (Table 6); the proportion of resistant clones in the CP 05 through CP 07 clones was high. Since susceptible clones were not advanced, there was an increase in percentage of resistant clones in 2009 compared to 2008. There were good correlations between the ratings obtained in whorl-inoculated tests and those obtained using natural infection (Sood *et al*., 2009). The correlations were excellent between ratings obtained from one year to the next with $r^2$ values ranging from 0.75 to 0.83.

*c* Comparison of rust reactions of CP 07 Series clones in Stage II and the clones advanced to Stage III for 2008 and 2009, respectively.

**Conclusions**

Orange rust appeared suddenly and has dramatically affected the production of sugarcane in Florida and several Central American countries. The disease impacted both total sugarcane production and the retention of cultivars in the cultivar development programs. A major cultivar, CP 80-1743, is being withdrawn from commercial production and a number of potential Stage IV clones were eliminated solely for their rust reactions.

In commercial fields, fungicide applications increased sugar productivity from a range of 7.9 to 26% on CP 80-1743 in 2008, indicating partial losses due to orange rust (James Shine, Raul Perdomo and Michael Irey, pers. comm.) Where there was better control of orange rust with more frequent fungicide applications in experimental plots, the losses were higher (up to 40%) reflecting the maximum loss due to the disease (Richard Raid, pers. comm.). The parental population and the crossing strategy had to be changed to reflect the need for rust resistance. Changes in *P. kuehnii* pathogenicity mean that constant monitoring of the susceptibilities of cultivars in commercial
production and in sugarcane breeding programs is required. At this time, there is not sufficient molecular and varietal reaction data to determine the origin of *P. kuehnii* in the western hemisphere. Since orange rust is dispersed by windblown urediniospores, it may spread and potentially may impact most sugarcane producing areas in the western hemisphere.

Résumé

Les symptômes de la rouille orangée ont été observés pour la première fois en Floride en juin 2007 sur le cultivar CP 80-1743. L’agent causal, Puccinia kuehnii, a été subséquemment vérifié morphologiquement et moléculairement ce qui a constitué le premier rapport de la rouille orangée dans l’hémisphère ouest. La maladie était prévalente à travers l’industrie de la canne à sucre en Floride, principalement sur les cultivars CP 80-1743 et CP 72-2086. L’objectif de cette recherche a été d’évaluer la réaction des cultivars industriels à la rouille brune et à la rouille orangée afin de déterminer leur impact sur le programme de développement des cultivars CP en Floride. Les réactions aux différentes rouilles de plusieurs cultivars plantés sur une grande échelle, les cultivars nouvellement homologués, les clones en sélection, les clones parentaux et les clones CP historiques ont été évalués afin de développer une stratégie de lutte basée sur la résistance pour contrecarrer l’arrivée de la rouille orangée. Les changements au programme pour augmenter le niveau de résistance à la rouille sont élaborés.
ROYAS DE LA CAÑA DE AZÚCAR EN LA FLORIDA

Resumen

Los síntomas de roya de la caña de azúcar de naranja se observaron por primera vez en la Florida en Junio de 2007, sobre el cultivar CP 80-1743. El agente causal, Puccinia kuehnii, fue verificado morfológica y molecularmente lo que se constituyó en el primer informe sobre presencia de la roya naranja de la caña de azúcar en el Hemisferio Occidental. La roya naranja está distribuida en toda la industria azucarera de la Florida, principalmente en las variedades CP 80-1743 y CP 72-2086. El objetivo de esta investigación fue evaluar la reacción de los cultivares comerciales tanto a la roya café como a la naranja de caña de azúcar y evaluar su efecto en el programa de desarrollo de cultivares CP en la Florida. Las reacciones de infección de varios cultivares comerciales ampliamente cultivados, de cultivares recién liberados y clones del programa de selección así como clones progenitores y clones históricos CP se evaluaron con el fin de desarrollar una estrategia de resistencia adecuada para hacer frente a la amenaza de la roya naranja en la industria azucarera de la Florida. Los cambios en el programa de mejoramiento para aumentar el nivel de resistencia en la progenie se presentan en detalle.
MONITORING THE SEVERITY AND VARIABILITY OF BROWN RUST (*Puccinia melanocephala*) IN SUGARCANE VARIETIES IN THE CAUCA VALLEY, COLOMBIA

jcangel@cenicana.org

KEYWORDS: Sugarcane, Brown Rust, Disease Incidence, Ribosomal DNA (Rdna), Resistance, Physiological Races.

Abstract

The varieties CC 85-92 and CC 84-75 are grown on more than 80% of the area planted with cane in the Colombian sugar industry; these varieties were initially resistant to brown rust disease. Brown rust has been present in Colombia since 1979. Genetic variability in *Puccinia melanocephala* is thought to have affected resistance in some varieties through the appearance of what are thought to be new races of the pathogen. This situation has been observed in some resistant varieties (e.g. CC 85-92, CC 84-75, CC 93-3895), where recently the disease has occurred at low severity. Therefore, an evaluation was made of the severity and possible variability of brown rust in the varieties selected by CENICAÑA in the Cauca River Valley. Samples were taken from plants from 1–14 months of age in the varieties CC 84-75, CC 85-92, CC 93-3895, CC 92-2804 and MZC 74-275 on 91 estates (10 sugar mills). On each plantation 20 stalks were selected at random, and the third leaf from the top visible dewlap leaf was taken from each stalk. Both disease reaction and severity were evaluated. Morphological and microscopic analyses of the structures found in the rust pustules were undertaken in leaf samples taken from each variety. Simultaneously, pathogen samples were collected and molecular techniques used (focusing on initiators of the ribosomal DNA (rDNA)) to detect possible genetic variation of *P. melanocephala*. The results showed that the disease reaction type in the varieties evaluated was 5 or less, with severities ranging from 0–12% leaf area affected. Variety MZC 74-275 showed susceptibility, with a reaction of 6 and a severity of 20% on the estates where it was evaluated. No differences were found among the morphological structures in the samples evaluated, all of which corresponded to *P. melanocephala*. The results obtained from the amplification of the ITS1 and ITS2 regions of the rDNA and from the PCR-RFLP did not show differences among the samples evaluated. These results could indicate that the variation of the pathogen is not reflected in its rDNA or that the molecular technique used was not sufficiently sensitive to detect small variations in the genome. Initial results about the presence or absence of gene Bru1 and susceptibility to brown rust are discussed.

Introduction

Brown rust of sugarcane caused by the fungus *Puccinia melanocephala* H. and P. Sydow was reported for the first time in the western hemisphere in 1978, spreading rapidly throughout the American continent.

In 1979, it was detected in the variety B 4362 in the provinces of Norte de Santander and Cesar in Colombia; two years later, it was found in the Cauca River Valley (Victoria *et al*., 1984; Victoria *et al*., 1988).

1
In Colombia, the disease occurs at greater severity in plants that are 4–5 months of age (Victoria et al., 1995); however, in older crops, the plant shows a certain degree of recovery, depending on varietal susceptibility (Victoria et al., 1995). In general, *P. melanocephala* delays plant development, which is manifested in a reduction in stalk length and the number of stalks per stool (Victoria et al., 1984) resulting in a decrease of up to 40% in crop production in some susceptible varieties (Raid and Comstock, 2006).

The best strategy for controlling diseases is cropping resistant varieties; therefore, a prime objective of the CENICAÑA varietal improvement program is to select rust-resistant varieties. To do this, the disease is assessed at 4.5 months crop age, using the scale of Purdy and Dean (1981), which determines the genotype-pathogen interaction (type of pustule: 0–9) and percent severity in the third leaf from the top visible dewlap leaf.

Depending on pustule type, varieties with a score over 5 are considered susceptible and 5 or less, resistant. Variety selection considers disease severity but seeks high stability of the varieties in their reaction to the disease, thereby achieving vertical and horizontal resistance simultaneously (Victoria et al., 1989). Nevertheless, according to Raid and Comstock (2006), rust resistance has not been stable in some cane varieties due to the genetic variability of the pathogen. Various authors have proposed the existence of pathogen races, based on changes in the susceptibility of varieties previously reported to be resistant (Liu, 1980; Dean and Purdy, 1984).

The existence of rust races, based on differential varietal reactions, has been found in India and Florida (Ryan and Egan, 1989; Shine et al., 2005). Evaluation of *P. melanocephala* races requires an effective methodology for identifying genetic variability among the possible different pathogen populations. Molecular markers like AFLP and ITS provide a useful tool for monitoring genetic changes in populations. In addition, analysis of rDNA sequences have been used to establish phylogenetic tree and genetic variations in fungi (Hibbet, 1992).

CENICAÑA’s varietal improvement program developed varieties in the series 84, 85, 92 and 93 and these have stood out in recent years for their agronomic and factory traits. These varieties are being multiplied and tested on a commercial scale by the sugar mills. Varieties CC 85-92 and CC 84-75 currently hold first and second place in area under cultivation respectively; but at this time there are other outstanding varieties such as CC 92-2804, CC 93-3895, which are still in the process of being multiplied.

In the past, these varieties had low rust infection; but, in the last three years, there has been a gradual increase in the incidence of the disease. It is possible that this response is due to an interaction between the pathogen and varietal resistance.

The purpose of this study was to evaluate the presence and severity of rust in varieties under different environmental conditions; to evaluate isolates of the fungus collected in commercial crops throughout the Cauca Valley; to use ITS and PCR-RFLP molecular markers to determine the possible existence of pathogen races; to assess the possible presence of resistance genes or whether the increased incidence of rust is due to environmental factors.

**Materials and methods**

**Evaluation of rust under different environmental conditions**

Brown rust incidence was assessed in plantations on 91 estates, in the following sugar mills: Castilla (4), Cabaña (4), Incauca (3), María Luisa (2), Mayagüez (3), Manuelita (22), Providencia (8), Risaralda (16), Riopaila (8), Sancarlos (18) and Sicarare (3) between 2006 and 2008.

The evaluation was conducted in crops ranging from 1–14 months of age in areas destined for both seed and commercial production. Varieties CC 85-92, CC 84-75, CC 93-3895, and CC 92-2804 were evaluated; the susceptible variety MZC 74-275 was used as the check.

In each plantation, a sample was taken from 20 randomly-selected sites within a crop. At all sites and in each variety, the third leaf from the top visible dewlap leaf on stalks was used to
evaluate pustule type or disease reaction (scale of 0–9) and the percent severity of the disease (0–100), based on the guidelines defined by Purdy and Dean (1981).

**Molecular evaluation**

**Samples**
Ten leaves of varieties CC 92-2804, CC 93-3895, CC 85-92, CC 84-75, MEX 52-29, MZC 74-275, CP 57-603, CC 98-68 and CC 94-5827 were collected in different commercial crops. The samples were placed in plastic bags and conserved in a Styrofoam (foamed polystyrene) cooler with ice until they reached the laboratory where the molecular evaluation was undertaken.

**Conservation of the pathogen and induction of sporulation**
Leaf pieces (approx. 20 cm long) were taken from diseased leaves with a Type 4 reaction (Purdy and Dean, 1981); that is, with chlorotic or red spots and unopened pustules. The leaf pieces were washed with distilled water, then by ethyl alcohol at 70% and again washed with distilled water. The fragments were placed in glass jars containing 50 mL benzimidazole solution (12.5 mg/L) (Asnaghi et al., 2001), each of which was placed within PVC cylinders with the openings covered with netting (tulle). They were then incubated under glasshouse conditions at 25°C, 60–85% RH for 1–2 weeks until sporulation.

**Extraction of the fungal DNA**
The methodology described by Virtudazo et al. (2001a) was used to enable DNA extraction from the spores contained in one pustule, so preventing the mixing of possible races in different pustules found on the same leaf.

**Amplification of DNA fragments**
ITS markers were used to amplify the ribosomal DNA (rDNA), a technique used in different phylogenetic and population fungal genetics studies (because there are multiple copies in the genome these are easy to amplify). Different pairs of initiators from both the rDNA and other regions of the genome were evaluated. The PCR products obtained after amplification were visualised in agarose gels al 1.5% (for fragments <1000 pb), run in TBE at 0.5 X and tinctured with ethidium bromide.

**Amplification of the ITS 1 and ITS 2 regions for the harvested population of P. melanocephala**
The regions with the best amplification were selected for evaluating the total population collected in the Colombian sugar zone. The ITS 1 region was selected for amplification (240 isolates in total), following the conditions described by Virtudazo et al. (2001a) with an annealing temperature of 56°C. The results were observed in agarose gels at 1.5%, tinctured with ethidium bromide.

**Enzymatic restriction of the resulting PCR products**
Different restriction enzymes (e.g. Hinf I, Xba I, Hae III, Alu I, Taq I, Mse I and Ava II) were used to find one that would digest the DNA and make it possible to visualise differences among the samples analysed. Fragments from the ITS 1 and ITS 2 regions (annealed PCR) were used. For the enzymatic restriction, 2.5 units of each tested enzyme were used with the associated buffer supplied by the commercial house, the latter at a final concentration of 1 X. The digestion temperature for the different enzymes was 37°C, except for Taq I, whose optimum temperature is 55°C. The digestion time for the different restriction reactions was 3 h 30 min., followed by a cycle of 80°C for 20 min. to denature the enzyme used. The results obtained with the different restriction enzymes were observed in agarose gels at 2.0%, run in TBE 0.5 X and tinctured with ethidium bromide.

**Results and discussion**
The measurement of pathogen paraphyses and urediniospores contained in rust pustules on leaves of the varieties CC 85-92 and CC 93-3895 confirmed that the infection was caused by P.
melanocephala, causal agent of brown rust (Virtudazo et al., 2001b). Abundant paraphyses were observed, all the urediniospores were ovoid in shape, and brown-coloured teliospores were observed. In general, all the traits observed coincided with the descriptions of *P. melanocephala* and not *P. kuehnii* (Virtudazo et al., 2001b).

**Evaluation of the rust under different environmental conditions**

Variety CC 85-92, evaluated on 23 estates in 9 sugar mills, had one Type 5 disease reaction with a rust severity less than 8% in plants 4–6 months of age. At younger ages (4 months), the greatest severity was 8% with a Type 5 reaction in plants on the Palosecal 5 estates of Incauca. At older ages, the severity ranged from 0–4%, with types 0–5 reaction.

Variety CC 84-75 was evaluated on 9 estates of the Providencia, Riopaila and Castilla sugar mills. The highest disease severity was 10% with a Type 5 reaction at crop ages of 4.6 and 5.0 months on the Venecia 340 and La Luisa 80 estates of the Riopaila Sugar Mill. At crop age less than 4 months, disease severity ranged from 0–8% with reactions from 0–3. At older ages, disease severity and reaction were both zero (Table 1).

**Table 1**—Incidence of brown rust in variety CC 84-75 on different estates and sugar mills in the Cauca Valley.

* R: Reaction (Scale 0–9); S: Severity (0–100%)

Variety CC 93-3895 was evaluated on 39 estates in 7 sugar mills. The greatest severity (15%) was found on the Esmeralda Estate of the Sancarlos Sugar Mill with a Type 5 pustule score at 4 months of age. At younger crop ages, disease severity ranged from 0–12% with reactions from 0–5. From 6–8 months, the score remained at 5, with severities ranging from 10–12%. At older ages (9 months), the severity was lower (Table 2). Variety CC 92-2804 was evaluated on three estates in the Sancarlos, Providencia and Risaralda sugar mills. Disease severity in these lots did not exceed 2%, with types 4 and 5 reactions. The check MZC 74-275 continued to show its susceptibility on all three estates with disease severities of 20% and a Type 6 reaction (Table 3).

It should be noted that every year CENICAÑA selects new varieties resistant to smut, brown rust and mosaic. This does not mean that these varieties are immune, given that immunity can easily cause the generation of pathogenic variations (new races) of the causal agents. In the case of brown rust, varieties with disease reactions from 0–5 are considered resistant, with severities less than or equal to 15% leaf area affected.

A reaction score of up to 5 is acceptable because climate (temperature, rainfall and RH) has little effect on disease severity with varieties of this rating; however, at higher scores, severity is highly affected by the climatic conditions (Victoria et al., 1989).

*R: Reaction (Scale 0–9); S: Severity (0–100%)

Brown rust severity evaluation in varieties CC 85-92, CC 84-75, CC 93-3895 and CC 92-2804 showed that the reactions reached a maximum of 5 with a severity under 12%, which means that these varieties remain at rust-resistant levels (Victoria et al., 1989).

Varietal selection and regional trial records suggest that disease severity has remained in the stated ranges.

Molecular evaluation

Genetic variability was assessed in the different rust samples collected on the affected plantations, using different ITS ribosomal markers and the PCR-RFLP methodology.

The results obtained did not show differences in the molecular size of the bands among the samples evaluated (Figure 1).

All the samples evaluated with the ITS initiators showed one intense band of approximately 670 pb, thereby making it impossible to obtain differences demonstrating pathogen variability. The PCR-RFLP technique increased the number of bands in each analysis, but did not show differences among the samples evaluated.

Figure 2 shows the results obtained after digestion of the ITS 1 region with restriction enzyme Alu I. The results obtained with the other enzymes were similar with no polymorphism among the samples.

![Fig. 1—PCR products (670 bp) of the amplification of the ITS 1 region of P. melanosephala in different isolates collected in the Colombian sugar zone. The result for 240 samples evaluated was similar to that recorded for these 19 samples. MP: Molecular weight marker, 50 pb.](image-url)
In addition to the ITS 1 region of the rDNA, other DNA regions of the pathogen were evaluated; however, again there was no polymorphism with the different initiators, in agreement with results obtained with the ITS 1 region analysis. Similarly, the results obtained using the amplified ITS 2 region after digestion with restriction enzymes did not show differences among the samples evaluated, as can be seen in Figure 3.

Molecular tools failed to link pathogen genetic variability with variation in disease severity in varieties. However, this situation does not mean that there are no allelic differences among different pathogen samples.

This could be the result of the low resolution of the techniques used, which are only capable of detecting macro modifications at the pathogen DNA level. Limiting the study to the ribosomal region of the DNA limits the scope of the evaluation, given that many of the changes at the genomic level of the populations are not necessarily reflected at the rDNA level, especially if these changes imply an increase in the performance of a group of individuals due to specific changes in genes related to pathogen virulence.

The exclusive utilisation of rDNA in this study was primarily due to the impossibility of obtaining large quantities of DNA from the limited fungal tissue available and the impossibility of *in vitro* cultivation given that it is a biotrophic organism, incapable of growing in axenic media (Braithwaite et al., 2009).

This situation limited the use of other molecular markers such as AFLP. This technique is capable of the rapid discrimination of samples due to the great polymorphism that it generates, but this also requires larger quantities of DNA (200–500 ng); this is not possible to obtain from just one rust pustule.
The potential limitation of the molecular techniques for detecting gene variation is reflected by the ability to separate genetically 1305 varieties of CENICAÑA’s germplasm using five microsatellites, but it was not possible to separate somatic variations (highly susceptible to rust) found in normally resistant variety CC 01-86 (Macea et al., 2009). The microsatellite analysis showed that both genotypes were similar. Recently, Garsmeur et al. (2009) reported the presence of a major gene (Bru1) associated with brown rust resistance in the variety R 570 and common to most rust-resistant varieties. According to these authors, only 13% of the resistant varieties lack the Bru1 gene, suggesting that their resistance is due to the presence of another resistance gene. The Bru1 gene found in the original CC 01-86 was not found in the somatic variations. Nevertheless, in CENICAÑA, brown rust has been observed with equal severity in varieties that do have the Bru1 gene (21.6% of the affected varieties have the gene) and those that lack it. In addition, the disease has also been absent in varieties that lack the Bru1 gene (34% of the resistant varieties) (Gutiérrez, A.F., unpublished information).

Conclusions

Brown rust was found affecting some resistant varieties developed by CENICAÑA. Rust resistance has been consistent in the varieties CC 85-92, CC 84-75, CC 93-3895 and CC 92-2804.

The results obtained in this study did not show genetic variability among different samples of brown rust collected from Colombian sugarcane crops.

Studies that use other more informative molecular markers, such as AFLP and cDNA-AFLP, or that include sequencing of the fragments similar to that obtained with PCR may be required to detect nucleotide changes among the evaluated samples. This will help confirm the existence or not of genetic diversity in the rust isolates.

MOTS CLÉS: Canne à sucre, Rouille Brune, Incidence de Maladie, Résistance, ADN Ribosomique (rDNA), Races Physiologiques.

Résumé
Les variétés CC 85-92 et CC 84-75, initialement résistantes à la rouille brune, sont cultivées sur plus de 80% de la superficie sous canne à sucre en Colombie. La maladie est présente en Colombie depuis 1979. La variabilité génétique du *Puccinia melanocephala* est estimée avoir affecté la résistance de certaines variétés par l’apparition de nouvelles races du pathogène. Cette situation a été observée dans quelques variétés résistantes (e.g. CC 85-92, CC 84-75, CC 93-3895) où la maladie était apparue à faible intensité. En conséquence, une évaluation de la sévérité et de la variabilité de la rouille brune a été effectuée dans les variétés sélectionnées par le CENICAÑA dans la vallée de la Rivière Cauca. Les échantillons ont été collectés des variétés CC 84-75, CC 85-92, CC 93-3895, CC 92-2804 et MZC 74-275, âgées de 1–14 mois, sur 91 établissements (10 sucreries). Pour chaque plantation, 20 tiges ont été choisies au hasard, et la troisième feuille de TVD collectée de chaque tige. La réaction et la sévérité face à la maladie étaient évaluées. Des analyses morphologiques et microscopiques de la structure des pustules de rouille étaient entreprises sur les échantillons de feuille pour chaque variété. Simultanément, des échantillons du pathogène ont été collectés et analysés par les techniques de biologie moléculaire (en se focalisant sur les initiateurs d’ADN ribosomique (rDNA)) pour détecter une éventuelle variabilité génétique du *P. melanocephala*. La réaction des variétés testées atteignait au maximum le niveau 5 sur l’échelle d’évaluation, avec des sévérités s’étendant de 0-12% de la surface de la feuille. La variété MZC 74-275 a montré une sensibilité de niveau 6 et une sévérité de 20% sur tous les établissements où elle a été évaluée. Aucune différence n’a été observée parmi les structures morphologiques dans les échantillons, toutes correspondaient au *P. melanocephala*. Les résultats obtenus de l’amplification des régions ITS1 et ITS2 de la rDNA et de la PCR-RFLP n’ont pas montré de différence parmi les échantillons examinés. Ces résultats démontreraient que la variabilité du pathogène ne se situait pas au niveau de son rDNA ou bien que les techniques moléculaires utilisées n’étaient pas suffisamment sensibles pour détecter des variabilités minimes dans le génome. Les résultats initiaux sur la présence ou l’absence du gène *Bru1* et la sensibilité à la rouille brune sont discutés.
SEGUIMIENTO Y VARIABILIDAD DE LA ROYA CAFÉ (*Puccinia melanocephala*) EN

ADN ribosomial (ADNr), Resistencia, Variación.

Resumen

Las variedades CC 85-92 y CC 84-75 ocupan más de los 80% del área sembrada con caña en el sector azucarero colombiano, variedades inicialmente resistentes a la roya cafí. Esta enfermedad se encuentra presente en Colombia desde 1979. La posible variación genética de *P. melanocephala* ha afectado la resistencia en algunas variedades probablemente debido a la aparición de nuevas razas del patógeno. Esta situación se ha observado en algunas variedades resistentes (CC 85-92, CC 84-75, CC 93-3895, etc.) y en donde recientemente se ha observado la enfermedad con baja severidad. Por lo cual se procedió a evaluar la severidad y variabilidad de la roya cafí en las variedades seleccionadas por Cenicana en el valle del río Cauca. Se realizaron visitas a 91 haciendas de 10 ingenios sembrados con las variedades CC 84-75, CC 85-92, CC 93-3895, CC 92-2804 y MZC 74-275. En cada plantación se tomó al azar la tercera hoja a partir de la hoja TVD de 20 tallos y se evaluó la reacción y severidad de la enfermedad. Un análisis morfológico y microscópico de las estructuras encontradas en las pústulas de las diferentes variedades se realizó en las muestras recolectadas. Simultáneamente se realizó la recolección de diferentes muestras del hongo y mediante el uso de técnicas moleculares (ADN ribosomal (ADNr)), se determinaron las relaciones filogenéticas y variaciones genéticas en el hongo. Se evaluaron plantaciones desde los 1 a 14 meses de edad. Los resultados mostraron que en las variedades evaluadas el tipo de pústula fue de 5 o menos con severidades entre 0 y 12%. En las haciendas evaluadas con MZC 74-275, la variedad presentó susceptibilidad con reacción 6 y severidad del 20%. No se encontraron diferencias entre las estructuras morfológicas en las muestras evaluadas y correspondieron a *P. melanocephala*. Los resultados de la amplificación de las regiones ITS1 e ITS2 del ADNr no mostraron diferencias entre las muestras evaluadas. Por esto se procedió a realizar digestión de los productos de PCR con enzimas de restricción, sin embargo tampoco se observaron diferencias entre las muestras. Estos resultados podrían indicar que la variación del patógeno no se refleja en su ADNr o que la técnica molecular utilizada no es lo suficientemente sensible para detectar pequeñas variaciones en el genoma. Resultados iniciales sobre la presencia o ausencia del gen Bru1 y la susceptibilidad a la roya son discutidos.
ROOT AND BASAL STEM ROT DISEASE OF SUGARCANE IN LAMPUNG, INDONESIA

By

REMAJA SITEPU, SUNARYO, KOKO WIDYATMOKO and HERI PURWOKO

PT Gunung Madu Plantations, Lampung, Indonesia
remajas@risetgmp.com

KEYWORDS: Xylaria sp., Stroma, Yield Loss.

Abstract

The root and basal stem rot disease is new to Indonesia. It was detected in 1993 on a commercial variety grown in Gunung Madu sugarcane plantation, Lampung. Infected plants have been more frequently found thereafter on newer varieties and the disease is becoming more important to the plantation. Based on field observations, the infection in contaminated fields may reach 11% stalk infection. Symptoms appear on mature plant crops (9 month and older), and on younger plants in ratoon crops (5 month and older), as yellowing or drying of cane leaves. Under very severe infection, the symptoms could be visible much earlier and may be followed by patches of dying stools across the field. Because of the rotten roots and basal stem, the infected plant is easily pulled out of the ground. The key indicator of the infection is the emergence of multiple branched stroma that protrude from the ground around the cane stool, and from the dead stubbles. In general, the disease characteristics are very similar to the root and basal stem rot disease reported from Taiwan. The CABI Identification Services, England, upon examinations on the anamorphic and teleomorphic states of the causal pathogen, has almost certainly confirmed that the causal pathogen in Indonesia and Taiwan is similar, namely Xylaria cf. warburgii. Yield loss assessment conducted on artificially inoculated plant crops in the field revealed that at 25–26% infection severity the particular disease could potentially reduce the cane and sugar yield by 12.3% and 15.4%, respectively.

Introduction

The root and basal stem rot, a relatively new and rare disease of sugarcane, was first reported from Taiwan. Fang et al. (1986) reported that the disease was caused by Xylaria cf. warburgii. A disease with similar characteristics was detected in 1993 in Indonesia, on a commercial variety grown in PT Gunung Madu Plantations (GMP), a sugar plantation in Lampung province (approximately 4°42'S/105°12’E).

The characteristics of the disease are similar to that reported from Taiwan. Quite often disease occurrence is recognised very late, where patches of drying and dying stools across the field have become very pronounced.

Infected plants have been more frequently found on newer varieties thereafter, and the disease is becoming more important in GMP. Based on field observations in 2002–2007, the infection in contaminated fields may reach 11% stalk infection (unpublished data). Fang et al. (1994) in Taiwan estimated that X. warburgii caused a yield loss of 5% in plant crops and 30% or higher in ratoons.

Despite the similarity, it was not clear whether the causal pathogen is the same as in Taiwan. The present paper reports the findings of studies related to the disease in GMP. The studies have been conducted since 2002, aiming to characterise disease infection in the field; to understand fungus morphology for necessary identification and pathogen confirmation; and to assess yield loss.
caused by the disease. The outputs are expected to complement current knowledge on this rare disease of sugarcane.

**Material and methods**

**Characterisation of disease infection in the field**

This is to characterise typical appearance of disease infection in the field, to help plantation staff to be alerted to any symptoms of disease. Spots with premature yellowing or drying leaves in mature plant crops were inspected. The stalks were pulled out and split longitudinally. Typical appearance of both above- and underground parts was then characterised upon confirmation of disease infection. Similar approaches but on younger canes were done in ratoons.

**Morphological description**

Materials from infected plants, including protruding stromata associated with the infection in the fields, were collected and brought to the laboratory for detailed morphological examination under the microscope. The morphological description was used for pathogen identification.

**Confirmation of pathogen**

The basal stems of the infected plants were thoroughly cleaned, split up, and chopped to take a small piece (ca. 1 cm³) of stem tissues covering the transitional zone of the advancing pathogen and healthy tissue in front of it. This material was rinsed and dipped in an alcohol solution for 5 min. and the rind was removed aseptically. The inner portion was finely sliced and transferred to a PDA medium containing terramycin 0.02%. The developing culture was purified and the pure isolates were further propagated on the same media to be used on second step propagation on coarse media.

Mango twigs media were used for second propagation, following Fang et al. (1986) and Fang et al. (1994). In the present study, the same isolates were also propagated on fine slices of sugarcane tissues. The mango twigs and sugarcane slices were dipped separately in water for 2 hrs and transferred into 500 mL flasks. About 300 g of each medium was put in a flask. The flasks and these coarse media were autoclaved for 1 h (121°C, 15 psi), and this step was repeated one more time the next day. One tube of pure isolates as already prepared (of 1 month age) was used to inoculate each flask of coarse medium, followed by incubation for 2 months under 26–28°C. The colonies produced were used to inoculate the plants in subsequent pot/poly-bag experiment.

The use of colonies on coarse media, rather than on standard agar media, was preferred for an inoculation under soil environment in a pot experiment. A previous experiment suggested that standard inoculum failed to enhance infection of fungus on target plants under such environment, likely because the inoculated fungus could not persist for a longer time due to limited nutrient reserves in the standard agar medium.

The fungi colony would find the mango twigs and sugarcane slices as better nutrient resources in the soil before any infection on target tissues could take place.

Sugarcane and maize were used as test-plants. They were grown on poly-bags filled with 10 kg pre-sterilised soils. Maize was selected for having a shorter life cycle which should facilitate the trial, while it was also reported as susceptible and responsive to root and basal stem rot disease infection in Taiwan (Fang et al. 1994).

Each poly-bag with two plants of either sugarcane or maize was inoculated by burying (5–10 cm deep) the previously prepared colonies (inoculated mango twigs and sugarcane tissues). Sterilised, non-inoculated mango twigs and sugarcane materials were buried instead in control treatments. Each treatment was replicated 5 times. Regular watering was done to maintain plant growth but no fertiliser was applied.

Any wilting, yellowing, or drying plant was pulled out of the poly-bag. The basal stem was split and observed for any disease symptom. The diseased tissues were again isolated to confirm the causal pathogen.
Yield loss assessment

A field experiment was carried out in plant cane in 2002–2003. Plot size was 9 rows x 10 m. Two local varieties (GM19 and PSGM88-5052) with three inoculum dosages (0/control, 250 g, and 500 g for each metre of row) were used. A complete randomised block design with 3 replications was applied.

Inoculum was prepared by shredding the roots and basal stems of diseased plants. The materials were air dried for 2–3 weeks under ambient temperature. At planting, these inoculum materials were broadcast on the bottom of planting furrows, and then the cane setts were manually planted and covered.

The observations were done at harvest age. Three rows in each plot were dug out and the number of millable stalks per metre was counted. The length of discoloration (representing infection symptom) and stalk diameter were measured, then the ratio of length of symptom to stalk diameter was calculated. The ratio figures were specifically used in the assessment of severity of infection, to eliminate any bias on disease impacts that may have resulted from variable stalk diameter within the stalk population. Disease infection severity was then calculated by the following formula,

\[ I = \sum \frac{(n \cdot v)}{N \cdot V} \times 100\% \]

where

- \( I \) = disease infection severity
- \( n \) = number of stalks having a common value of disease symptom (in 3 sample rows)
- \( v \) = value of symptom (0, 1, 2, 3, or 4), see Table 1 for classification
- \( N \) = total number of stalks (in 3 sample rows)
- \( V \) = highest value of symptom (=4)

Table 1—Classification of symptom value.

<table>
<thead>
<tr>
<th>Symptom length : stalk diameter (x)</th>
<th>Symptom value (v)</th>
</tr>
</thead>
<tbody>

</tbody>
</table>

Ten sample stalks from each plot were weighed and subsequently crushed by using a laboratory mill for juice pol analysis. Differences of stalk weight and pol % juice between controls (without artificial inoculation) and treated plots (with artificial inoculation) would represent yield and sucrose losses.

Results and discussion

Characterisation of disease infection in the fields

In general, the characteristics of disease infection were similar to those described in Taiwan. In plant crops, disease infection is visible on mature plants of 9 months or older. When the rotten section at the basal stem becomes so extensive and reaches ground level, the leaves would start yellowing and drying. At this condition, the plants are easily pulled out of the ground because the roots and the basal stem have already rotted and dried. Upon splitting, the infected tissues looked pale and many lateral lines or spots, dirty white in colour, are clearly visible, representing fungal mycelia.

In ratoon crops, the drying leaves could be found on younger canes, namely on 5–7 month old plants. The symptoms here appear earlier because the infection is actually a continuation of
previous infection (in plant crops), developing from old stubbles to the newly growing tillers (secondary infection). There will be patches of depleted tiller population under very severe infection. These patches are visible as early as on 1.5 to 4 month old canes. The size of the patches varies from very small to 100 m² or even wider, wherein invasion of weeds would easily take place.

The key indicator of the infection of root and basal stem rot disease in the field is the occurrence of white tipped black stromata protruding from the dead stubbles or from underground parts around the sugarcane stool. Upon splitting, the diseased tissues smell like rotten wood. A strong sour smell is never associated with this disease.

Under closer observation, there are actually two types of stroma found in the fields. The first one has multiple branches with abundant white conidia easily visible on their tips, which is easily found in the contaminated fields.

The second one has a sausage-like fruiting body, a single structure with no branches. Both stroma have black external appearance but they are white inside. A detailed morphological description was obtained after microscopic examination.

**Morphological description and pathogen identification**

The multiple-branched stroma is the anamorphic state and may be considered as sterile stroma (Fang et al., 1994). Conidia isolates from GMP consisted of single cells, hyaline, and have an oval form. The conidia size here is bigger compared to those reported from Taiwan. On average they are 5.0–13.0 µm long by 2.5–8.0 µm wide, compared to 4.0–8.0 µm by 1.8–2.1 µm of the Taiwanese (Fang et al., 1994).

The second type with sausage-like fruiting body is the teleomorphic state. It is clear under the microscope that the rough surface of the fruiting body actually consists of perithecia, and reported as perithecial-stroma by Fang et al. (1994). The size of the ascospores is also slightly bigger compared to those found in Taiwan. They are 13.8–15.8 µm by 4.6–5.3 µm while, in Taiwan, they are 11–12 µm by 4–5 µm (Fang et al., 1994).

Based on the above morphological description, supported by available references particularly from Taiwan, it is suggested that the pathogen associated with root and basal stem root disease in GMP, Indonesia, is a *Xylaria* sp. Alexopoulos and Mims (1979) stated that the Xylariaceae family are mostly saprophytic or weakly parasitic of fungi on woody plants.

Their stromata are usually epixylous, stipitate, filiform to sausage-shaped, black outside but mostly white internally, and produce their perithecia over the entire fertile portion above the stipe.

Specimens for identification have been sent to CABI (Centre for Agriculture and Bioscience International) Identification Services, England. The Centre’s taxonomist at first had some difficulties in making identification when only the anamorphic state was available.

After the teleomorphic state was made available, he reported that the specimens were almost certainly the same species as the sugarcane pathogen referred to in Taiwan as *Xylaria* cf. *warburgii*. This species was originally described from New Caledonia from rotten fruit of *Sloanea* (Elaeocarpaceae), and is unlikely to be conspecific with the sugarcane fungus. ITS (internal transcribed spacer) sequence analysis confirmed that the fungus was a species of *Xylaria*, but there are no publically accessible ITS sequences of *X. cf. warburgii* (Cannon, 2009a, b).

**Confirmation of pathogen**

Fungus mycelia grew more profusely on mango twigs compared to on sugarcane slices. At the time of inoculation into the poly-bag, the mycelia have nearly covered the entire surface of the mango twigs while, on sugarcane slices, the mycelia did not grow on the sugarcane rind surface.

Disease infection was observed on the 75th day on maize plants, where initial symptoms have been visible at the basal stem and the leaves turned into straw colour. On sugarcane plants, the typical symptoms at ground level developed after 5.5 months. The extent of infection on the two test plants is presented in Table 2.

It is shown that the infection took place only on plants inoculated with either mango twigs or sugarcane slices which were already colonised by the fungus, and there was no infection on plants ‘inoculated’ by sterilised materials. The infected maize and sugarcane plants in the poly-bags showed the same symptom as those on naturally infected plants in the fields. Because of restricted environment in the poly-bags, disease symptoms on sugarcane plants were developed earlier, on 5.5 month old plants, compared to 9 month old plants under natural environment in the fields.

The infected maize plants were chopped and some 20 pieces of infected tissues were then isolated in the laboratory. The culture produced the same fungus as originally inoculated. It confirmed that this particular fungus species, having such typical stromata which is easily found with or around the diseased plants in the fields, is the causal pathogen of the root and basal stem rot disease in GMP, Indonesia.

Cane seedpieces (setts) were used in this poly-bag experiment. Upon splitting the infected stalk, it could be suggested that the infection started from the sett roots or from root primordia encircling the nodes. Lines of mycelia were clearly visible on the nodes but not on the internodes. The infection was then expanded from the setts toward basal parts of the newly growing tillers.

Yield loss assessment

The two varieties used did not cause any significant effect on infection severity, stalk population, stalk weight, and pol % juice. There was also no significant effect on all parameters related to interaction of variety x inoculum dosage.

Table 3—Effect of inoculum dosage on plant crop.

<td>0.10</td>
<td>0.60</td>
</tr>
</tbody>
</table>

Inoculum dosage, however, gave significant effect on infection severity, stalk weight, and pol % juice, but not on stalk population (Table 3). The infection on sugarcane plants through artificial inoculation under a field environment took place effectively. The infection severity was only 0.30% on the controls (without artificial inoculation), significantly lower than on 250 g and 500 g inoculum treatments (25.09% and 26.22% respectively). There was no significant difference between 250 g and 500 g inoculum treatments. (The smaller dosage should be sufficiently effective for use in any future studies involving field inoculation).

The ‘healthy’ plants (controls, without artificial inoculation) had significantly higher stalk weight compared to the diseased ones of the other two treatments, which suffered from 25.1% and 26.2% infection severity. Compared to the controls, the stalk weight of the other two treatments was 12.3% lower. Similarly, the pol % juice (representing sucrose content) on the diseased plants was...
significantly lower (around 3.5% in percentage) compared to the controls. Roughly, with infection severity of 25–26%, the root and basal stem rot disease could potentially reduce the cane and sugar yield on plant crops by 12.3% and 15.4%, respectively.

Conclusions

The root and basal stem rot disease found in GMP sugarcane plantation, Indonesia, is almost certainly caused by *Xylaria* cf. *warburgii*, similar to the causal pathogen of root and basal stem rot disease in Taiwan. However, the size of fungus conidia and ascospores here is somewhat larger compared to the Taiwanese.

The disease typically caused yellowing or drying of leaves on mature plant crops (9 month old) and on younger plants on ratoons (5 month old). Under very severe infection the symptoms could be visible much earlier and there will be patches of dying stools across the field. The most important indicator of disease infection in the field is the emergence of multiple branched stromata off the ground, around the cane stool, and from the dead stubbles.

At 25–26% infection severity on plant crops, the root and basal stem rot disease could potentially reduce cane and sugar yield by 12.3% and 15.4%, respectively.

REFERENCES

mortalité de souches à travers le champ. De par le fait que les racines sont pourries, la plante infectée est facilement arrachée. L’indicateur clé de l’infection consiste en une apparition de branches multiples de stroma sortant de terre autour de la base de la souche et des souches mortes. En général, les caractéristiques de la maladie sont similaires à la pourriture basale des racines et de la tige comme rapporté au Taiwan. Le CABI Identification Services, en Angleterre, après examen des stades anamorphique et téléomorphique, a presque confirmé que l’agent causal en Indonésie et au Taiwan est similaire, notamment le *Xylaria cf. warburgii*. Une évaluation de l’effet de la maladie sur le rendement a été effectuée en inoculant les plantes artificiellement au champ. Il a été démontré qu’une infection de 25–26%, pourrait occasionner une chute potentielle en rendement de canne et en sucre de 12.3% et 15.4%, respectivement.

**PUDRICIÓN BASAL DEL TALLO Y RAÍCES DE LA CAÑA DE AZÚCAR EN LAMPUNG, INDONESIA**

Por

REMAJA SITEPU, SUNARYO, KOKO WIDYATMOKO y HERI PURWOKO

*PT Gunung Madu Plantations, Lampung – Indonesia*

**Resumen**

La pudrición basal del tallo y raíz es una enfermedad nueva para Indonesia. La afección se detectó en 1993 en una variedad comercial cultivada en Gunung Madu, Lampung. Desde entonces, se han encontrado plantas afectadas con mayor frecuencia en las nuevas variedades, convirtiéndose la enfermedad en importante para las plantaciones comerciales. Con base en las observaciones de campo, la infección en los campos afectados puede llegar a 11% de tallos enfermos. Los síntomas aparecen en las plantillas con plantas maduras (9 meses de edad o más), y en las socas, en plantas más jóvenes (5 meses o más), como un amarillamiento o secamiento de las hojas. En los casos de mayor severidad, los síntomas pueden ocurrir mucho antes, seguidos por la producción de parches de cepas muertas en el campo. Debido a la pudrición basal de los tallos y raíces, las plantas afectadas se pueden arrancar con facilidad. Un indicador clave de la infección es la aparición de estromas ramificados que aparecen en la tierra, alrededor de las cepas afectadas o brotes muertos. En general, las características de la enfermedad son muy similares a la pudrición basal del tallo y raíz registrada en Taiwán. Los servicios de identificación de CABI, Inglaterra, en los exámenes a los estados anamórfico y teleomórfico del patógeno causal, confirmaron que los agentes causales en Indonesia y Taiwán son similares, es decir, *Xylaria cf. warburgii*. La evaluación de pérdidas en la producción realizados en plantas inoculadas artificialmente en el campo mostraron que con una severidad entre el 25–26%, la enfermedad puede reducir la producción de caña y azúcar en 12.3% y 15.4%, respectivamente.
RESISTANCE SCREENING OF PROMISING SUGARCANE CLONES TO TWO RACES OF GUMMING DISEASE BACTERIUM

By

S. DHAYAN and A.S. SAUMTALLY
Mauritius Sugar Industry Research Institute (MSIRI), Réduit, Mauritius
ssaumtally@msiri.intnet.mu

KEYWORDS: Disease Resistance, Gumming Disease, Sugarcane, Xanthomonas Axonopodis Pv. Vasculorum.

Abstract
TWO RACES of the gumming disease bacterium (Xanthomonas axonopodis pv. vasculorum), Races 1 and 2, commonly infect sugarcane varieties in Mauritius. Clones selected from the 3rd clonal stage (years 4–5) of the breeding program are screened for resistance to these two races. From 1998 to 2007, 878 clones were tested in disease resistance trials in localities where the races are prevalent. Inoculated spreader rows of a susceptible variety act as the source of inoculum for the test varieties. Evaluation to Race 1 was carried out at one site; whereas, testing against Race 2 was conducted at two to four sites. Screening showed that 99% of clones were immune to Race 1. Of the 9 clones that showed infection, seven were classified as resistant, one slightly susceptible and one susceptible. In contrast, the percentage of clones showing immunity to Race 2 was much lower (14%). Resistance, slight susceptibility, susceptible, and high susceptibility to Race 2 were 44%, 23%, 13% and 6%, respectively, among the remainder of the clones. Ratings were consistent across locations for 78% of clones. Evaluation at more than one site was consequently justified. The pathogen was isolated from commercial fields in regions prone to the disease and in germplasm collections during the period 1998–2007. Race characterisation was based on cultural characteristics and pathogenicity tests. Race 1 was readily recovered in noble cane collections. Apart from one instance in 1998, it was absent in commercial fields. These surveys confirmed that commercial varieties were highly resistant to Race 1 and, therefore, of insignificant importance in Saccharum hybrids. Gumming disease prevalent in plantations was therefore almost exclusively caused by Race 2. This race was predominant and resistance screening against it in different environments is necessary.

Introduction
Gumming disease of sugarcane caused by Xanthomonas axonopodis pv. vasculorum is present in some 25 countries (Rott and Girard, 2000). The population of the pathogen is heterogeneous and five groups have been characterised on the basis of fatty acid analysis and genetic variability (Dookun et al., 2000; Saumtally, 1996). It is considered as the most important bacterial disease of sugarcane in Mauritius and three races, Races 1, 2 and 3 have been reported in order of their appearance (Ricaud and Autrey, 1989). Race 1 dates back to 1848, infects noble cane (Saccharum officinarum) and was presumably introduced when sugarcane was brought for cultivation on the island. Noble canes are no longer cultivated but this race can be readily found in germplasm collections. Race 2 appeared in 1964 and caused an epidemic on cultivar M 147/44. It is frequently encountered in parts of the island on susceptible varieties. Race 3 appeared in epidemic proportion in 1980 and particularly affected varieties M 442/51, M 31/45 and M 377/56. The latter two varieties were released as resistant to the disease. With the eradication of M 377/56, Race 3 has
been absent in sugarcane fields for a number of years. Control of gumming disease relies on preventive measures such as sanitation, disease-free planting material and, more importantly, the cultivation of resistant varieties. The latter has been very effective in minimising the spread of the disease and has led to its eradication in Australia and West Indies as well as reducing its impact in Brazil, the Caribbean Islands and Fiji (Ricaud and Autrey, 1989). In Mauritius, screening of clones is during years 4–5 of the 9–12 year selection program, when the number of varieties is reduced to less than 150. Variety evaluation is conducted at different sites, in relationship to the distribution of the races of the pathogen. Because of the absence of Race 3 during recent years, screening to this race has been discontinued. This paper analyses the results of variety evaluation to Races 1 and 2 from 1998 to 2007, and discusses the necessity of screening varieties to the disease in the light of the distribution of the races around the island.

Materials and methods

Resistance screening and disease ratings

Varieties selected from the 3rd clonal stage of the breeding program (years 4–5) were planted in July each year in resistance trials for evaluation of resistance to \( \textit{X} \alpha \textit{pv. vasculorum} \). Testing for resistance to Race 1 was conducted at one site (Réduit), while trials for resistance to Race 2 were established at two to four sites (Case Noyale, Ferney, Médine and Yemen). In all trials, highly susceptible varieties, acting as spreader rows, were inoculated in January with a bacterial suspension of either Race 1 or Race 2 at a concentration varying from \( 1 \times 10^8 \)–\( 10^9 \) cells/mL. Varieties under evaluation were planted on 3 m-row flanked by the artificially infected varieties. Test varieties along a row were also separated by a strip of inoculated varieties. Mixed \( \textit{S officinarum} \) clones acted as spreader rows for Race 1, while varieties M 147/44 and M 377/56 were used as inoculum lines for Race 2. The pathogen was naturally transmitted by leaf contact to the test varieties planted without replication.

Standards included in Race 1 trials were varieties M 147/44, M 31/45, M 377/56, M 3035/66 (all resistant), B 34104 and M 55/1182 (both highly susceptible). With the exception of M 31/45, also a resistant standard for Race 2, all resistant controls for Race 1 were included in Race 2 trials as susceptible checks, while M 442/51 was the slightly susceptible control for this race. Assessment was carried out 6 and 8 months after inoculation on a qualitative scale based on the severity of infection as follows: absence (immune), short stripes on old leaves (resistant), medium length stripes on old leaves (slightly susceptible), long stripes on old leaves with or without short stripes on young leaves (susceptible). Varieties are considered highly susceptible when they exhibited one or more of the following symptoms: heavy striping with several long stripes, leaf chlorosis, gum exudation and death of stalks. A second 3-point scale was also used to quantify abundance of foliar and systemic infection and further assess the degree of infection: I (low), II (intermediate) and III (high). For any given year, the same clones were evaluated at the different sites.

Collection of isolates and race characterisation

Isolates of \( \textit{X} \alpha \textit{pv. vasculorum} \) were collected from commercial sugarcane fields during island-wide surveys and from variety collections from April to October during 1998–2007. Inspections for gumming disease in susceptible varieties were made at locations known to be foci of infection. Sites surveyed were Belle Rive, Étoile, Ferney, Le Val, Quatre Soeurs (East), Case Noyale, Le Morne, Médine, Yemen (West), Quatre Bornes and Réduit (Centre). Varieties examined for symptoms were: \( \textit{S officinarum} \) clones, M 147/44, M 377/56, M 351/57, M 555/60, M 3035/66, M 1557/70, M 1286/89, M 2454/95, R 570 and R 579. The pathogen was isolated from sugarcane leaves or stalks. Infected leaf strips were surfaced disinfected with 70% ethanol for 1 min, washed in sterile distilled water (SDW) and directly streaked on sucrose peptone medium (composition per litre: peptone, 5.0 g; \( \text{KH}_2\text{PO}_4 \), 0.5 g; \( \text{MgSO}_4 \cdot 7\text{H}_2\text{O} \), 0.25 g; sucrose, 20 g; agar 15.0 g; pH 7.0). Diseased stalks were washed and the node thinly sliced after removing the rind. The sliced pieces
were allowed to diffuse in 5 mL SDW for 30 min before streaking the suspension on sucrose peptone medium. The incubation period was 3–5 days at 30°C.

Races were distinguished by their growth habit on TZC agar slants (composition per litre: peptone, 10 g; glucose, 5 g, casein hydrolysate, 1 g; tetrazolium chloride, 0.05 g; agar 15 g; pH 7.2) after 7–10 days incubation at 30°C. Race 1 is distinguished from Race 2 by the formation of a compact growth at the top of the tube owing to its viscous exopolysaccharide (EPS). In contrast, the EPS of Race 2 is more fluid and the colony flows down to the bottom of the slant. Confirmation of race identity was obtained by pathogenicity tests using noble cane varieties Iscambine Stripe, Senneville (*S. officinarum*) as well as hybrids M 147/44, M 31/45 and M 3035/66. Inoculated plants required monitoring for symptom development for up to two months. Race 1 infects the noble canes but none of the hybrids. Race 2 induces symptoms in all varieties, except M 31/45. Symptoms expression also differed between the two races. Race 1 only rarely causes slight leaf chlorosis. This symptom is common and intense in plants inoculated with Race 2.

Inoculum pressure was adequate in the trials. For Race 1, the highly susceptible checks displayed the most severe symptoms of the disease. On the other hand, *Saccharum* hybrid controls were all immune to this race. For Race 2, the highly susceptible cultivars M 147/44, M 377/56 and M 3035/66 exhibited susceptibility to high susceptibility in all trials in conformance to their observed field reactions. The resistant variety M 31/45 displayed a resistant reaction to the two races, while M 442/51 was slightly susceptible to Race 2.

Screening to Race 1 revealed that most of the clones were immune. Of the 878 clones tested, 99% did not show any symptom to this race. Of the 9 clones that were infected, seven were resistant (M 1226/91, M 1954/91, M 1487/92, M 2773/94, M 2655/95, M 1641/97 and M 2181/00), one slightly susceptible (M 3096/94) and one susceptible (M 1866/90). When comparing the reactions of Race 1 resistant clones to that obtained with Race 2, all were more susceptible to the latter race, except clone M 1954/91 which was also resistant. Clone M 3096/94 was slightly susceptible to both races. However, inversely to the other clones, M 1866/90 susceptible to Race 1 was resistant to Race 2.
Resistance trials to Race 2 from 1998–2007 showed that the ratings were consistent for most of the clones across two or more sites where the varieties were evaluated. However, in 196 cases (22%), the reactions were variable. Overall, the percentage of promising clones immune, resistant, slightly susceptible, susceptible and highly susceptible to Race 2 were 14%, 44%, 23%, 13% and 6% respectively (Figure 1). Combining immune, resistant and slightly susceptible reactions, more than 80% of the varieties had adequate resistance to Race 2.

![Fig. 1—Summary of reaction of clones to Race 2 of gumming disease evaluated from 1998–2007.](image)

**Collection of isolates and race characterisation**

Two hundred and sixty isolates were collected between 1998 and 2007 from 10 sugarcane varieties and 13 *S. officinarum* clones situated at 11 locations. Isolations on culture media were taken mostly from foliar stripes, as these were the most frequently encountered symptom, but also from systemically infected stalks. In the latter cases, the varieties concerned were *S. officinarum* and the hybrid M 3035/66. Smooth, circular and very mucoid yellow colonies appeared after 3–4 days on sucrose peptone and recognisable as that of *Xa* pv. *vasculorum*.

The race of the pathogen was determined by sub-culturing the colonies from sucrose peptone agar to tube slants of TZC medium, where the bacterium produced dark red colonies. Race 1 could be differentiated by its compact mucoid growth in contrast to the less viscous Race 2 that flowed down the tube after 4–5 days incubation. Pathogenicity tests were used to differentiate Races 1 and 2.

For Race 1 inoculated in *S. officinarum* clones Iscambine Stripe and Senneville, foliar stripes were yellow at first, then turning necrotic along most of the length of the stripe. Leaf chlorosis in noble canes was slight and of rare occurrence, as the infection progressed and became systemic. Race 1 was not capable of causing lasting infection for more than two weeks in hybrid varieties and foliar symptoms eventually disappeared. In contrast, Race 2 produced long yellow stripes and intense leaf chlorosis in hybrids M 147/44, M 377/56 and M 3035/66 and *S. officinarum* clones. None of the two races could infect variety M 31/45.

Of the 260 isolates obtained, 97 of them belonged to Race 1. The race was isolated from *S. officinarum* clones in germplasm collections present at Réduit. It was absent at all other sampling sites, except in one instance in 1998 when it was found in variety R 570 at Quatre Soeurs. It was not
found in subsequent surveys, except at Réduit. Race 2 was not isolated from *Saccharum* hybrids at Réduit but could be isolated from plantations at all other locations.

**Discussion**

In breeding programs across the world, resistance to main diseases is one of the major objectives. In Australia, clones are tested for resistance to diseases such as chlorotic streak, Fiji leaf gall, leaf scald, mosaic, orange rust, pachymetra root rot, ratoon stunt, red rot, smut and yellow spot in disease resistance trials and Final Assessment Trials before being approved for cultivation by the industry (Croft *et al.*, 2000, Croft, *et al.*, 2008, Magarey *et al.*, 2009). In Louisiana and Florida, USA, varieties are evaluated for dry top rot, eye spot, leaf scald, mosaic, ratoon stunt, rust, smut and yellow leaf. In Mauritius, sugarcane varieties are tested against gumming, leaf scald, rust, smut and yellow spot. The general policy is that a variety susceptible to a particular disease is not recommended in an area where the disease is prevalent.

Variety improvement programs aim at crossing parents with adequate resistance to obtain a high proportion of resistant progeny. Nonetheless, owing to the heterozygous polyploid nature of sugarcane, resistance screening is necessary. Resistance is an important component in the management of sugarcane diseases and has proved powerful for controlling gumming disease. Screening needs to take into account the occurrence of variants of the pathogen that exist in the environment. Thus, evaluation of clones to gumming disease was started in Mauritius in 1932 and at that time resistance trials were established against Race 1.

With the appearance of new races, clones were simultaneously screened in 1964 and then in 1982 to Race 2 and Race 3 respectively. Gumming disease is considered to be a serious threat and, during the past 25 years, only two susceptible varieties, M 3035/66 and R 579, have been released in Mauritius for specific localities where the disease is not prevalent. This approach has been instrumental in managing the disease effectively.

In countries such as Brazil and Australia, the cultivation of resistant clones has been successful to the extent that the disease has been eradicated or reduced to low levels. Legislation for the replacement of susceptible varieties by resistant ones has been promulgated in Australia and Mauritius during gumming disease epidemics with positive effects (Ricaud and Autrey, 1989). In Mauritius, with the replacement of variety M 377/56, Race 3, the cause of an epidemic on this variety, can no longer be observed in sugarcane fields.

Data obtained from resistance trials from 1998 to 2007 showed that 99% of clones tested were immune to Race 1. Resistance to Race 2 was also high (58%), reaching over 80% if slightly susceptible varieties are included. However, compared to Race 1, the magnitude of resistant clones was much less. Race 1 occurs mostly at Réduit and, in that respect, this location had been chosen for variety testing against this race.

In contrast, Race 2 is more widely distributed, hence the choice of diverse sites and also as a measure of its importance in commercial fields. Screening against Race 2 at more than one location is justified owing to discrepancies recorded between sites. The final disease rating of a variety to this race is based on the highest score obtained. Surveys conducted during 10 years showed that Race 1 was recovered only once in commercial fields. In contrast, Race 2 was more predominant on *Saccharum* hybrids and is almost exclusively the race isolated from commercial sugarcane fields. The results of screening and race distribution indicate that the potential of Race 1 in causing disease in hybrids is low compared to Race 2.

The marked difference in variety reactions calls for a reassessment of the status of the races of the bacterium. The variability could well be more profound. Races 1 and 2 are distinguishable by several methods, including cultural characteristics, pathogenicity tests, serology, fatty acids profile, restriction fingerprinting and restriction fragment length polymorphisms (Dookun *et al.*, 2000; Saumtally, 1996; Vauterin *et al.*, 1995).
Despite the fact that the occurrence of Race 1 is insignificant in commercial fields and almost all the clones evaluated are resistant, it is proposed to continue screening with regards to the development of new types of varieties, with different genetic background compared to current ones, meant for biomass and fibre production. Furthermore, gumming disease is known to infect palms, broom bamboo, Guatemala grass and maize. A thorough search of $Xa$ pv. *vasculorum* on these hosts would provide a more comprehensive study on race distribution of the pathogen.

**Conclusions**

The establishment of systematic resistance trials to races of the gumming disease pathogen in Mauritius is a unique situation in sugarcane variety screening. The disease reactions of the various clones and island-wide collection of isolates have allowed an assessment of the threat posed by the disease.

The low ability of Race 1 to cause disease in current sugarcane genotypes, the absence of Race 3 in sugarcane fields and an overall decrease in gumming disease pressure during the last 25 years is comforting. Nevertheless, the identification of resistant varieties should continue so as to further decrease inoculum pressure.

**Acknowledgements**

The authors wish to thank Mr S. Sullivan for his participation in disease resistance trials and Dr H. Khoodoo for the collection of isolates from 2005 to 2007.

MOTS CLÉS: Résistance aux Maladies, Gommose, Canne à Sucre, Xanthomonas Axonopodis Pv. Vasculorum.

Résumé

DEUX RACES de la bactérie de la gommose (Xanthomonas axonopodis pv. vasculorum), Races 1 et 2, causent régulièrement une infection de la canne à sucre à Maurice. Les clones issus du 3ème stade clonal (4–5 années) du programme d’amélioration génétique sont évalués pour leur résistance aux deux races. De 1998 à 2007, 878 clones ont été testés dans des essais d’évaluations dans divers sites où les races sont présentes. Des rangs de canne des variétés sensibles artificiellement inoculées agissaient comme source de dissémination de la maladie aux variétés en évaluation. Le criblage à la Race 1 fut effectué sur un site et sur deux à quatre sites pour la Race 2. Les résultats de ces essais ont montré que 99% des clones étaient immunes à la Race 1. Des 9 clones qui étaient infectés à divers degrés, sept étaient résistants, un légèrement sensible et un sensible. Le pourcentage de clones démontrant une immunité à la Race 2 était bien plus faible (14%). Les pourcentages de clones résistants, légèrement sensibles, sensibles et très sensibles étaient de 44%, 23%, 13% et 6% respectivement. L’évaluation était consistante d’un site à l’autre pour 78% des clones. L’établissement des essais sur plus d’un site est conséquemment nécessaire pour une évaluation fiable. Le pathogène a été isolé des champs industriels dans les régions où la maladie est présente ainsi que dans les collections du germoplasme pendant la période 1997–2007. La race de la bactérie fut déterminée sur la base des caractéristiques en milieux de culture et des tests de pathogénicité. La Race 1 était couramment isolée des cannes nobles conservées en collection. À part un cas en 1998, cette race était absente des champs commerciaux. Ces prospections ont confirmé que les variétés industrielles étaient très résistantes à la Race 1 et elle était de ce fait, d’importance mineure. La maladie de la gommose présente dans les champs industriels était donc presque exclusivement causée par la Race 2. Le criblage des variétés contre la Race 2 dans différents environnements est conséquemment nécessaire.
ESQUEMA DE RESISTENCIA A LA GOMÓSIS BACTERIANA EN CLONES AVANZADOS DE CAÑA DE AZÚCAR

Por

S. DHAYAN y A.S. SAUMTALLY
Mauritius Sugar Industry Research Institute (MSIRI), Réduit, Mauritius
ssaumtally@msiri.intnet.mu

Palabras clave: Resistencia a Enfermedades, Gomósis de la Caña de Azúcar, Xanthomonas axonopodis pv. vasculorum.

Resumen
EXISTEN DOS RAZAS de la bacteria causal de la gomósis (Xanthomonas axonopodis pv. vasculorum), razas 1 y 2 que comúnmente infectan a las variedades de caña de azúcar en Mauricio. Los clones seleccionados en el tercer estado clonal (a los 4–5 años) del programa de mejoramiento son examinados para detectar la resistencia a estas dos razas. Desde 1998 hasta 2007, 878 clones fueron evaluados en ensayos de resistencia en las localidades donde son más frecuentes las dos razas. Surcos de una variedad susceptible se inocularon para que se constituyeran en fuente de inóculo para las variedades de la prueba. La evaluación contra la raza 1 se llevó a cabo en un sitio, mientras que contra la raza 2 se llevó a cabo en dos a cuatro sitios. Los resultados mostraron que el 99% de los clones fueron inmunes a la raza 1. De los 9 clones que mostraron infección, siete fueron clasificados como resistentes, uno como levemente susceptible y uno como susceptible. En contraste, el porcentaje de los clones que mostraron inmunidad a la raza 2 fue mucho menor (14%). La resistencia, levemente susceptible, susceptible, y alta susceptibilidad a la raza 2 en el resto de los clones fue de 44%, 23%, 13% y 6%, respectivamente. Las calificaciones fueron consistentes entre localidades para el 78% de los clones. La evaluación en más de un sitio por tanto se justificó. El patógeno siempre se aisló en los campos comerciales en las regiones propensas a la enfermedad y en las colecciones de germoplasma durante el período 1998–2007. La caracterización de las razas se basó en las características culturales y pruebas de patogenicidad. La raza 1 se ha aislado continuamente en colecciones de cultivares nobles de caña. Excepto por un caso en 1998, siempre ha estado ausente en los campos comerciales. Estos estudios confirmaron que las variedades comerciales son altamente resistentes a la raza 1 y, por tanto, de poca importancia para los híbridos de Saccharum. La presencia de la gomósis en las plantaciones comerciales es exclusiva de la raza 2, por tanto, su detección y evaluación por resistencia en contra de ella en diferentes ambientes se considera necesario.
DISTRIBUTION OF SUGARCANE YELLOW LEAF VIRUS (SCYLV) IN COMMERCIAL CULTIVARS IN MAURITIUS AND ITS POTENTIAL IMPACT ON YIELD

By

Mauritius Sugar Industry Research Institute (MSIRI), Rèduit, Mauritius

KEYWORDS: Luteovirus, Melanaphis sacchari, Saccharum officinarum, Yellow Leaf, Yield Loss.

Abstract

Sugarcane yellow leaf virus (ScYLV) is present in most sugarcane producing countries and has been shown to be the cause of yellow leaf disease of sugarcane. This study focused on the distribution of ScYLV in commercial sugarcane varieties in Mauritius and attempted to assess its impact on cane and sucrose yields of three varieties: M52/78 (early maturing), M1400/86 (middle maturing) and M2593/92 (late maturing). An island-wide survey of 88 fields planted with 20 different varieties revealed that ScYLV was widely distributed in all varieties except M1176/77 which always tested negative for the presence of the virus by tissue blot immunoassay (TBlIA) and reverse transcriptase PCR. The incidence of ScYLV did not reflect that of the aphid vector Melanaphis sacchari which was collected from 8% of fields only, implying that the main cause of the spread of the virus in Mauritius was infected cane setts. The potential impact of yellow leaf on Mauritian cultivars was assessed by measuring and comparing yield parameters of TBlIA positive and TBlIA negative cane stool samples in a pair wise design under commercial field conditions. This study showed that, for plant cane, yields were comparable for varieties M52/78, M1400/86 while, in M2593/92, TBlIA positive stools had higher sucrose content but lower weight than TBlIA negative stools. These findings highlight the need for additional research on the main commercial varieties of sugarcane in order to determine the economic importance of the disease in Mauritius.

Introduction

Yellow leaf of sugarcane is caused by Sugarcane yellow leaf virus (ScYLV) and has been reported in many sugarcane producing countries (Lockhart and Cronjé, 2000). The virus is classified as a polerovirus of the family Luteoviridae (D’Arcy and Domier, 2005) and is transmissible by aphid vectors and infected seed cane (Schenck and Lehrer, 2000; Zhou et al., 2006). Previous reports on the occurrence of yellow leaf of sugarcane estimated the potential yield losses in the range of 10–40% (Vega et al., 1997; Lockhart and Cronjé, 2000; Grisham et al., 2002). It is generally agreed that yields of different genotypes of sugarcane are affected at varying extents under different climatic conditions. Differences in virulence and infection capacity of different genotypes of the polerovirus have also been reported (Abu Ahmad et al., 2007). While some cultivars, such as H78-4153 (Schenck and Lehrer, 2000), are considered as resistant to the disease, others such as SP71-6163 and R577 (Rassaby, 2001) have been shown to have reduced sugar yields by as much as 20% compared to virus-free canes. Of the commercial varieties of sugarcane cultivated on 64 000 ha in Mauritius, the distribution of ScYLV and varietal responses to yellow leaf locally were undefined with the exception of M1658/78 and M695/69 which have been assessed in a previous study (Moutia and Saumtally, 1999). The varietal responses for R570, R575 and R579, which are also planted in Mauritius, have been studied in Reunion Island (Rassaby, 2001; Rassaby et al., 2004; Abu Ahmad et al., 2007). The epidemiology and effect on yield of the
disease have not been established in Mauritius. The relative importance of vegetative propagation or vectors in the spread of the disease is not known. The occurrence of aphids is believed to be low in sugarcane fields, but their distribution and identity needs to be ascertained.

Materials and methods

Distribution of ScYLV

An island-wide survey was undertaken and leaf samples of 20 commercial varieties were collected from 88 fields visited randomly at 25 sites, covering all sugarcane growing areas as well as climate and soil types. The youngest completely unrolled leaves (F1) were sampled across the fields in a zigzag pattern. Between 26 and 251 leaves were collected per site, depending on area and variety distribution. A total of 3008 leaves were sampled. The plants sampled were checked for aphid species Melanaphis sacchari (Zehnt) and Rhopalosiphum maidis (Fitch), known to have the potential to transmit ScYLV. An overall rating was given to the infection levels in the fields surveyed based on the occurrence of disease symptoms. A scale of 0 to 3 (Table 1; Figure 1) was used to rate the severity of typical symptoms of yellow leaf.

TBIA and RT-PCR

Leaves were tested by tissue blot immunoassays (TBIA) using a cross-absorbed polyclonal antibody developed at the Mauritius Sugar Industry Research Institute (MSIRI) (D08, Y. Moutia) and the technique developed by Schenck et al. (1997). Confirmatory tests were carried out on subsamples by reverse transcriptase PCR on extracts of total nucleic acids (Joomun and Dookun-Saunttally, 2008).

Yield loss assessment

Three plant cane fields of an early maturing variety (M52/78), a middle variety (M1400/86), and a late harvest variety (M2593/92) were chosen for the evaluation of the impact on yields. Fields were chosen taking into consideration cultural parameters such as irrigation and slope to ensure minimum field variation among the selected stools. The choice was also based on known incidence of yellow leaf from data gathered in the survey. Selected fields were those where the probability of finding virus-free stools was reasonably high (>15 %) to allow the analysis to be carried out in a
pair wise design. The sites were Mon Desert Alma (field 114), Henrietta (field 7278) and St Antoine (field 5025) for M52/78, M1400/86 and M2593/92 respectively.

Cane stools were tested by TBIA to differentiate between stools that were free from the disease and those that were infected. Two F1 leaves were sampled from each stool, one from the primary stalk and one from the youngest stalk. Three hundred and eighty five stools were individually tested by TBIA.

Once the ScYLV negative stools had been identified, they were tagged (stools A) in the field and the next ScYLV positive stool in the same cane row was tagged as a paired sample (stools B). Stools were hand cut at the base and individual millable stalks were measured in length (up to the top visible dewlap) and diameter (at the centre of the stalk) prior to the whole stool being weighed and sent to the mill where brix, pol and fibre parameters were determined.

Statistical significance of differences in means of yield parameters between ScYLV positive and ScYLV negative stools were determined by carrying out one-way pair wise T-tests at 90% (P<0.01) and 95% (P<0.005) confidence for the respective pairs of stools. This analysis was performed using the GenStat Discovery 7th Edition (DE3) software.

**Results**

**Survey of the incidence of ScYLV in local commercial varieties of sugarcane**

The survey revealed that ScYLV is widely distributed in Mauritius being prevalent in all commercial varieties tested except for M1176/77 (Figure 2).
Variety M1176/77 always tested negative for the presence of ScYLV both by TBIA and RT-PCR. Variety R573 showed a comparatively low percentage of infection (6% of samples from 10 different fields) although leaf symptoms were observed (score 2; Table 2). A similar observation was made for variety M52/78 in one field at Britannia, in the south of the island, where severe symptoms (score 3) correlated with a low percentage infection (5%). This variety was the third least infected variety sampled with 28.8% of samples tested positive by TBIA. Variety M1551/80 also tested negative for ScYLV but only one field was tested.

Severe symptoms (score 3) of the disease were observed in varieties M387/85, M 95/69, M703/89, M1186/86, M1400/86, M2024/88, M2593/92, R570, R573 and R575 but the symptom severity varied for different ratoon stages and locations. Among these varieties, R570, R573, M52/78 and M1400/86 did not show any symptom of yellow leaf (score 0) in some fields. Out of 88 fields that were visited, 50 exhibited asymptomatic canes but had a high level of infection with a mean of 58% plants testing positive with TBIA.

The maize aphid *R. maidis* was not observed in any of the fields visited. *Melanaphis sacchari* were observed in 10 fields in 8 sites only (Figure 2). The incidence of aphids was low in the fields visited (8%) and only one field at Joli Bois (Savannah, south of Mauritius) was severely infested with hundreds of aphids collected.

The impact of ScYLV on yield

One hundred stools of M52/78 were analysed and 32 tested negative in TBIA. Sixteen pairs of stools were compared and the statistical t tests carried out showed that there were no significant differences between the mean values of each of the yield parameters for this variety. Similarly, 165
stools of variety M1400/86 were tested by TBIA and 31 stools (18.8%) tested negative for ScYLV. Apart from the mean diameter of stalks which was 1.2% significantly greater at \( p<0.01 \) in TBIA negative stools than in TBIA positive stools, none of the other differences in means were statistically significant at 95% confidence. Hence, under the prevailing conditions, no significant differences were found between the yields of TBIA positive and TBIA negative stools for this variety.

For variety M2593/92, 120 stools were initially tested by TBIA and 61 stools (50.8%) tested negative for ScYLV. Table 3 summarises the results of the cane analysis and the derived yield indicators. TBIA negative stools and TBIA positive stools were not significantly different for average fresh weight per stool or average stalks per stool.

Canes from TBIA negative stools had greater mean lengths (3.25%, \( p=0.031 \)) and diameters (2.87%, \( p=0.01 \)) than TBIA positive stools. Canes from TBIA positive stools had a higher sucrose content than TBIA negative stools as shown by the Pol % Cane (+3.4%, \( p=0.016 \)), Brix (+2.4%, \( p=0.035 \)) and IRSC (+3.9%, \( p=0.016 \)). There were no significant differences between TBIA negative and TBIA positive stools for sugar content/stool, Pol % dry matter values (Pol % DM), % fibre or % dry matter.

### Discussion

Results from the survey on the incidence of ScYLV in different locations revealed that environmental effects were minimal and the distribution of the virus was related to the variety grown. The high percentage of infected canes in commercial fields planted in 2006 and 2007 and the low occurrence of aphid vectors in these fields possibly imply that the main source of propagation of ScYLV is via systemically infected cane setts. However, as aphid populations vary greatly during the season, monitoring over a longer period is necessary to draw meaningful conclusion. The spread of viral infection to neighbouring plants by aphids has been observed to be relatively slow and in the range of a few metres per year (Lehrer et al., 2007). Rassaby et al. (2004) also reached the conclusion that the virus is mainly propagated by planting infected cuttings. This is
further supported by the fact that recently released cane varieties showed high incidence of the virus in the absence of aphid vectors [M703/89 (97.8%), M1400/86 (74.7%), M2593/92 (55.1%)]. The incidence of the virus in R570, the main variety planted in Mauritius, was 50.9%, which correlates well with previous studies carried out in Reunion Island (Rassaby et al., 2004; Abu Ahmad et al., 2007). Varieties R579 and M703/89 are popular with sugarcane growers in Mauritius and they showed a ScYLV incidence as high as 98–100%. It was practically impossible to compare virus-free and infected stools in commercial fields planted with these varieties because of the high incidence of disease. Such a comparison would require generating clean material by \textit{in vitro} meristem cultures.

The sampling method and paired design for the yield loss assessment ensured that the inherent variations in the field were minimal. Results showed that variety M2593/92 could be more susceptible to yellow leaf than M52/78 and M1400/86 as it exhibited severe foliar symptoms (score 3). Yield parameters for the latter two varieties were comparable for healthy and infected stools; therefore, these varieties could be rated tolerant to yellow leaf in plant cane.

M2593/92 had higher sucrose content in stalks from infected stools than for TBIA negative stools. This observation does not agree with previous reports on other varieties where yellow leaf was associated with reductions in sucrose content in stalks and 10–40% decreases in cane yield (Vega et al., 1997; Lockhart and Cronjé, 2000; Grisham et al., 2002).

In this study, the tonnage of variety M2593/92 was 8.68% greater for TBIA negative stools while the decrease in yield of TBIA positive stools was compensated by higher recoverable sucrose content (+3.94 in IRSC, p=0.016, Table 3), resulting in a buffering effect of the potential loss in the yield of sugar in infected stools. The difference in tonnage was lower (8.68%) than that typically reported and could be attributed to the specific varietal response to infection under the prevailing conditions of the study.

During the maturation period of sugarcane, vegetative growth is balanced with sucrose accumulation. The increase in sucrose content in infected stools of M2593/92 could be attributed to a decrease in vegetative growth in favour of sucrose accumulation, typical of luteovirus infections (Harrison, 1999), as shown by the decrease in average length and diameter of stalks of diseased stools (Table 3).

Infection by ScYLV has been found to cause alteration in photosynthetic metabolism and plant carbohydrate metabolism (Gonçalves et al., 2005) and similar observations in susceptible varieties have been made previously for varieties M1658/78 and S17 (J-F. Y. Moutia, pers. comm.). The increase in sucrose content of susceptible varieties is not expected to constitute an increase in the yield of sugar of infected fields because the resultant effect would be that the genetic potential of the variety would not be achieved, since the stunting would reduce stalk development and metabolic disturbances would result in accumulation of reducing sugars in leaves. This increase in reducing sugars in juice (Fontaniella et al., 2003) would negatively impact upon the juice quality.

Since canes do not recover from infections (Rassaby et al., 2004), a cumulative increase in viral titre from the primary infection, notwithstanding localised aphid infestation patterns (McAllister et al., 2008), could hypothetically cause more pronounced losses in tonnage and yields of sugar in older ratoons than in plant canes. Rassaby et al. (2002) observed a reduction in stalk height, cane diameter, weight and sugar content in cultivar R577 but not in cultivars R570 and R579 in plant cane. The impact of the disease was higher in the first ratoon.

**Conclusions**

Yellow leaf is a complex disease and interactions among different parameters such as abiotic and biotic stress, virus genotype (Abu Ahmad et al., 2007), physiological age, plant genetic resistance and ratooning need to be studied more closely. A precautionary approach should be adopted while assessing the varietal resistance based on symptoms. While the extremes (highly resistant, e.g. M1176/77 and highly susceptible, e.g. M695/69) are more consistently defined, the
middle range of varieties constitute a challenge for precise ratings due to their differential response to infection under varying conditions.

The present study updated the information on the distribution of ScYLV in the main commercial cane varieties and attempted to assess its potential impact on yield of three popular varieties in Mauritius under commercial field conditions. The virus was detected in 18 out of 20 varieties, showing that current cultivars could be extensively infected. Variety M1176/77 appeared to be resistant as none of the 275 samples tested was infected. It is a potential parent in the development of resistant varieties. No yield loss was observed in the evaluation, but it is necessary to conduct a more in-depth study using diseased compared with disease-free planting material established in separate plots to assess the effect. The ScYLV strain has also to be taken into account. Only the REU strain, least virulent, has been observed in commercial varieties (Joomun and Dookun-Saumtally, 2008). A management strategy for yellow leaf disease in Mauritius should also comprise the development of clean nurseries that could include, if necessary, planting field borders with resistant varieties and spraying aphicides within these borders during the peak period of aphid movement.

Acknowledgements

The authors wish to thank Mr J-F. Y. Moutia for supplying the polyclonal anti- ScYLV antibody used in the TBIA and Mr N. Joomun for carrying out confirmatory tests by RT-PCR.

Le Sugarcane yellow leaf virus (ScYLV), agent causal de la maladie de la feuille jaune, est fréquemment observé dans la plupart des pays producteurs de canne à sucre. Cette étude met l’emphase sur la distribution du virus dans les variétés commerciales mauriciennes et tente d’évaluer l’impacte potentiel de la maladie sur les rendements en canne et en sucre de trois variétés, la M 52/78 (maturation tôt dans la saison), la M 1400/86 (maturation en milieu de saison) et la M 2593/92 (maturation en fin de saison). Un échantillonnage de 88 champs établis dans 20 régions différentes de l’île a révélé que le ScYLV était présent dans toutes les variétés testées sauf la M
1176/77 qui fut testée par les techniques d’immuno empreintes (TBIA) et RT-PCR. L’incidence du virus ne corrobore pas à la distribution du puceron, *Melanaphis sacchari*, (seulement 8% des champs étaient infestés par le vecteur), suggérant que la cause principale de la transmission du virus à Maurice est par boutures infectées. L’impacte potentiel du virus sur le rendement fut analysé en comparant différents paramètres de rendement entre des pairs de fossés infectés et non infectées de champs commerciaux. les feuilles provenant de ces fossés étant au préalable testés par le TBIA. Cette étude a démontré que, pour la cane vierge, les remènements entre la canne infectée et non Infectée étaient comparables pour les variétés qui mûrisissent tot et en milieu de saison. Pour la variété tardive M 2593/92, les fossés malades étaient plus riches en saccharose que les fossés sains. L’impacte potentiel de la maladie de la feuille jaune sur la cane à sucre à Maurice fut déduit en considérant les récentes publications ainsi que les observations faites pendant cette étude. Ces résultats suscitent l’intérêt pour plus de recherche sur l’impacte de la maladie sur les variétés commerciales afin d’en déduire les retombées économiques.

**Resumen**

El virus de la hoja amarilla (ScYLV) se encuentra presente en la mayoría de los países productores de caña de azúcar y se ha demostrado ser la causa de la enfermedad de hoja amarilla de la caña de azúcar. El presente estudio se centró en la distribución de SCYLV en variedades comerciales de caña de azúcar en Mauricio y trató de evaluar su impacto en las producciones de caña y sacarosa de tres variedades: M52/78 (maduración temprana), M1400/86 (maduración media) y M2593/92 (maduración tardía). Un estudio a escala de la isla en 88 campos sembrados con 20 variedades diferentes, mostró que SCYLV se distribuyó ampliamente en todas las variedades excepto M1176/77, que siempre resultó negativa a la presencia del virus mediante pruebas inmunológicas del Tissue Blot (TBIA) y amplificación por PCR. En Mauricio, el áfido vector *Melanaphis sacchari* se encontró solamente en el 8% de los campos, lo que indica que la causa principal de la propagación del virus en los campos comerciales es el uso de semilla infectada. El impacto potencial de la hoja amarilla en cultivares de Mauricio se evaluó mediante la medición y comparación de los parámetros de producción de cepas TBIA positivas y y TBIA negativas en un diseño apareado en condiciones de campo comercial. Este estudio mostró que, para la caña plantilla, las producciones fueron comparables para las variedades M52/78, M1400/86, mientras que en M2593/92, las cepas TBIA positivas tuvieron un contenido de sacarosa superior y menor peso que las cepas TBIA negativas. Estos resultados destacan la necesidad de investigación adicional sobre las principales variedades comerciales de caña de azúcar con el fin de determinar la importancia económica de la enfermedad en Mauricio.
IDENTIFICATION OF SOURCES OF RESISTANCE TO SUGARCANE RED ROT

Abstract

RED ROT, caused by Colletotrichum falcatum Went, adversely affects sugarcane stand establishment in Louisiana by rotting planted stalks. Since cultivar resistance is the most effective control method, a study was conducted to identify sources of resistance to red rot and evaluate variability within Saccharum species and Erianthus. Saccharum spontaneum, S. robustum, S. sinense, S. officinarum, S. barberi, and Erianthus clonal accessions were evaluated for resistance alongside susceptible commercial cultivars in three experiments. Harvested stalks were inoculated with C. falcatum. Following a 6-week incubation, each stalk was split and rated for red rot symptoms including number of nodes passed (NP), number of nodes rotted (NR), internode rot severity (IRS), and a rot index (RI) that takes into account both the extent of node damage and internode rot. Significant differences were detected among species and accessions within species for all traits. Among the Saccharum species, S. barberi, S. robustum and S. spontaneum exhibited the lowest red rot symptom severity means, while S. officinarum and S. sinense had the highest severity means. A high level of variation was observed within S. spontaneum with RI means ranging from two to 29. Three of 31 S. spontaneum accessions (10%) had an NR mean less than 5, and 26% had a mean less than 10. S. barberi exhibited a high level of resistance, with RI means ranging from one to 20. Four of 14 S. barberi accessions (29%) had an RI mean of less than 5 (highly resistant), and six (43%) had a mean of 10 or less (moderately resistant). The least amount of variation was seen among the Erianthus accessions, with all showing little, if any, red rot symptoms. The Erianthus genus possesses high resistance and should be used as parental material in breeding programs where enhanced red rot resistance is needed. Other more easily utilised sources of resistance to red rot within the Saccharum germplasm are selected S. spontaneum and S. barberi accessions.

Introduction

Red rot, caused by Colletotrichum falcatum Went, damages sugarcane (inter-specific hybrids of Saccharum L.) by rotting standing cane and planted stalks (Singh and Lal, 2000). In Louisiana, red rot adversely affects stand establishment by rotting planted seedcane (Abbott, 1938). Red rot is difficult to control through hot-water and fungicide treatments (Singh et al., 2008). Therefore, the disease is controlled with host plant resistance. A heritability study conducted in Louisiana indicated that resistance can be increased by careful cross-based selection (Yin et al., 1994). However, an additional finding of this study was that the frequency of resistance was low within both breeding and selection populations. The results suggested that the introgression of genes from related wild germplasm might be needed to enhance red rot resistance in the parent population.
In India, a high frequency of resistance was demonstrated among *S. spontaneum* clones (Satyavir *et al.*, 1994; Srinivasan and Alexander, 1971). The objectives of this study were to identify sources of red rot resistance in *Saccharum* species and *Erianthus* that might be utilised in future breeding efforts to develop resistant cultivars and evaluate variability in resistance within this material.

### Materials and methods

Resistance screening experiments were conducted in 2004, 2005, and 2008. A total of 90 *Saccharum* and nine *Erianthus* clonal accessions were evaluated for resistance to sugarcane red rot. The accessions evaluated are part of a collection maintained at the USDA-ARS Sugarcane Research Unit, Houma, LA. *Saccharum* accessions tested represented five species, as well as a limited number of commercial sugarcane cultivars (Table 1). Variable numbers of accessions were evaluated each year. Accessions in *Erianthus* included four *E. arundinaceus*, two *E. bengalense*, and one each of *E. procerus* and *E. ravennae*.

Data were assessed yearly to determine if there were differences between species and among clones within each species during any given year. In addition, a set of clones from each of the *Saccharum* species was included in a multi-year analysis to determine genotype, environment, and genotype x environment interactions. Fourteen *S. barberi*, 11 *S. sinense*, seven *S. officinarum*, seven *S. robustum*, and 31 *S. spontaneum* clones were analysed in 2004 and 2008 along with the susceptible commercial cultivar LCP85-384. The screening population varied among experiments, and not all clones were included in the multi-year analysis due to the lack of some materials for additional testing and the receipt of new imports into the collection as the study progressed.

### Table 1—Number of *Saccharum* and *Erianthus* accessions screened for resistance to red rot in 2004, 2005, and 2008, and across all three years (Total number). A multi-year analysis was conducted on a subset of *Saccharum* clones in 2004 and 2008.

The accessions were planted in February 2004, 2005, and 2008 from nodal cuttings and grown in 37.8 L containers in a soil-less potting medium. In December of each year, four undamaged stalks of each accession were cut, and the leaves were removed. Stalks were then dipped in a 0.26% solution of sodium hypochlorite for 10 minutes to surface disinfect and they were inoculated with *C. falcatum*. A 3.2-mm-diameter hole was drilled into, but not through, the centre internode of all four stalks of each accession, and 100 μL of a conidial suspension of *C. falcatum* (3.8 x 10⁸ spores/mL) was introduced. Stalks were wrapped inside a perforated sheet of polyethylene and kept moist for 6 weeks at room temperature. Following incubation, all stalks were split longitudinally and assessed for disease severity. Each stalk was rated for the following symptoms: i) number of nodes passed (NP) by internode rot symptoms in each direction from the inoculation point, ii) number of nodes exhibiting rot symptoms (NR), and iii) internode rot severity (IRS) in each internode, including the one inoculated and three in either direction. IRS was visually rated 1–6 based on the amount of rot observed in each internode, where 1 ≤ 10%, 2 = 11 to 25%, 3 = 26 to 50%, 4 = 51 to 75%, 5 = 76 to 90%, and 6 > 90% of the internode tissue exhibited red discoloration. A single IRS rating was given to each stalk by averaging the seven internodes.
assessed. A rot index (RI) was calculated based on a combination of traits. It was calculated as $RI = (NP + NR) \times \log_{10} (IRS+1)$.

The effect of species and accession on red rot susceptibility was determined by analysis of variance using the PROC MIXED procedure in SAS (SAS Institute, 2001) with replication and years as random variables. Differences between species and accession least square means were compared using the pdiff option (Saxton, 1988) at the 0.05 probability level.

**Results and discussion**

A species effect was found for all four traits analysed in all three single-year analyses. In 2004, differences were found among clones within all *Saccharum* species for all traits analysed. The single *Erianthus* accession included in the 2004 analysis was more resistant than the average of other species for all traits. On average, *S. robustum* and *S. barberi* were the most resistant of the *Saccharum* species. In 2005, less significance was seen among the accessions within species. For every trait, all nine *Erianthus* clones showed near complete resistance to red rot. This resulted in a lack of significance among accessions within this genus, and the *Erianthus* genus, as a whole, was more resistant than all the *Saccharum* species. Despite the relatively large number of *S. sinense* clones (11) included in 2005, the only traits showing significant differences among the clones were NR and RI. A lack of significance was observed among the three *S. officinarum* clones for NP, NR, and RI in 2005, but this could be an artifact of the low sample size and does not necessarily indicate a lack of overall variation within the species. Differences were detected for all traits among clones within *S. barberi* and *S. spontaneum*. In 2008, *Erianthus* again showed complete resistance, while all other species showed differences among accessions.

This study did not attempt to evaluate variability in resistance within commercial cultivars. A previous study (Yin *et al*., 1994) found a high frequency of susceptibility in the current cultivar population.

When data from all three years were combined, differences were found among species for NP, NR, IRS and RI. The nine *Erianthus* clones showed near complete resistance and were more resistant than the other species for all four traits. The species were ranked in order of average resistance for each of the four measured traits, and these rankings were summed to give an overall ranking of resistance. The order of overall ranking was as follows: *Erianthus* > *S. robustum* > *S. barberi* > *S. spontaneum* > *S. sinense* and *S. officinarum* > commercial sugarcane (hybrid clones). While the number of clones per species in the combined 3-year data set was unbalanced, it gave a general idea of relative resistance among the species.

A subset of each of the *Saccharum* species and the commercial sugarcane cultivar LCP85-384 were included in a 2004 and 2008 multi-year analysis to determine significant genotype, year, and genotype by year interactions. Significant differences ($\alpha=0.05$) were found between species for all traits except IRS (Table 2). Year and species by year effects were significant for NP, NR, IRS, and RI ($\alpha=0.05$). The species were analysed individually to determine the effect of year, accession and accession by year on each of the four red rot criteria (Table 2). Significant effects were found for accession for all four traits; however, year was not always significant. For NP, no significant year effect was seen within *S. officinarum*, *S. sinense*, or the commercial cultivar, and for NR and IRS, year was insignificant for *S. barberi*, *S. spontaneum*, and the single commercial clone tested. RI showed no year effect for *S. barberi*, and LCP85-384. All accession by year effects were significant with the exception of NP for *S. robustum*. The ratio of variety F-values to interaction F-values was determined to assess the relative importance of variety by year interaction (Graybosch *et al*., 1996). For all traits and species analysed, the variety F-values were greater than the interaction, with the exception of NP, IRS, and RI for *S. sinense*. There were no common *Erianthus* clones in 2004 and 2008, so they were not included in the multi-year analysis. However, eight of the nine clones analysed across the three years showed complete or near complete resistance to red rot in all traits analysed.
Table 2—Summary of red rot scores for accessions included in multi-year analysis.

Species, number of nodes passed (NP), nodes rotted (NR), internode rot severity (IRS), and rot index\(^a\) (RI) are shown along with accession (A) and year (Y) mean separation and accession by year interaction (A*Y) analyses.

*indicates significance at the \(\alpha=0.05\) level** indicates significance at the \(\alpha=0.01\) level. NS=nonsignificant. \(^a\)RI was calculated as RI = (NP + NR) \times \log_{10} (IRS+1).

A previous study conducted by Yin et al. (1994) showed that RI had the highest heritability of the four traits measured. This trait aims to combine different susceptibility traits of the disease to obtain an overall assessment of damage to both the stalk and the buds. RI scores less than five were highly resistant (showing minimal stalk and bud rot), while those less than 10 were moderately resistant. Variation was observed for RI within each of the Saccharum species (Figure 1). The highest level of variation was observed within S. spontaneum with RI means ranging from 2 to 29. Three of 31 accessions (10%) had an RI mean less than 5, and eight (26%) had a mean less than 10. The percentages of S. spontaneum clones with resistant and moderately resistant ratings in the Indian studies were 37 and 65% (Srinivasan and Alexander, 1971) and 35 and 71% (Satyavir et al., 1994), respectively. While less variation was observed among the S. barberi, a higher percentage of resistance was found within this species than was found within the others. Rot index ranged from one to 20 within S. barberi. Four of 14 accessions (29%) had a RI mean of less than 5, and six (43%) had a mean of 10 or less. The resistant and moderately resistant rating frequencies found in India for this species were 33 and 48% (Srinivasan and Alexander, 1971) and 6 and 22% (Satyavir et al., 1994), respectively.

When considering clones for disease resistance breeding, not only is the trait mean important, but also the variation within each species and the ease with which genes can be introgressed into commercial varieties. Erianthus clones showed the most consistent and most complete resistance to red rot. This suggests Erianthus could make an important contribution to an effort to enhance resistance in sugarcane. This is in agreement with a study conducted by Ram et al. (2001) who found that twelve out of 18 Erianthus clones tested showed resistance to red rot. However, it is not the only source of resistance genes, and certainly not the easiest to cross with elite sugarcane cultivars.

A wide range of variation was seen in S. spontaneum. While the overall average resistance of evaluated clones in this species was not as high as was demonstrated in India, there were still many clones that could be exploited for potential sources of resistance. S. spontaneum clones are more easily crossed with commercial sugarcane than Erianthus and produce more seed. Therefore, they are arguably the better candidates to utilise as more readily and rapidly exploitable sources of red rot resistance. Limited numbers of clones of the other Saccharum species were analysed, but the results indicate that, as a whole, S. barberi clones had a high level of resistance and could be easily exploited. S. barberi also had the highest ratio of variety to interaction F-values, indicating that, as a whole, this species is more stable across years and another good candidate for source genes for red rot resistance. The 3-year analysis results ranking suggested S. robustum might provide a source of resistance, but highly resistant clones were not detected in the species. Individual clones of S.
S. sinense, S. robustum, and S. officinarum might be identified that could serve as potential sources of resistance. However, individual clone resistance levels must be conclusively determined before using these Saccharum species in breeding due to variation among clones.

The significant interaction between year and accession for all species calls into question the ability to breed for resistance to red rot. However, this does not necessarily contradict successful breeding for the trait. As is observed with many screening studies, even with a significant interaction term, clones can be identified that have stable resistance across years. For example, in our multi-year analysis, we included 31 S. spontaneum accessions, and while statistical significance was found for the interaction between accessions and year, four clones were among the top 10 for resistance in both 2004 and 2008. This indicates that, with careful selection, enhanced resistance can be achieved through breeding. S. spontaneum clones identified as possessing red rot resistance in our study include but are not limited to: IND81-144, Guangxi 87-22, SES147B, and IN84-42. Of the S. barberi clones analysed, Dhalula and Ganapathy showed stable resistance. It does not appear necessary to heavily screen Erianthus clones for parental selection since most appear to possess near complete resistance to red rot. Furthermore, resistance to red rot in Erianthus makes it more attractive when considering the genus as a source of genes for other traits, such as low temperature tolerance. Transmitting an unfavourable trait, such as susceptibility to red rot, will not be a problem while introgressing the other traits of interest in this genus.

Résumé
LA MORVE ROUGE, causée par Colletotrichum falcatum Went, affecte de manière négative la plantation de la canne à sucre en Louisiane en provoquant une pourriture des boutures. Comme la résistance variétale est le moyen de lutte le plus efficace, une étude a été entreprise pour identifier les sources de résistance et évaluer leurs variabilités parmi les espèces de Saccharum et d’Erianthus. Les acquisitions clonales de Saccharum spontaneum, S. robustum, S. sinense, S. officinarum, S. barberi, et d’Erianthus ont été évaluées pour la résistance parallèlement aux cultivars commerciaux sensibles dans trois essais. Les tiges récoltées ont été inoculées au C. falcatum. Après six semaines d’incubation, chaque tige a été fendue et notée pour les symptômes de la morve rouge, en incluant le nombre de nœuds attaqués par la maladie (NP), le nombre de nœuds pourris (NR), la sévérité d’entreœufs attaqués (IRS), et l’index de pourriture (RI), qui tient compte de l’étendue des dégâts causés au nœud et à l’entreœuf. Des différences significatives ont été détectées parmi les espèces et les acquisitions inter-espèces pour tous les caractères. Parmi les espèces de Saccharum, S. barberi, S. robustum et S. spontaneum ont manifesté les moyennes de symptômes les moins sévères, alors que S. officinarum et S. sinense avaient les moyennes de sévérité les plus élevées. Un niveau élevé de variabilité a été observé parmi l’espèce S. spontaneum avec des moyennes de RI s’étalant de 2 à 29. Trois des 31 acquisitions de S. spontaneum (10%) avaient une moyenne de NR de moins que 5, et 26% avaient une moyenne de moins que 10. S. barberi a manifesté un niveau de résistance élevé, avec des moyennes RI s’étendant de un à 20. Quatre des 14 acquisitions de S. barberi (29%) avaient des moyennes RI de moins que 5 (très résistantes), et six (43%) avaient des moyennes de 10 ou moins (modérément résistantes). La variabilité la plus faible a été observée parmi les acquisitions d’Erianthus, toutes démontrant peu ou pas de symptômes de morve rouge. Le genre Erianthus possède donc une résistance élevée et devrait être utilisé comme parent dans les programmes d’hybridation génétique là où la résistance est requise. L’autre source de résistance à la morve rouge, plus facilement accessible, est le germoplasme de l’espèce Saccharum, dont certaines acquisitions de S. spontaneum et S. barberi.
IDENTIFICACIÓN DE FUENTES DE RESISTENCIA A LA PUDRICIÓN ROJA DE LA CAÑA DE AZÚCAR

PALABRAS CLAVES: Saccharum, Colletotrichum falcatus, Glomerella.

El muermo rojo o pudrición roja, causada por Colletotrichum falcatus Went, afecta negativamente el establecimiento de la caña de azúcar en Luisiana debido a la pudrición de los tallos sembrados. Debido a que la resistencia de los cultivares es el método de control más eficaz, se realizó un estudio para identificar las fuentes de resistencia a la pudrición roja y evaluar la variabilidad dentro de cada especie de Saccharum y Erianthus. Clones de accesiones de Saccharum spontaneum, S. robustum, S. sinense, S. officinarum, S. barberi y Erianthus se evaluaron en su resistencia a la enfermedad junto a cultivares comerciales susceptibles, en tres experimentos. Tallos cortados fueron inoculados con C. falcatus. Después de una incubación de 6 semanas, cada tallo se dividió longitudinalmente y calificaron los síntomas de la pudrición roja, incluyendo el número de nudos atravesados (NP), número de nudos podridos (NR), la severidad de la podredumbre del entrenudo (IRS), y un índice de pudrición (RI) que tiene en cuenta tanto la magnitud del daño de los nudos como la pudrición de los entrenudos. Se detectaron diferencias significativas entre las especies y las adhesiones dentro de las especies para todas las variables. Entre las especies de Saccharum, S. barberi, S. robustum y S. spontaneum exhibieron la menor severidad media de incidencia de la pudrición roja, mientras que S. officinarum y S. sinense exhibieron la mayor severidad media de incidencia de la enfermedad. Un alto nivel de variación se observó en S. spontaneum con RI que tuvo un rango de variación de 2 a 29. Tres de 31 accesiones de S. spontaneum (10%) tuvieron una media de NR inferior a 5, y 26% tenían una media de NR menor de 10. S. barberi mostró un alto nivel de resistencia, con medias de RI que variaron del uno al 20. Cuatro de 14 accesiones de S. barberi (29%) tuvieron una media de RI inferior a 5 (muy resistente), y seis (43%) tuvieron una media de RI de 10 o menos (moderadamente resistente). La menor variación en los resultados se observó entre las accesiones de Erianthus, con todas mostrando muy poco o ningún síntoma de pudrición roja. El género Erianthus posee una alta resistencia y debe ser utilizado como material progenitor en los programas de mejoramiento que requieran mejorar la resistencia a la pudrición roja. Otras fuentes de mayor facilidad en su utilización como fuentes de resistencia a la pudrición roja en el germoplasma de Saccharum, se pueden buscar en las accesiones de S. spontaneum y S. barberi.
UNRAVELLING PATHOGENICITY OF XANTHOMONAS ALBILINEANS, THE CAUSAL AGENT OF SUGARCANE LEAF SCALD

KEYWORDS: Genome, Functional Genomic Analysis.

Abstract

Xanthomonas albilineans is a systemic, xylem-invading pathogen that causes leaf scald in sugarcane. Symptoms vary from a single, white, narrow, sharply defined stripe to complete wilting and necrosis of infected leaves, leading to plant death. X. albilineans produces the toxin, albicidin, that blocks chloroplast differentiation, resulting in disease symptoms. Albicidin is the only previously known pathogenicity factor in X. albilineans, yet albicidin-deficient mutant strains are still able to efficiently colonise sugarcane. The complete genome of strain X. albilineans GPE PC73 from Guadeloupe was recently sequenced and annotated, providing a valuable tool to help identify new pathogenicity factors in this pathogen. In attempts to identify additional pathogenicity genes, site-directed deletions of candidate pathogenicity genes and also random Tn5 insertion mutagenesis were used, both followed by inoculation of sugarcane plants with new strains containing introduced mutations. Knockout mutagenesis of albXXI, which encodes a phosphopantetheinyl transferase that activates non ribosomal peptide synthetases (NRPSs), resulted in reduced capacity to colonise the sugarcane stalk by GPE PC73. Knockout mutagenesis of quorum sensing genes, rpfF and xanB2, did not affect albicidin production nor sugarcane colonisation by X. albilineans strain XaFL07-1 from Florida. However, four independent Tn5 insertion mutations of an OmpA family gene strongly affected both disease symptom development and sugarcane stalk colonisation without affecting albicidin production in strain XaFL07-1. Other candidate pathogenicity genes are currently being investigated.

Introduction

Leaf scald, a vascular bacterial disease, is one of the major diseases of sugarcane (Rott and Davis, 2000). It was first recorded in Australia in 1911 by North, but strong presumptive evidence exists that the disease was prevalent in the Fiji Islands by 1908, if not earlier (Martin and Robinson, 1961). Today, the disease occurs in most sugarcane growing locations. Successful isolation of the causal agent, Xanthomonas albilineans, was reported in 1920 by Wilbrink who was also able to reproduce the symptoms of the disease after artificial inoculation (Wilbrink, 1920).

Although X. albilineans is thought to be mainly transmitted by infected cuttings, aerial transmission of this pathogen also occurs, and epiphytic life of the pathogen appears to be an important step in the epidemiological cycle of the disease (Autrey et al., 1995a; Champoiseau et al., 2009). Control of leaf scald is achieved by various methods including use of resistant cultivars and prophylactic measures (use of disease-free nursery material, disinfection of harvesting tools, etc.). Successful control based on resistance implies knowledge of genetic diversity and variation in pathogenicity of the pathogen. The objective of this paper is to review the literature on pathogenicity of X. albilineans and its genetic basis, and report recent research unravelling pathogenicity of this pathogen.
Leaf scald symptoms and colonisation of the sugarcane stalk

In the field, the symptoms of sugarcane leaf scald are sometimes classified into two different forms, chronic and acute (Martin and Robinson, 1961; Ricaud and Ryan, 1989). It is unknown if these two forms are caused by entirely different sets of genes in different strains of the pathogen, by gene regulation differences among similar strains, or by external, environmental factors that may act on identical strains. The chronic form is characterised by chlorotic streaks on leaves which are parallel to the main veins. These are generally white to yellow narrow ‘pencil-line’ streaks, but they can also be several millimetres wide. Their colour often becomes reddish with age. They are the only external symptoms which develop on resistant cultivars (Rott and Davis, 2000). As the disease progresses, a necrosis of the leaf tissue around the chlorotic streaks may be observed which extends progressively from the tip towards the base of the leaf. The streaks also tend to widen and become more diffuse on leaves reaching maturity. The fine central line which is characteristic of the disease can, however, always be seen in the centre of the lesion. The widening of the lines coincides with the chlorosis or the bleaching of the leaf tissue. Chlorosis or bleaching may affect all the leaves, and this discoloration is followed by a desiccation of leaf extremities which curl inwards, giving the shoot or the stalk a tapered aspect. The stalks can be stunted and the leaves wilted, brown, and bent at the ends. This process, which looks like a scalding, explains the name given to the disease.

A common symptom observed in the chronic form of leaf scald in mature cane arises from abnormal development of side shoots on stalks with basal side shoots generally being more developed than those higher up, in contrast to the opposite situation commonly observed in healthy stalks. These diseased side shoots may show similar symptoms to those on the main stalk. Longitudinal sections of diseased stalks show reddening of the vessels near the nodes and sometimes in the internodes. Lysigenous cavities may be observed in severely diseased canes. The whole stalk may die in susceptible cultivars.

The acute form of leaf scald disease is characterised by a sudden wilting of mature stalks, often without previous development of symptoms associated with the chronic form. Previously symptomless sugarcane dies as if it had been killed by drought. This acute form often occurs after a period of rain followed by a period of prolonged dry weather, but seems to be limited to highly susceptible cultivars.

Another important feature of leaf scald is the existence of a latency phase (Martin and Robinson, 1961; Ricaud and Ryan, 1989). Sugarcane plants can be infected by X. albilineans for weeks or months without exhibiting symptoms or symptoms are so inconspicuous as to escape detection. This latency phase comes to an end for unknown reasons, and symptoms of the chronic or acute forms of leaf scald disease will then appear.

Regardless of the disease form observed, X. albilineans multiplies in the xylem and systemically colonises the entire host plant: the leaves, the stalk and the roots (Champoiseau et al., 2006b; Klett and Rott, 1994). The pathogen can be easily isolated from pencil line symptoms but rarely from chlorotic parenchymatic tissue (Birch, 2001). Pathogen population densities vary according to the sugarcane cultivar and the plant location, and resistance of sugarcane is linked to limited colonisation of the sugarcane stalk (Rott et al., 1997).

Genetic basis of albicidin biosynthesis and structure of albicidin

Birch and Patil first showed in 1985 that a potent phytotoxin and antibiotic was produced by X. albilineans (Birch and Patil, 1985a and 1985b). Albicidin is a small molecule synthesised by a unique, large, and mixed PKS (polyketide synthase)-NRPS (non ribosomal peptide synthetase) gene cluster. Albicidin has been shown to cause leaf scald foliar symptoms in sugarcane by inhibiting the replication of proplastic DNA and consequently blocking the differentiation of chloroplasts (Birch and Patil, 1987a and 1987b). On a molecular level, it has been found to be a potent and novel DNA gyrase inhibitor (Hashimi et al., 2007). The albicidin biosynthesis gene cluster was cloned and
 sequenced (Rott et al., 1996; Royer et al., 2004). It contains 20 ORFs including one PKS-NRPS gene (\textit{albI}) and two NRPS genes (\textit{albIX} and \textit{albIV}), as well as several putative resistance, regulatory and modifying genes (Figure 1). \textit{In silico} analyses showed that nonproteinogenic substrates incorporated by AlbI and AlbIX are unique and remain unknown (Royer et al., 2004). Two other genes located in other parts of the genome are also critical for the biosynthesis of albicidin: \textit{albXXI} which encodes a phosphopantetheinyl transferase (Royer et al., 2004) and \textit{albXXII} which encodes the heat-shock protein HtpG (Vivien et al., 2005).

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{physical_map.png}
\caption{Physical map of the albicidin biosynthesis gene cluster.}
\end{figure}

Preliminary analyses by NMR (Nuclear Magnetic Resonance) spectroscopy and mass spectrometry (MS) performed in the 1980s with purified albicidin did not result in the determination of the complex structure of albicidin (Birch and Patil, 1985a and 1985b). However, these structural analyses showed that albicidin has about 38 carbon atoms and an estimated molecular mass of 842 Da. According to these reports, the albicidin structure contains a methyl group, a carboxyl group and at least three aromatic rings (Birch and Patil, 1985a and 1985b).

\textit{X. albilineans} is a slow growing bacterium and production yields of albicidin are low; it was extremely tedious to obtain sufficient amounts of albicidin for structure elucidation. To overcome this problem, Vivien et al. (2007) used heterologous expression by transferring all albicidin biosynthesis genes into the fast growing bacterium \textit{X. axonopus pv. vesicatoria} and obtained a significant increase of albicidin production. Even larger quantities of purified albicidin have more recently been obtained (Cociancich et al., 2007 and 2009), which may allow elucidation of the structure of albicidin.

\section*{Variation in pathogenicity and genetic diversity of \textit{Xanthomonas albilineans}}

Breakdown of varietal resistance to leaf scald has sometimes been attributed to the development or introduction of new strains but has never been unequivocally proven. Variation in pathogenicity among strains of \textit{X. albilineans} is known to occur, and published data support the possible existence of different races in Mauritius (Autrey et al., 1995b). The outbreak of leaf scald in Florida in the late 1980s was closely associated with the appearance of a genetically new strain of the pathogen (Davis et al., 1997). The capacity of \textit{X. albilineans} to colonise sugarcane stalks and/or to cause symptoms varies according to the strain of the pathogen, indicating the existence of different pathotypes within the species (Champoiseau et al., 2006a; Daugrois et al., 2003; Huerta-Lara et al., 2009; Mohamed et al., 1996).

First evidence of genetic diversity of \textit{X. albilineans} was described by Rott and collaborators who reported the existence of three serovars and six lysovars of the pathogen (Rott et al., 1986 and...
1994). Subsequently, existence of different genetic profiles or genetic variation in *X. albilineans* was reported by several authors using various techniques, but the correlation between genetic diversity and variation in pathogenicity was rarely investigated (Alvarez et al., 1996; Huerta-Lara et al., 2009; Jaufeerally-Fakim et al., 2002; Lopez et al., 2001; Shaik et al., 2008; Yang et al., 1993). Existence of at least eight genetic groups (A-H) were identified by restriction fragment length polymorphism with pulse-field gel electrophoresis (RFLP-PFGE), and most strains associated with new outbreaks of leaf scald belonged to PFGE group B (Davis et al., 1997). Fourteen haplotypes and two major genetic groups (ALB-RFLP A and ALB-RFLP B) were identified among 137 worldwide strains of *X. albilineans* using DNA probes harbouring the albicidin biosynthetic genes (Champoiseau et al., 2006a).

Not surprisingly, albicidin production *in vitro* varies according to the strain of *X. albilineans*. However, variation in albicidin production and variation in pathogenicity are not necessarily related to the diversity of albicidin biosynthesis genes. High variation in pathogenicity was shown to exist in genetically closely related strains of *X. albilineans* in Guadeloupe (Champoiseau et al., 2006b) and no relationship was found either among the amount of albicidin produced *in vitro* and the pathotypes and genetic diversity of the pathogen (Renier et al., 2007). Albicidin is therefore necessary but not sufficient for leaf scald development, and it appears to be one virulence factor acting coordinately with other virulence factors.

**The genome of *Xanthomonas albilineans* and pathogenicity**

The complete genome of *X. albilineans* strain GPE PC73 from Guadeloupe has been recently sequenced and annotated (Pieretti et al., 2009). This work revealed that the size of this genome (3.7 Mb) was relatively small in comparison to the size of the genomes of other xanthomonads sequenced to date (approximately 5 Mb). Interestingly, *X. albilineans* possesses 522 genes that are not conserved in other sequenced species of the *Xanthomonadaceae* family, and is missing the hypersensitive response and pathogenicity (Hrp) secretion system. This type III secretion system (T3SS) is found in most other pathogenic xanthomonads and is used for injection of protein pathogenicity effectors into plant cells. *X. albilineans* also lacks all genes involved in biosynthesis of xanthan gum which are involved in formation of biofilm, an important factor in virulence of plant pathogenic bacteria.

The remarkable absence of a type III secretion system of the Hrp injectisome family in the genome of *X. albilineans* implies that pathogenicity of *X. albilineans* relies on other secretion systems. Small molecules, such as albicidin, which require only pumps to be secreted by the bacterium and to enter the plant cell, may play an important role in pathogenicity of this pathogen.

This assumption is based on findings that the genome of *Xa* contains 12 NRPS genes clustered in four genomic regions potentially involved in the biosynthesis of four small molecules. These 12 NRPS genes are very different from those described in other microorganisms, and cover almost 4% of the bacterial genome.

Three of these 12 NRPS genes were previously described as required for the biosynthesis of albicidin (Royer et al., 2004).

**Identification of new pathogenicity genes of *X. albilineans***

If albicidin is a major factor in symptom development, it is not the only one involved in disease progress. Mutants of *X. albilineans* that do not produce the toxin are still able to colonise the sugarcane leaf and stalk (Birch, 2001; Marguerettaz et al., unpublished results). Therefore, several studies have recently been started to identify new pathogenicity genes in *X. albilineans*.

**Quorum sensing genes**

The genome sequence of *X. albilineans* revealed candidate genes potentially involved in pathogenesis. These candidates include a cluster of genes called rpf (regulation of pathogenicity...
factors) involved in the biosynthesis of a small diffusible signalling molecule. This molecule called DSF (Diffusable Signalling Factor) is synthesised by RpfF which exhibits similarities to long-chain fatty acyl CoA ligases (Barber et al., 1997; Dow 2008). DSF mediates cell-to-cell signalling (= quorum sensing) and disruption of genes rpfF or rpfC (a hybrid two-component DSF sensor) resulted in reduced or deficient virulence in different xanthomonads, such as X. campestris pv. campestris, X. oryzae pv. oryzae and X. axonopodis pv. citri (Chatterjee et al., 2008; Dow, 2008). However, mutants of rpfF and rpfC in X. albilineans strain XaFL07-1 from Florida were still able to produce albicidin, to colonise the sugarcane stalk and to induce leaf scald symptoms including ‘pencil-line’ streaks, chlorosis and necrosis of leaves (Rott et al., 2009b). DSF is therefore not essential for albicidin production or sugarcane colonisation by X. albilineans.

Xanthomonas species also produce another quorum sensing molecule called DF (Diffusable Factor) encoded by xanB2 (previously called pigB). In X. campestris pv. campestris, DF regulates the production of both yellow pigments (xanthomonadins) and extracellular polysaccharide (EPS), and these two bacterial products are crucial to the epiphytic survival and pathogenicity of the pathogen on its host plants (Poplawsky and Chun, 1997 and 1998). However, mutants of xanB2 in X. albilineans strain XaFL07-1 from Florida were still able to produce albicidin, to colonise the sugarcane stalk and to induce leaf scald symptoms including ‘pencil-line’ streaks, chlorosis and necrosis of leaves (Rott et al., 2009a). DF is therefore not essential for albicidin production or sugarcane colonisation by X. albilineans, and these two characteristics may not be controlled by quorum sensing or may involve another regulatory pathway. However, it is possible that DF, like in X. campestris pv. campestris, is crucial to the epiphytic survival of X. albilineans during aerial transmission of the leaf scald pathogen.

NRPS genes

Other genes putatively involved in pathogenicity of X. albilineans include NRPS genes that are involved in the biosynthesis of small molecules. As mentioned above, the genome of X. albilineans encodes 12 large non-homologous non-ribosomal peptide synthetases (NRPSs). Three of these NRPSs, encoded in the same gene cluster, were previously described as involved in albicidin biosynthesis (Royer et al., 2004). The function of the remaining nine NRPSs is currently unknown but it has been hypothesised that they may be involved in biosynthesis of small molecules playing a role in sugarcane-X. albilineans interactions. NRPS enzymes need posttranslational activation by a phosphopantetheinyl transferase enzyme in order to be functional (Lambalot et al., 1996). The genome of X. albilineans strain GPE PC73 contains the gene albXXI which encodes a phosphopantetheinyl transferase and which was previously shown to be required for albicidin biosynthesis (Huang et al. 2000; Royer et al., 2004). This gene may therefore be used for post-translational activation of all NRPSs encoded by X. albilineans. Inactivation of albXXI in X. albilineans strain GPE PC73 resulted in suppression of leaf scald symptoms and reduced capacity to colonise the sugarcane stem when compared to the wild type strain (Marguerettaz et al., 2009). This suggested that at least two secondary metabolites synthesised by NRPSs are involved in virulence of X. albilineans strain GPE PC73: (i) albicidin, which causes the white pencil line streaks on the leaves, and (ii) at least another molecule necessary for stalk colonisation.

Outer membrane protein A gene

Tn5 (transposome) mutagenesis was also used in an attempt to identify additional pathogenicity factors in X. albilineans. Sugarcane cultivar CP80-1743, moderately susceptible to leaf scald, was inoculated by the decapitation method (Champoiseau et al., 2006a) with 780 independently derived Tn5 insertions in Florida strain XaFL07-1. Leaf scald symptoms were recorded on emerging leaves one month after inoculation, and stalk colonisation by the pathogen was determined two months after inoculation. In addition to the previously identified albicidin biosynthetic gene cluster mutations, four new Tn5 mutants were identified that produced no or very
few leaf symptoms. These mutants produced albicidin \textit{in vitro} but did not efficiently colonise sugarcane stalks. The transposon insertion site of all four mutants was found to be located in Orf XAAlc_0557 of the \textit{X. albilineans} genome. This gene is predicted to encode an OmpA family outer membrane protein, a previously unrecognised and apparently essential pathogenicity factor in \textit{X. albilineans} (Rott \textit{et al}., 2009a).

Other genes

Additional Tn$\text{5}$ mutants affected in symptom development or in sugarcane stalk colonisation have been obtained, such as mutants affecting production of exopolysaccharides (EPS) and lipopolysaccharides (LPS) (Rott \textit{et al}., unpublished data). These mutants will be further investigated and more mutants will also be tested by sugarcane inoculation to identify additional pathogenicity genes in \textit{X. albilineans}.

Conclusion

The xylem-invading mechanisms of plant pathogenic bacteria are still not well characterised. The \textit{X. albilineans}/sugarcane pathosystem is an original model in plant pathology to study xylem-invading pathogens, and certain aspects of its invasive ability may be unique.

First, \textit{X. albilineans} is constrained within the xylem, but disease symptoms result from changes in chlorenchyma cells; nevertheless, the bacteria are rarely found in chlorotic leaf areas.

Second, \textit{X. albilineans} infections can be latent for many weeks or months before occurrence of acute disease, and this latency phase ends for unknown reasons. It is thought that this phase change is most likely regulated by particular pathogenicity genes of the pathogen.

Third, \textit{X. albilineans} does not possess a Hrp secretion system. Finally, \textit{X. albilineans} produces albicidin, a unique and specific toxin that causes foliar leaf scald symptoms.

Extensive research has been conducted on \textit{X. albilineans} since its first description more than a century ago. Important knowledge regarding the biology of this pathogen has been gained, and genetic diversity studies and pathogenicity studies showed that this pathogen is variable and evolving. However, more studies are needed to understand the \textit{X. albilineans}/sugarcane pathosystem, especially the interactions between the host and the pathogen.

Recent description of the genome of \textit{X. albilineans} will certainly result in new and significant progress, especially regarding the molecular basis of pathogenicity of this pathogen and its interactions with sugarcane.

First genes involved in pathogenicity, such as genes involved in albicidin biosynthesis and in an outer membrane protein have been identified, and more will certainly follow in the near future. Several mutagenesis techniques are already used to identify new candidate genes potentially involved in pathogenesis.

Other methods such as microarray technology will also be used to investigate the full breadth of the response of \textit{X. albilineans} to the sugarcane host environment during colonisation of the xylem, and maybe also during the epiphytic life of the pathogen.

**MOTS CLES: Génome, Analyse Génomique Fonctionnelle.**

**Résumé**

*Xanthomonas albilineans* est un agent pathogène colonisant le xylème et l’agent causal de l’échaudure des feuilles de la canne à sucre. Les symptômes varient d’une très fine ligne foliaire blanche à un flétrissement complet et la nécrose des feuilles infectées, conduisant à la mort de la plante. *X. albilineans* produit la toxine albicidine qui bloque la différenciation des chloroplastes, ce qui aboutit à l’apparition de symptômes foliaires. L’albicidine était le seul facteur de pathogénie connu jusqu’à récemment, même si des souches non productrices d’albicidine étaient toujours capables de coloniser la canne à sucre. Le génome complet de la souche de *X. albilineans* GPE PC73 originale de Guadeloupe a récemment été séquencé et annoté, fournissant ainsi un outil fort utile à l’identification de nouveaux facteurs de pathogénie chez cet agent pathogène. Afin d’identifier de nouveaux gènes de pathogénie, des mutants de délétion dirigée et d’insertion aléatoire (Tn5) ont été produits puis inoculés à des plants de canne à sucre. La mutation du gène *albXXI*, qui code pour une phosphopantetheinyln transférase activant les enzymes NRPS («Non Ribosomal Peptide Synthetases»), a réduit la capacité colonisatrice de la tige de canne à sucre chez la souche GPE PC73 de *X. albilineans*. La délétion par mutagenèse dirigée des gènes de signalisation cellulaire *rpfF* et *xanB2* n’a apparemment pas eu d’effet sur la production d’albicidine ou la colonisation de la tige de canne à sucre par la souche de *X. albilineans* XaFL07-1 originaire de Floride. Cependant, quatre mutations Tn5 indépendantes d’un gène de la famille OmpA a fortement affecté le développement de symptômes et la colonisation de la tige, sans modifier la production d’albicidine, chez la souche XaFL07-1 de *X. albilineans*. D’autres gènes candidats de pathogénie sont actuellement à l’étude.

PALABRAS CLAVES: Genoma, Análisis Genómico Functional.

Resumen

XANTHOMONAS albilineans es un patógeno sistémico, que invade el xilema y causa la escaldadura de la hoja de la caña de azúcar. Los síntomas pueden variar desde la aparición de una sola raya blanca, angosta, bien definida hasta tener una completa marchitez y necrosis de las hojas afectadas, lo que lleva a la muerte de la planta. Además, X. albilineans produce la toxina, albicidina, que bloquea la diferenciación de cloroplastos, lo que resulta en la aparición de los síntomas de la enfermedad. La albicidina ha sido conocida como el único factor de patogenicidad asociado con X. albilineans, y es así como cepas mutantes con deficiencia en la producción de la albicidina, son capaces de colonizar de manera eficiente la caña de azúcar. El genoma completo de la cepa X. albilineans GPE PC73 proveniente de Guadalupe se secuenció recientemente, proporcionando así una herramienta muy valiosa en la identificación de nuevos factores de patogenicidad de este agente causal. En un intento por identificar los genes patogénicos adicionales, se produjeron supresiones de genes candidatos así como inserciones al azar por mutagénesis de Tn5, seguidos por la inoculación de plantas de caña de azúcar con las nuevas cepas que contienen las mutaciones introducidas. El bloqueo por mutagénesis de albXXI, que codifica la transferasa fosfopantetienil y que activa los péptidos sintetasas no ribosomales (NRPSs), produjo una reducción en la capacidad de la cepa GPE PC73 de colonizar el tallo de la caña de azúcar. El bloqueo por mutagénesis de genes quorum sensing, rpfF y xanB2, de X. albilineans cepa XaFL07-1 de Florida no afectaron la producción de la albicidina ni la colonización de la caña de azúcar. Sin embargo, cuatro mutantes por inserción independiente del gen Tn5 de la familia Ompa, en la cepa XaFL07-1, fueron afectados fuertemente tanto en el desarrollo de los síntomas de la enfermedad como en la colonización de tallos de la caña de azúcar sin afectar la producción de la albicidina. Otros genes de patogenicidad están siendo investigados.
GENETIC DIVERSITY OF SUGARCANE YELLOW LEAF VIRUS IN A SUGARCANE SELECTION PLOT IN GUADELOUPE (FWI)

KEYWORDS: SCYLV, Genetic Diversity.

Abstract

The genetic diversity of Sugarcane yellow leaf virus (SCYLV) was investigated in a sugarcane selection plot in Guadeloupe to determine the incidence of the different known virus genotypes (BRA-PER, CUB and REU) in a breeding progeny. Four F1 leaves were randomly collected from each of 154 sugarcane clones and tested for the presence of SCYLV by tissue blot immunoassay (TBIA). The leaf samples were stored at –80°C until total RNA was extracted from SCYLV-infected leaves. The virus genotypes were determined by RT-PCR and primer pairs specific to each virus genotype. Eighty-two percent of the tested leaves were infected by SCYLV and all known virus genotypes occurred in the selection plot. The majority of plants were infected by genotypes CUB or REU, or by a mixture of these two genotypes. This situation was completely different from the situation observed in commercial fields in Guadeloupe where the incidence of SCYLV is much lower and where most plants are infected by genotype REU. The significance of this striking situation will be further investigated.

Introduction

Yellow leaf of sugarcane is an emerging disease that was first reported as yellow leaf syndrome in Hawaii and Brazil at the end of the 1980s (Rott et al., 2008). It was subsequently found to be associated with a member of the Luteoviridae family called Sugarcane yellow leaf virus or SCYLV that was assigned to the genus Polerovirus (Rott et al., 2008; D’Arcy and Domier, 2005).

Sequencing of the almost entire genome of 13 SCYLV isolates revealed that SCYLV was genetically heterogeneous, and four genotypes of the virus were identified: BRA for Brazil, CUB for Cuba, PER for Peru, and REU for Réunion Island. Genotypes BRA and PER, that are closely related, cannot be easily distinguished, and were assigned to a group of genotypes called ‘BRA-PER’ (Abu Ahmad et al., 2006a).

This latter genotype is widely distributed, whereas the other ones are geographically restricted (Abu Ahmad et al., 2006b). Recently, a new genotype named IND was reported in India (Viswanathan et al., 2008).

Because (i) infected plants are frequently symptomless, and (ii) efficient diagnostic methods were only available by the end of the 1990s, SCYLV was spread all over the world through infected germplasm. So far, the virus has been reported in at least 30 countries (Rott et al., 2008).
Consequently, many of the sugarcane clones that are imported into CIRAD’s sugarcane quarantine in Montpellier (France) are infected with SCYLV, and have to be cleaned up from the virus before distributing to other countries (Chatenet et al., 2001; Girard et al., 2007). During the process of SCYLV detection in CIRAD’s quarantine, we recently noticed that a high proportion of SCYLV-infected clones received from CIRAD’s sugarcane breeding station in Guadeloupe (FWI) were infected by genotype CUB. This situation was unexpected because other data from Guadeloupe indicated that REU was the most common genotype on this island (Daugrois et al., 2008).

Leaf samples were therefore collected in the sugarcane selection plot used to distribute sugarcane clones from Guadeloupe to the sugarcane quarantine in Montpellier. These samples were tested to analyse the incidence and the genetic diversity of SCYLV in this selection plot, and to compare this genetic diversity to the one occurring in commercial fields in Guadeloupe.

Materials and methods

**Selection of leaf samples**

Four F1 (= top visible dewlap) leaves were randomly sampled from each of 154 sugarcane clones planted in a selection plot at CIRAD’s research station in Guadeloupe (FWI). These clones were progenies of 14 crosses and they were at third selection stage of a family selection. After tissue blot immunoassay (see below), the leaves were stored at –80°C until further processing. RT-PCR detection and genotyping tests were performed with two successive sets of leaf samples: in the first step, 38 out of the 154 sugarcane clones were randomly selected among the clones, and two leaves per clone were individually analysed. This sample selection will be thereafter called set A. Later on, 18 sugarcane clones were selected for additional analyses among clones that tested either positive or negative by TBIA using all four sampled leaves. This sample selection will be called set B. Each leaf of set B was individually tested by RT-PCR.

**Virus detection by tissue blot immunoassay**

Tissue blot immunoassay (TBIA) was performed as described by Schenck et al. (1997), except that nitrocellulose membranes and Fast Blue salt (Sigma®) were used. TBIA membranes were analysed with a stereomicroscope (x10) to determine positive reactions.

**Virus detection and genotyping by RT-PCR**

**RNA extraction**

One hundred mg of each selected leaf sample was used for RNA extraction with QIAGEN® RNeasy Plant Mini Kit (Qiagen, Valencia, CA) following the manufacturer’s protocol. Total RNA was eluted in DEPC RNase-free water and stored at –20°C for future use.

**RT-PCR test with generic primers**

A specific SCYLV genome fragment from the coat protein coding region was amplified by RT-PCR using primers ScYLVf1 (GACAGACTCGGCCAGTGGTCGTG) and ScYLVr1 (GTAAGCCATTGTTGAACGCTGCG). The RT-PCR reaction was performed using QIAGEN® OneStep RT-PCR Kit.

The 25 µL RT-PCR reaction mix consisted of 1 µL of eluted RNA, 17.05 µL of RNase-free water, 5 µL of RT-PCR buffer (5X), 0.5 µL of dNTP mix (10 mM), 0.10 µL of each primer (100 µM), 1 µL of RT-PCR mix and 0.25 µL of RNase inhibitor (Invitrogen, Carlsbad, CA). The RT-PCR program was as follows: 50°C for 30 min, 95°C for 5 min, 30 cycles at 94°C for 1 min, 71°C for 1 min and 72°C for 30 sec with a final 72°C extension for 10 min. The PCR product was analysed by electrophoresis through a 1.0% agarose gel in TAE buffer, stained with ethidium bromide and visualised under UV light. The SCYLV amplification product had an expected size of 219 bp.
**Virus genotyping**

Only samples that tested positive with SCYLV generic primers were used to identify the SCYLV genotype(s) by RT-PCR with genotype specific primers. The amplification of a specific genome fragment from each SCYLV genotype was performed as described by Ahmad et al. (2006b), except that QIAGEN® OneStep RT-PCR Kit was used. The 25 µL RT-PCR reaction mix consisted of 1 µL of eluted RNA, 12.05 µL of RNAse-free water, 5 µL of Q solution, 5 µL of RT-PCR buffer (5X), 0.5 µL of dNTP mix (10 mM), 0.10 µL of each primer (100 µM), 1 µL of RT-PCR mix and 0.25 µL of RNAse inhibitor (Invitrogen ref.10777-019).

The RT-PCR program was as follows: 50°C for 30 min, 95°C for 5 min, 30 cycles at 94°C for 1 min, 56°C for 1 min and 72°C for 1 min with a final 72°C extension for 10 min. The PCR products were analysed by electrophoresis through a 1% agarose gel in TAE buffer, stained with ethidium bromide and visualised under UV light. The SCYLV amplification products of SCYLV genotypes BRA-PER, CUB and REU had expected sizes of 362, 450, and 905 bp, respectively.

**Statistical analyses**

All statistical analyses were made using SAS software v.9.1. Frequency comparisons between different sugarcane populations of RT-PCR positive and negative samples as detected with generic primers were made using Fisher’s exact test under freq procedure. Frequency comparisons of virus genotypes between the same sugarcane populations were made among RT-PCR positive samples as detected with generic primers using Fisher's exact test.

Comparisons of virus genotype frequencies within set A and set B pooled data were made under GLM procedure after arcsin transformation of genotype proportions.

**Results**

**SCYLV detection by TBIA**

Five hundred and twenty out of 632 sampled leaves (82%) tested SCYLV positive by TBIA. Additionally, at least one virus-infected leaf was found for 143 out of 154 sugarcane clones (93%). The virus was not detected in 112 plants (18%) and 11 sugarcane clones (7%).

**Detection by RT-PCR**

Among the 76 leaves of set A (38 sugarcane clones), 65 were positive for SCYLV by RT-PCR. Five leaves that tested negative by TBIA were positive by RT-PCR, and seven leaves that tested positive by TBIA were negative by RT-PCR. Fifty five of 61 leaves of set B were SCYLV-positive by RT-PCR, and eight leaves that were TBIA negative tested positive by RT-PCR. Frequencies of RT-PCR positive leaves were not different between set A and set B (P = 0.44, Fisher’s exact test).

**Genotyping**

The three SCYLV genotypes (BRA-PER, CUB and REU) were found in sets A and B, and the observed genotype incidences are detailed in Table1. Because incidences of genotypes BRA-PER, CUB and REU were not different between sample sets A and B, the data from both sets were pooled for further analyses. Virus genotype CUB had the highest incidence, followed by genotype REU and genotype BRA-PER (Table 2).

Most samples were infected by a single virus genotype (47.4%), but patterns of co-infection combining two or three genotypes were also found. Seventeen (12.4%) of the leaves were RT-PCR negative, 8 leaves (5.8%) were infected by BRA-PER only, 16 leaves (11.7%) by REU only, and 41 leaves (29.9%) by CUB only.

Five leaves (3.6%) were infected simultaneously by BRA-PER and REU, 10 leaves (7.3%) by BRA-PER and CUB, and 36 leaves (26.3%) by CUB and REU. Four leaves (2.9%) contained all three virus genotypes.

Interaction between plant characteristics and virus genotype incidences

The plant genetic background (i.e. crosses) and the characteristics of TBIA positive clones were studied taking into account virus genotype incidences.

The progenies of two crosses (#28 and #160) represented by more than 20 leaf samples were chosen and compared together, but also to the other remaining sampled crosses (Table 3).

RT-PCR positive sample frequencies of these three plant genetic groups varied from 75% to 95%. The plant genetic background had a significant effect on RT-PCR positive leaf frequency (P = 0.037) and also a strong effect on CUB and REU incidences, but not on BRA-PER incidence (Table 3).

Virus genotype incidences between the three groups of clones varied from 56% to 98%, 33% to 71% and 13% to 30% for CUB, REU and BRA-PER, respectively.

The sugarcane clones were distributed into two groups according to TBIA results. The first group (= group 1) contained all clones with four TBIA-positive leaves and the second group (group 2) contained all clones with at least one TBIA-negative leaf. We may assume that clones belonging to group 1 were more susceptible to SCYLV than clones belonging to group 2.

The frequency of RT-PCR-positive clones was compared within these two groups (Table 4), and it was significantly higher in group 1 that included the most susceptible clones as determined by TBIA. The incidence of each SCYLV genotype within the RT-PCR positive leaves was then compared between groups 1 and 2. Incidence of genotype CUB was not different in group 1 and group 2.

The same result was found for SCYLV genotype BRA-PER. In contrast, the frequency of REU genotype varied between the two groups (P = 0.014): 56% and 25% for groups 1 and 2, respectively. This latter result suggested that SCYLV genotype REU is able to infect the susceptible clones more easily than the other ones.

**Interaction between genotypes**

Because CUB was the most frequent genotype in the studied population, the incidence of genotypes REU and BRA-PER in CUB positive and CUB negative leaves was investigated. The incidence of genotype REU in CUB positive and CUB negative leaves was 44% and 45%, respectively. The frequency of genotype BRA-PER in CUB positive and CUB negative leaves was 15% and 28%, respectively, but this difference was not significant (P = 0.11).

**Discussion and conclusion**

A very high percentage of sugarcane clones of the selection plot (93%) were found infected with SCYLV, indicating rapid infection of plants after planting the seedlings a few years ago (assuming that SCYLV cannot be transmitted through true seed or fuzz; Rott et al., 2008). This situation is completely different from the situation observed in commercial fields in Guadeloupe where only few plants (0.5–37 %) were found infected by the virus (Daugrois et al., 2008). However, high incidence of SCYLV in commercial cultivars was described in Hawaii (Schenck and Lehrer, 2000) and in Réunion Island.

In this latter location, almost all plants of cultivar R575 were infected with the virus (Rassaby et al., 2004). The high variation of SCYLV incidence between CIRAD’s breeding station in Guadeloupe and commercial fields could be attributed to low resistance to yellow leaf of the sugarcane cultivars used as parents in the crossings. This hypothesis is supported by our data suggesting that the genetic background of the crosses used in the selection plot played a role in the
number of RT-PCR positive leaves (presence of the virus) and the number of leaves harbouring the different virus genotypes. This situation should be taken into account in breeding sugarcane for resistance to SCYLV.

Furthermore, the nature and dynamics of aphid vector populations might also account for the striking differences between the sugarcane selection plot and commercial fields in Guadeloupe (Edon Jock, 2008). SCYLV genotype REU was more frequently detected in the group of sugarcane clones considered as the most susceptible (all four analysed leaves tested positive by TBIA) than in the other group of clones (at least one leaf tested negative by TBIA).

This result is in agreement with previous experiments performed in Guadeloupe in which genotype REU was less aggressive than the other virus genotypes (Abu Ahmad et al., 2007).

The most frequent virus genotype in the selection plot was CUB, whereas genotype REU is the most frequent, if not to say the only one, in commercial fields of Guadeloupe. Additionally, a high proportion of leaf samples were co-infected with two different virus genotypes. We even found four single leaves (representing two clones) in which the three genotypes were present together.

The detection of all three SCYLV genotypes in a single plant is most likely related to the setup of the selection plot on a research station where sugarcane clones and genetic resources have been introduced for a long time, especially when sugarcane yellow leaf was unknown and/or when efficient detection tools were not available. It would be interesting to investigate whether the situation observed in Guadeloupe is unique or encountered in other locations where breeding stations are used to produce and select new cultivars.

This study shows that SCYLV genotype CUB has a better fitness than genotypes BRA-PER and REU among the breeding progenies of the selection plot in Guadeloupe. The reasons that account for this better fitness should be further investigated. Interestingly, the detection of genotype CUB remained confidential until very recently in Guadeloupe (Daugrois et al., 2008).

Occurrence of genotype CUB may have been underestimated because the detection primers that were used up to recently failed to detect this genotype in several circumstances (Girard et al., 2008). Alternatively, its occurrence may be very recent and, therefore, genotype CUB may be an emerging genotype in Guadeloupe.

The high proportion of leaves in which two different virus genotypes (and even three genotypes in four leaves) were detected suggests that the presence of one genotype in a plant does not prevent infection by another genotype in the same plant. These multiple infections were most likely favoured by the planting of clones near SCYLV-infected sugarcane germplasm and in the presence of large and active aphid populations.

To conclude, the results of this experiment give rise to at least two important questions: 1/ Does this situation, observed on a sugarcane breeding station, dictate the disease situation in sugarcane commercial fields within the next several years?, and 2/ Will the co-existence of two or three different SCYLV virus genotypes in the same plants promote the genesis of new virus genotypes that could be more virulent? Large fields of investigations regarding yellow leaf of sugarcane remain unexplored or insufficiently explored so far.

Acknowledgments

We would like to express our thanks to Dr Monique Royer for designing the new SCYLV primers used in this study.

MOTS CLEFS: SCYLV, Génotypes.

Résumé

La diversité génétique du Sugarcane yellow leaf virus (SCYLV) a été étudiée dans une parcelle de sélection de canne à sucre en Guadeloupe pour déterminer l’incidence des différents génotypes connus du virus (BRA-PER, CUB and REU) dans une descendance. Quatre feuilles F1 ont été collectées au hasard sur chacun des 154 clones de canne à sucre et testées pour la présence de SCYLV par la technique d’immuno-empreintes (TBIA). Les échantillons foliaires ont été stockés à –80°C en attendant l’extraction de l’ARN total des feuilles infectées par le SCYLV. Les génotypes du virus ont été déterminés par RT-PCR en utilisant des paires d’amorces spécifiques de chaque génotype. Quatre-vingt-deux pour cent des feuilles testées étaient infectées par SCYLV et tous les génotypes connus du virus étaient présents dans la parcelle de sélection. La majorité des plantes étaient infectées par les génotypes CUB ou REU, ou par un mélange de ces deux génotypes. Cette situation est totalement différente de celle observée dans des champs commerciaux en Guadeloupe où l’incidence du SCYLV est beaucoup plus faible, et où la plupart des plantes sont infectées par le génotype REU. La signification de cette situation surprenante fera l’objet d’autres études.
DIVERSIDAD GENÉTICA DEL SUGARCANE YELLOW LEAF VIRUS EN UNA PARCELA DE SELECCIÓN DE CAÑA DE AZÚCAR EN GUADELOUPE (FWI)

Resumen
La diversidad genética del Sugarcane yellow leaf virus (SCYLV) fue investigada en una parcela de selección de caña de azúcar en Guadalupe (FWI = Caribe francés) para establecer la incidencia de diferentes genotipos conocidos de este virus (BRA-PER, CUB y REU) en una descendencia. Cuatro hojas F1 (primera hoja totalmente desarrollada) fueron recolectadas al azar sobre cada uno de los 154 clones de caña de azúcar y la presencia de SCYLV fue determinada con la técnica de ‘tissue blot immunoassay’ o TBIA. Las muestras de hojas fueron almacenadas a –80°C y el ARN total fue extraído de las hojas infectadas por el SCYLV. Los genotipos del virus fueron determinados por RT-PCR utilizando tres pares de cebadores específicos de cada genotipo. Un ochenta y dos por ciento de las hojas analizadas estaban infectadas por el SCYLV y todos los genotipos conocidos del virus estaban presentes en la parcela de selección. La mayor parte de las plantas estaban infectadas por los genotipos CUB o REU, o por una mezcla de estos dos genotipos. Esta situación es totalmente diferente a la observada en los campos comerciales en Guadalupe donde la incidencia del SCYLV es mucho más baja y donde la mayoría de las plantas están infectadas por el genotipo REU. Las causas de esta situación asombrosa serán investigadas más adelante.
ORANGE RUST DISEASE OF SUGARCANE

By

R.C. MAGAREY

KEYWORDS: Orange rust, Puccinia kuehnii, Resistance, Early Warning, Fungicides.

Abstract

An outbreak of orange rust (Puccinia kuehnii) in the Australian sugarcane industry in 2000 caused devastating yield losses and significant financial hardships to cane farmers, sugar factories and the local communities that were reliant on the crop. The epidemic was first recognised in the year 2000, but later analyses suggest that orange rust was present in central (Mackay) region crops at least 1–2 years (in 1998–1999) prior to detection. This was evident in comparative sugar factory productivity data for several varieties and in yield loss analyses in breeding selection trials. Yield loss studies (breeding selection trials and fungicides) suggested losses of around 40% from orange rust. Resistance assessments showed there to be a high level of disease resistance in many commercial varieties. Fungicide research led to the application of fungicides to commercial crops to minimise yield losses. Large quantities of resistant seed-cane were transported long distances from neighbouring regions to assist farmers in replanting susceptible crops. Genetic analyses suggested that there were minor variations in the pathogen ‘pre-’ and ‘post-epidemic’; some variation was observed in pathogen isolates collected from its geographical range around the world. Possibilities for remote detection of the disease were investigated and techniques could be used to provide early warning of the presence of the disease.

Introduction

Recent detections of orange rust (Puccinia kuehnii) in North and Central America have continued to emphasise the new-found importance of this disease in commercial crops.

Originally restricted to south Asia, south east Asia, and the Pacific (Ryan and Egan, 1989; Magarey et al. (2002b, 2003a)), the disease has now been detected in the western hemisphere in North and Central America (Chavarria et al. (2009), Comstock et al. (2008), Ovalle et al. (2008), Flores et al. (2009)).

Australian evidence suggests that the recent outbreak, as reported by Magarey (2000), Magarey et al. (2001a, 2001b, 2002a, 2003b), are more serious than those occurring earlier in history.

A new, more aggressive strain of the pathogen may be the reason for these observations (Braithwaite et al., 2009).

In this paper, epidemiological considerations associated with the disease, the major effects of orange rust, the framework used in Australia for implementation of management strategies, potential early warning techniques and the presence of disease resistance in Australian germplasm are reviewed.
History of Orange Rust in Australia

Orange rust has been reported within the Australian sugarcane industry since the late 1800s, though the accuracy of some disease records has been questioned (Ryan and Egan, 1989). With the disease common in neighbouring Papua New Guinea, the centre of diversity of several *Saccharum* species, it is likely that orange rust entered Australia with PNG germplasm. Despite this, 20\textsuperscript{th} century reports of diseased commercial crops were rare. When brown rust (*Puccinia melanocephala*) first entered the Australian industry in 1978, that disease became known as ‘rust’ – there was no recognised need to distinguish brown rust from orange rust in commercial crops emphasising the minor importance of orange rust. As such, there were no purposeful orange rust disease assessments, screening for resistance, or regular reporting of the area affected in commercial crops.

Strains of *Puccinia kuehnii*

The rapid appearance of the disease in a widely-planted variety that had for a number of years shown no evidence of the disease lent weight to the hypothesis that the epidemic arose from a new pathogen strain. Molecular analysis of historical Australian samples (1898), samples collected from Indonesia, Papua New Guinea, Central America and from within the Australian sugarcane industry could not clearly pinpoint the nature of the strain change, but did show pathogen variation (Braithwaite *et al.*, 2009).

Braithwaite *et al.* (2009) concluded that isolates from commercial crops clustered together and this included the 1898 Australian isolate plus more recent isolates. Two other clades (groups) included *P. kuehnii* isolates from wild and garden canes in Indonesia and PNG. Though morphologically similar to *P. kuehnii*, there was more variation in these samples and they pose a potential further threat to the Australian (and other) sugarcane industry. They concluded there is a greater diversity in *P. kuehnii* isolates than thought previously (Braithwaite *et al.*, 2009).

Orange Rust epidemic in 2000

The status of orange rust changed in the year 2000 with its detection in the widely-planted commercial Australian variety, Q124. The epidemic was severe, crop canopies were largely dead, and biomass production stifled. Many very poorly-grown crops were present in the central (Mackay) region; symptoms included thin, rubbery, pithy, shortened stalks and senescing leaves.

Farmers venturing into their fields on machinery emerged with orange-coloured shirts and hats, and there were reports of concrete veranda floors covered with an orange film. Urgent action was needed to minimise crippling yield losses, and a major industry program involving research, strategic economic incentives and on-farm strategies was implemented to minimise economic effects.

Orange rust was first reported in Q124 crops in January 2000 in the Mackay district of central Queensland. Q124 is susceptible to yellow spot (*Mycovellosiella koepkei*) disease and previous high rainfall years favoured this disease. Observations in January 2000 suggested, however, that the observed symptoms were different to those of yellow spot; samples were dispatched to a pathologist who identified the disease as orange rust based on pustule and spore characteristics.

Rapid escalation in disease severity accompanied progress of the normal wet season and reports soon came of the disease in most other parts of the industry, including northern, Herbert, Burdekin and southern production areas. Orange rust was not seen in the southern-most Australian production area of northern New South Wales until the following year. By March 2000, the regions where Q124 was widely planted (central and Herbert) were badly affected with crop canopies in very poor health. Crops yields plummeted compared to previous years and individual farmers, sugar factories and service companies all were badly affected financially.
Evidence for early incidence

There is strong evidence that the disease first affected sugarcane crops in the central district before January 2000, there being two lines of evidence. Yield loss assessments in BSES plant improvement selection trials showed a relationship between orange rust resistance and yield in 1999-harvested crops in the central part of the Mackay district (Magarey et al., 2009a).

These losses were not seen further afield but in central Mackay trials only. Additionally, relative commercial crop yields in two significant Mackay varieties (one susceptible during the epidemic (Q124) and one that remained resistant (Q135)) showed that Q124 very significantly out-yielded Q135 in the mid-1990s, but by 1998 a trend to lower relative yield in Q124 emerged; the difference grew significantly post-2000.

With the presence of two leaf diseases, it is reasonable to conclude that orange rust was not detected in Q124 for 1–2 years. Close observation of individual leaves is needed to separate orange rust from yellow spot and this didn’t occur until orange rust severity rose significantly.

This provides an object lesson – that vigilant crop observations by pathologists trained in endemic and exotic diseases are needed to ensure an early warning of impending disease epidemics.

Yield loss research

Yield loss data have been published elsewhere, but a brief summary provides an indication of the extent of losses.

Breeding selection trials

Breeding selection trial analyses are based on relating the yield of a range of clones (80+) to their orange rust resistance in individual trials (Magarey et al., 2003b). The technique has been used to quantify yield losses caused by a range of endemic Australian diseases (Magarey et al., 2003b, 2009a).

Losses at individual sites in the Mackay region in the year 2000 reached 58% (tonnes cane / ha), though the mean figure was around 40%.

This was further emphasised by the relative performance of Q124 within selection trials; before 2000 Q124 was the most productive variety but, during and after 2000, it became one of the lowest yielding (Magarey et al., 2003b). Losses were not restricted to biomass, but included sugar content (CCS) with a reduction of 1 to 2 units.

Fungicide studies

Fungicide studies have also been reported elsewhere (Magarey et al., 2002a; Staier et al., 2003). Several experiments undertaken near Mackay showed yield improvements between treated and untreated plots of 40%, reinforcing the selection trial estimates. Reductions in sugar content of around 1–2 units again were reported (Staier et al., 2003).

Management of the epidemic

Magarey et al. (2001a) report on the management strategies associated with the epidemic. A focused, industry-based strategy, implemented as soon as the epidemic was recognised, greatly assisted with epidemic management.

The main components were:

i. the supply of orange rust resistant varieties that were free of systemically transmitted pathogens, from as far afield as 500 km away,

ii. the acceleration of resistant clones within the plant improvement program,

iii. the gaining of resistance data on both clones and parent canes and modified selection and crossing programs, and

iv. the application of effective fungicides to susceptible crops, thus minimising losses during the establishment of resistant crops.
Varieties

There was no problem identifying susceptible clones in variety trials in badly affected districts; senescing crop canopies in very poor health were very obvious. Quantitative resistance screening techniques were developed which utilised comparative standard varieties of known disease reaction (Magarey and Bull, 2009). Plant breeders discarded susceptible clones from selection programs and pathologists screened parent varieties for resistance to ensure suitably resistant crosses were made between parents (Magarey and Bull, 2009). Data showed that a high level of resistance was present within the Australian sugarcane germplasm (Magarey et al., 2003b; Magarey et al., 2009a, Magarey, 2006). The replacement of the highly susceptible Q124 in district crops effectively ended the epidemic. It has not been difficult since then for plant breeders to release high-yielding commercial varieties possessing a high level of disease resistance.

In the central and Herbert (the two most affected) districts, planting material of replacement resistant varieties was quickly made available in 2000 and 2001. The Mackay sugar factories offered financial incentives for farmers to replant susceptible crops with resistant varieties and the economics of the situation drove a rapid transition to resistant crops. In other districts, the situation was not as severe and farmers transitioned to resistant crops without direct assistance.

Fungicides

There have been no historical fungicide applications for leaf disease control in Australian crops. In fact, there are only rare reports of this on a world basis (Autrey et al., 1983). The need for a rapid disease control was so urgent in the Mackay region that widespread fungicide application occurred in-lieu of transition to resistant varieties. Staier et al. (2003) report on research undertaken in 2001 with the fungicides propiconazole, cyproconazole and mancozeb. Good control was achieved with as little as two spray applications, as long as the applications were made sufficiently early (when leaf area diseased reached 5%). Knowledge of the effect of weather conditions (Magarey et al., 2004, Staier et al., 2004) and predictive modelling assisted in minimising fungicide applications. The products were granted temporary registration and over 30 000 ha treated (Staier et al., 2003). Aerial applications were undertaken in 2001, but low sugar prices and the successful transition to resistant canes led to no, or very limited, further fungicide applications in the following years.

Epidemic considerations

Previous disease epidemics in Australia

There have been many disease epidemics in the Australian sugarcane industry, including those caused by sugarcane mosaic, leaf scald, Fiji leaf gall, brown rust, Pachymetra root rot and more recently sugarcane smut. Almost all began when the affected region had been widely cropped with one variety for a period of around 10 years.

Examples include Fiji leaf gall in southern Queensland where NCo310 dominated plantings (>80% of crops) for at least 10 years (Egan, 1982). The variety Q90 was widely planted in the northern region (>60% production) in the 1970–1980 period before Pachymetra root rot and brown rust both drastically reduced commercial yields. In central Queensland, the highly productive Q124 was widely grown, and constituted >80% of the regional production before the orange rust outbreak. It seems that whenever a single variety exceeds, on an extended basis, approximately 60% of production, a disease epidemic is initiated.

Progress of the orange rust epidemic

Progress of the orange rust epidemic was very rapid; the disease spread the length of the Australian sugarcane industry (approximately 2100km) in just over 12 months – though pre-detection disease occurrence suggests spread is likely to have begun in 1998 or 1999. Similar spread was observed with the Australian brown rust incursion; Ryan and Egan (1989) reported that P. melanocephala also spread through the industry within 12 months.
In contrast, spread of Fiji leaf gall (Egan, 1982) and sugarcane smut (Magarey et al., 2009b) have been much slower thus allowing more time for the transition to resistant varieties. The slower spread is no doubt a consequence of the involvement of a slower spreading vector with limited infective ability (Fiji leaf gall) and the limited target infection court for sugarcane smut (compared to orange rust). The orange rust yield effects quickly drove Mackay region farmers to transition to more resistant varieties and this is illustrated in Figure 1.

![Fig. 1—The orange rust crop resistance profile for Central Queensland 1995–2009: this provides a measure of the average resistance of crops grown in the region. The 2000 epidemic greatly influenced farmer variety choice, thus leading to a sudden surge toward resistant crops.](image)

Comparison to smut

Smut has not spread as quickly (Magarey et al., 2009b). The lower initial percentage of smut resistant varieties in the Australian industry has made the smut epidemic variety transition more difficult. Magarey et al. (2009b) suggest that smut will spread across an individual region (to reach all farms) within 2–3 years from first detection and will build up approximately 10-fold annually leading to very significant yield losses in susceptible crops 2–3 years from the first crop detection in that crop.

Remote detection

Mackay Sugar Limited (operating Mackay sugar factories) cooperated with researchers to develop remote sensing systems for orange rust detection (Apan et al., 2004). Several methodologies were investigated.

The authors concluded that accessing hyperion imagery enabled the remote detection of diseased crops possible. This offers other sugarcane industries scope for early detection of orange rust in order to speedily introduce appropriate management systems. Magarey et al. (2008, 2009c) found that spore trapping using commercial spore traps (‘spore and pollen samplers’, Burkard, England) could provide up to 24 months early warning for the presence of sugarcane smut (previous to the finding of field symptoms in a region). The system they used incorporated a specific molecular assay to confirm the presence of *Ustilago scitaminea* spores on trap tapes; similar systems could be developed for orange rust with assays specific to *P. kuehnii*.

Discussion

The Australian sugarcane industry suffered very significant financial losses in the midst of the orange rust epidemic in the 2000–2002 period. These losses were greatly contributed to by industry reliance on a single, high yielding variety, Q124. The relative abundance of high-yielding resistant varieties enabled a rapid transition to resistant commercial crops, and now the disease provides no direct financial constraint to sugarcane production.
Following the epidemic, there has been considerable discussion on the benefits / disadvantages of cropping a large proportion of a region to one specific variety. Such a strategy involves considerable risk to both farmers and factories from the potential occurrence of a disease epidemic. Australian experience lends credence to the view that the widespread planting of a single variety will lead to a disease epidemic. However, economic analyses suggest if a variety is of unparalleled productivity, the local sugarcane industry may make greater monetary returns by taking the risk and growing individual varieties until no longer possible because of disease-associated yield losses. Discussions on limiting variety production gathered momentum in Australia following the orange rust outbreak, but there has been no implementation. Previous high financial returns don’t always provide a viable way forward when a disease epidemic hits. When the orange rust epidemic occurred, factory through-puts were suddenly cut and immediate financial returns were drastically reduced, making it very difficult for some factories, farmers and local businesses to remain viable.

The widespread planting of single varieties may also lead to fundamental changes in pathogen populations and the predominance of hitherto minor pathogens. The longer-term costs and implications of this are not always considered. Is it the new strain of *Puccinia kuehnii* that developed in Australian Q124 crops the one that has now invaded Central and North America? Would this have happened if Q124 had not been so widely planted in Australian cropping regions? These and other questions remain to be answered.

Résumé

UNE EPIDEMIE de la rouille orangée (*Puccinia kuehnii*) dans la culture de la canne à sucre en Australie en 2000 a causé des pertes importantes et des difficultés financières aux planteurs de canne, sucreries et communautés locaux qui dépend de cette culture. L’épidémie a été constatée en 2000, mais les analyses ultérieures tendent à montrer que la rouille orangée était présente dans la région centrale (Mackay) depuis au moins 1–2 ans (en 1998-1999) avant sa détection. Cela était évident à partir des données comparatives des sucreries sur la productivité de plusieurs variétés ainsi que de l’analyse des pertes de rendement dans les essais de sélection. Les études de l’effet de la rouille orangée sur le rendement (essais de sélection variétale et de fongicides) ont démontré des pertes d’environ 40%. L’évaluation des variétés pour la résistance a montré un niveau de résistance élevé parmi plusieurs variétés commerciales. La recherche sur les fongicides a conduit à une application des fongicides dans plusieurs plantations industrielles afin de minimiser les pertes de rendement. Une importante quantité de boutures des variétés résistantes a été transportée sur de grandes distances des régions avoisinantes pour aider les fermiers à remplacer les variétés sensibles. Les analyses génétiques n’ont montré que des variations mineures dans le pathogène, avant et après l’épidémie, alors qu’une certaine variabilité a été observée parmi les isolats du pathogène collectés sur son étendue géographique à travers le monde. La possibilité de téldétection de la maladie a été étudiée et des techniques pourraient être mises en place comme moyen d’alerte précoce de la présence de la maladie.
ENFERMEDAD DE LA ROYA NARANJA
DE LA CAÑA DE AZÚCAR

R.C. MAGAREY

BSES Limited

PALABRAS CLAVE: Roya Naranja, Puccinia kuehnii, Resistencia, Alarma Temprana, Fungicidas.

Resumen
EN EL 2000, el brote de roya naranja (Puccinia kuehnii) causó severas pérdidas tanto en el campo como en las fábricas y serias dificultades financieras a los cultivadores y todas las comunidades relacionadas con el cultivo de la caña de azúcar. La epidemia se reconoció como tal en el año 2000, pero análisis posteriores demostraron que la roya naranja estaba presente en la regional central (Mackay), al menos durante 1–2 años (en 1998–1999) antes de esta fuera detectada como tal. Esto fue evidente en los análisis comparativos de productividad de varias fábricas y diversas variedades así como por las pérdidas en productividad de las diversas pruebas del proceso de mejoramiento. Los estudios sobre pérdidas en productividad (pruebas del proceso de mejoramiento como con fungicidas) indicaron que éstas fueron alrededor del 40% debido a la roya naranja. Las evaluaciones de resistencia mostraron que existe un alto nivel de resistencia a la enfermedad en muchas variedades comerciales. La evaluación de fungicidas llevó a su aplicación en muchos cultivos comerciales para reducir al mínimo las pérdidas en productividad. Grandes cantidades de semilla de variedades resistentes fueron transportadas a grandes distancias para ayudar a los cultivadores en el replante de cultivos susceptibles. El análisis genético sugiere que existen pequeñas variaciones en el patógeno ‘pre-’ y ‘post-epidemia’, puesto que se encontraron ligeras diferencias entre los aislamientos recolectados en diferentes regiones del mundo. Las posibilidades de detección temprana de la enfermedad fueron investigadas así como las técnicas que se podrían utilizar para proporcionar una alerta temprana sobre la presencia de la enfermedad.

KEYWORDS: Leaf Scald,
Sugar Cane, Resistance Test.

Abstract

LEAF SCALD, caused by X. albilineans, is a quarantined disease in Cuba and not much is
known on how it behaves under the environmental conditions of the country. Because
of this, we did a molecular characterisation of the inoculum employed to artificially
inoculate sugarcane plants at two varietal resistance trials and we developed a scale to
characterise the severity of the infection in the progeny The work has allowed progeny
evaluation of the families resulting from the hybridisation program for their reaction to
leaf scald. The months of September and October were the best times to plant genotypes
for selection and evaluation of leaf scald resistance.

Introduction

Leaf scald, caused by Xanthomonas albilineans (Ashby) Dowson, was first reported in Cuba
at the end of the 1970s.

During 1978–1982, leaf scald was detected in 14 foci scattered through 7 provinces of the
country (Rivera et al., 1979).

Years later, X. albilineans was detected in latently infected plants obtained through tissue
culture and in commercial plantations. The danger of a resurgence of the disease was pointed out
(Peralta et al., 1997).

Leaf scald is found in more than 54 countries and, during recent years, there have been
several outbreaks in different cane areas of the world, with significant losses being reported in
highly susceptible varieties (Rott and Davis, 2000).

The most effective methods used by geneticists and plant pathologists to control the disease
have been the use of resistant varieties and the use of healthy seed.

Because leaf scald has been reported to be influenced by the environment, there is a need to
study the different phytopathological principles that determine the behaviour of leaf scald in Cuba
and to obtain a greater efficiency in identifying new resistant varieties.

Materials and methods

The research was done at two research centres: one for the study of the diseases in Cuba,
part of the Provincial Sugar Cane Experiment Station of Camaguey located in Tayabito, on a brown
soil with carbonates, using two different planting times, March (Cycle A) and September (Cycle C),
and the second at the Matanzas Sugar Cane Experiment Station in Jovellanos on a red ferrous soil,
using the same planting cycles.
The methodology and experimental design were directed towards phytopathological concepts necessary to work with the disease caused by *X. albilineans* under Cuban conditions consisting of the following phases:

- Characterisation of isolates of *Xanthomonas albilineans* using AFLP, at two experiment stations in Cuba studying the disease.
- Determination of an evaluation scale to characterise the different disease reactions.
- Determination of the periods and times of greater occurrence of the disease under Cuban environmental conditions.

**Characterisation of isolates of *Xanthomonas albilineans* through AFLP at the two test centres for the disease in the country**

*Bacterial cultures* The bacterial cultures were centrifuged at 5000 rpm for 20 min and the sediment was used for the purification of the genomic DNA utilising the commercial method and reagents Wizard Genomic DNA (cat #A1120, Promega, USA). The integrity of the DNA was verified with agarose gels (0.8%) visualised with EtBr.

*Genomic Analysis* Genomic analysis was done by means of Amplified Fragment Length Polymorphism (AFLP) following the procedure described by Vos *et al.*, (1995) and according to European Patent 0534858 (Keygene, Belgium).

**Determination of an evaluative scale for the characterisation of the different effects caused by the disease**

To examine the role of bacterial concentration on genotypes resistance, as well as to define an evaluation scale, the study was divided into 4 fundamental aspects:

1. Define the symptoms and the severity of the infection.
2. Determine the dilutions required to make the counts of colony making units (ufc).
3. Compare the number of ufc in symptomatic and asymptomatic plants.
4. Determine the relationship between the ufc and the severity of the infection.

Afterwards, monthly evaluations were done, registering the number of plants with each degree of intensity in the scale that the proper methodology establishes. Having information on the severity of the disease and in order to differentiate intermediate responses from the varieties to this pathogen, a discriminant analysis was conducted.

**Determining the seasonal periods of greater occurrence of leaf scald under Cuban environmental conditions.**

The resistance against leaf scald of 377 new varieties of sugarcane and check varieties, (My5514, resistant; L 55-5, susceptible), was tested, utilising two different periods, Fall (September) and Spring (March), of planting and inoculation.

**Results and discussion**

Molecular characterisation of the samples of DNA of *Xanthomonas albilineans* analysed by means of AFLP with the combination of primers P (PstI) and M (MseI) is shown in Figure 1.

In the 4 combinations used, a great consistency and resolution of the amplified bands of DNA was observed.

The sections of gels with the greater resolution show they were amplified with different intensities, approximately 38 bands for the combination of primers A, 39 bands for B, 34 bands for C and 37 bands for the combination D.

At the same time, in all cases, a high similarity in the amplification bands is demonstrated and polymorphic bands of DNA were not identified.

The conclusion was that, under the conditions of this work, no significant variability was detected, demonstrating that both cultures are similar at this genomic level. Table 1 shows the primers used, and Figure 1 shows the amplification bands.

With no differences detected in the inocula used in the two Test Centres, a rating scale was developed for use under Cuban environmental conditions.

Based on a review of the results of the severity of the infection on plant cane and on ratoon crops and after applying the discriminatory analysis, 5 groups of varieties were characterised, based on their response to the infection (Table 2).

The definitive groups were decided on the maximum severity of infection shown in any of the evaluations on both ages of the crop.

Resistants, Intermediates, Susceptibles
When the group of varieties showing the greatest severity of infection in the ratoon stage was examined, it was noted that when the severity did not go over 10%, neither has the level exceeded 10% in the plant cane stage, emphasising the criteria of several researchers that the 10% level of severity could be the limit of expression of resistance in leaf scald.

An interesting element of concern is determining those times when the disease presents itself with greatest incidence in Cuba, thus making it possible to evaluate varieties more efficiently.

A comparison of the effect of the disease on both ages of the cane, whether as plant cane or ratoon, in relation to their classification degree can be seen in Figure 2. As can be seen, material planted in September showed greater damage by the disease as plant cane, whereas those planted in March showed greater losses as ratoon crop, which indicates that genotypes in September plantings can be evaluated quicker, but it is evident that both planting dates should be evaluated.

![Fig. 2—Comparison of the effect of the disease in relation to both age of the crop (plant cane and ratoon) and different planting dates (fall and spring).](image)

**Conclusions**

- Isolates of *Xanthomonas albilineans* used in the two Test Centres for varieties and parents in Cuba are similar at this genomic level; therefore, the information that is obtained can be extrapolated.
- A new scale showing different degrees of the severity of leaf scald infection is now available for Cuba.
- In fall planted cane (September), individuals can be separated as per their resistance without the need to get to the ratoon stage; to get more conclusive results, both plant cane and ratoons should be evaluated.

Résumé

L’echaudure, causée par *X. albilineans*, est une maladie de quarantaine à Cuba et il existe peu d’informations sur le comportement de la maladie sous les conditions environnementales prévalant dans ce pays. De ce fait, nous avons effectué une caractérisation moléculaire de l’inoculum utilisé pour l’inoculation artificielle de la canne à sucre de deux essais de résistance à la maladie et nous avons développé une échelle d’évaluation pour déterminer la sévérité de l’infection de la descendance. Cette étude a permis d’évaluer la progéniture des familles issues du programme d’hybridation génétique pour leurs réactions à l’echaudure. Les mois de septembre et d’octobre étaient les plus indiqués pour la plantation des génotypes, leurs sélections et l’évaluation de leur résistance à l’echaudure.

PALABRAS CLAVE: Escaldadura de la Hoja, Caña de Azúcar, Resistencia.

Resumen

La escaldadura de la hoja, causada por *X. albilineans*, es una enfermedad de cuarentena en Cuba y no se sabe mucho sobre cómo se comportamiento bajo las condiciones ambientales del país. Debido a esto, se hizo una caracterización molecular del inóculo empleado para infectar artificialmente las plantas de caña de azúcar en dos ensayos de resistencia varietal, usando una escala para caracterizar la gravedad de la infección causada. El trabajo permitió evaluar la progenie de las familias derivadas del programa de hibridación en su reacción a la escaldadura de la hoja. Los meses de septiembre y octubre fueron la mejor época para seleccionar y evaluar los genotipos en su resistencia a la escaldadura de la hoja.
PHYTOSANITARY SERVICE IN THE SUGARCANE INDUSTRY IN CUBA

By

MERIDA RODRÍGUEZ, EIDA RODRÍGUEZ, J. MATOS and M. CASAS
merida@inica.minaz.cu

KEYWORDS: Sugar Cane, Pest Control, Phytosanitary Service.

Abstract

Results obtained from 2000 to the present due to the implementation and generalisation of a Phytosanitary Service (SEFIT) is presented. This service has made an impact on the presence and control of pests and in moderating losses caused by them in cane production. It takes into account the active participation of the human capital inserted into the service, its qualification process, the recognition and registration of pests, pursuit of quality seed production, and developing main links to obtain healthy plants and pest control. Recommended measures take into account the biology and protection of the environment. The Service includes an automated version, unique of its type in Cuba, which allows making decisions regarding the integrated handling of harmful organisms, and consideration of the epidemiological of the strains, crop conditions, and commercial cultivars. It is also involved in the regulation of those factors presenting phytosanitary problems. The advances in the organisation of the phytosanitary service in sugarcane in our country are shown. This scientific and technical service offered by the National Sugarcane Research Institute (INICA) has shown significant benefits by preventing losses of sugar in excess of 700 000 tonnes, (market value of US$216 933), due only to smut. In addition, there were other benefits, such as lowering of indexes and percentages of infestation by pest, preventing the introduction of exotic organisms, and the reduction of rates of biological control products used to reduce incidence of pests and diseases.

Introduction

Currently, 139 pathological disorders have been reported on sugarcane worldwide, caused by pathogenic microorganisms, environmental disorders, parasitic plants and other causes. In Cuba, only 58 of these have been detected and of these, only 8 or 10 are considered of economic importance (Chinea and Rodriguez, 1994).

On the other hand, of the more than one thousand insects known to occur on sugarcane, only borers cause large economic losses to the sugar industry. Other pests of importance in Cuba are rodents, defoliating and sucking insects and nematodes.

Proper use of biological controls has resulted in decreased population levels of these pests and consequently decreased losses.

The Phytosanitary Service (SEFIT) is a new organisation created to make recommendations for recording and controlling new pests and reducing losses, with active participation of producers after receiving proper training.

Materials and methods

Results of phytosanitary research and production practices on sugarcane were compiled, and a diagnosis by visual symptoms made of the knowledge which was made available to experienced producers. Two annual samples were established in selected fields, on different plant age, time of planting and harvest, and varieties. For pest evaluation, in plant and ratoon crops, a stratified
sampling of 6 fields was conducted and the results obtained were grouped in ranges of 1–4 categories, where number 1 represented absence (INICA, 2006). With this information, a database was created and processed using an automated system.

**Results and discussion**

The information gathered from research and production data and the results from the report applied to experienced producers served as the basis for establishing the work methodology.

The development of this program raised the comprehension and execution level of actions in the implementation of the Service as well as raising the control level of pests with emphasis on environmental conservation.

From the results obtained, together with information disclosure and training, the Service was extended to all cane production areas.

This novel automated system is designed to analyse and classify pests and diseases by order of location importance, level of damage, and recommendations for control.

**Behaviour of sugarcane diseases: smut, rust and leaf scald**

Smut and rust are diseases that have been established in the country for more than two decades and remain in the first order of importance.

The management obtained by the composition of varieties, both at the national and provincial level, has allowed the reduction of these disorders.

Table 1 shows that areas affected by diseases at an intensity of severity from medium to severe has remained for the last three years in a range (percentage) of 5% in the case of smut and at not a very significant value in the case of rust and leaf scald.

In the case of diseases, recommendations such as proper management and planting of resistant varieties, together with diversification with other field and forestry crops in the cane growing areas, have contributed to a reduction in the inoculum pressure in the ecosystem.

**Behaviour of insect pests and rodents**

Borers and rodents constitute the most harmful species to sugarcane in Cuba. In the period in which their presence was analysed (Medium + intense), the area of intense infestation did not exceed 7% of the sampled area for *Diatraea saccharalis* and 16% for rats, the latter maintaining a similar status as the one reported in previous years.

This result has been favoured by the recommendations and the campaigns of liberation of biological controls, as well as the elimination of rats in cane areas, infrastructures and towns nearby. The defoliators and elaterids have not shown attacks of significance (Table 2)

In the case of borers and rodents, a reverse behaviour is observed, the bigger contribution to damage being from borers in the stools of the spring crop of that year, which is in accordance with results that have demonstrated that the succulence of new plantings induces the proliferation of insect pests.

From the environmental standpoint, a reduction of other detrimental agents was obtained as well as the prevention of exotics, which was made possible by the application of recommendations offered by the Service for the optimum varietal composition, the evaluation of the quality of the seed used for replanting plantations, and the activation of phytosanitary awareness with all of its components.

Chemical products are not included among the recommended control practices, except in the case of rodenticides due to the little availability and stability of biological control practices under field conditions.

Conclusions

- It was defined that the main biotic factors affecting the sugarcane crop in Cuba are: smut, rust, leaf scald, borer (*D. saccharalis*) and rodents.
- It was determined that, at the national level, the incidence of the levels of smut, leaf scald, borers and rodents did not surpass the medium level, whereas the incidence of damage by rust was low.

PALABRAS CLAVE: Caña de Azúcar, Control De Plagas, Servicio Fitosanitario.
Resumen
Se presentan los resultados obtenidos desde 2000 hasta el presente sobre la la aplicación y la generalización del Servicio Fitosanitario (SEFIT). Este servicio ha gran tenido un impacto sobre la presencia y control de plagas y en la moderación de las pérdidas causadas por ellos en la producción de caña de azúcar. Tiene en cuenta la participación activa del capital humano inserto en el servicio, su proceso de calificación, el reconocimiento y registro de las plagas, la búsqueda de producción de semilla de calidad y el desarrollo de diferentes vínculos para obtener plantas sanas y control de las plagas. Las medidas recomendadas tienen en cuenta la biología y protección del medio ambiente. El servicio incluye una versión automatizada, único de su tipo en Cuba, que permite la toma de decisiones sobre el manejo integral de organismos nocivos y la consideración de los aspectos epidemiológicos de las cepas, las condiciones de los cultivos y cultivares comerciales. También participa en la regulación de los factores que presentan problemas fitosanitarios. Se presentan los avances en la organización de los servicios fitosanitarios en la caña de azúcar en nuestro país. Este servicio técnico y científico es ofrecido por el Instituto Nacional de Investigación de la Caña de Azúcar (INICA) y ha demostrado beneficios significativos mediante la prevención de las pérdidas de azúcar en más de 700 000 toneladas (con valor en el mercado de USD$ 216 933), debido sólo al carbón. Además, hubo otros beneficios, tales como la reducción de los índices y porcentajes de infestación por plagas, la prevención de la introducción de organismos exóticos y la reducción de las cantidades de productos de control biológico para disminuir la incidencia de plagas y enfermedades.
EVALUATION OF A REUNIONESE VARIETY INFECTED BY RATOON STUNTING DISEASE

By

C. ROUSSEL, L. CORCODEL,
A. THONG-CHANE and L. BARAU
eRcane– PB 315– 97494 Sainte Clotilde Cedex–La Réunion– France
roussel@ercane.re

KEYWORDS: RSD, Variety,
Agronomic Evaluation, Juice Quality.

Abstract

R583 is a sugarcane variety adapted to the high altitude and dry conditions in the west part of Reunion Island. R583 is susceptible to ratoon stunting disease (RSD) caused by the bacteria Leifsonia xyli subsp. xyli (Lxx). The aim of this preliminary study was to evaluate the agronomic results and juice composition of R583 infected by RSD prior distributing the variety. Despite its susceptibility to RSD, agronomic trials have shown a 33% improvement in tonnes of sucrose per hectare compared to the widely grown variety R577. Juices from infected stalks were analysed. Differences in juice composition highlighted should not negatively affect sugar mill performance. Considering the risks of the susceptibility of R583, the improvement of sugar yield and the results of juice analysis, a decision was taken to distribute the variety with appropriate precautions.

Introduction

R583 is a variety well-adapted to high-altitude (above 500 m), dry and non-irrigated area. The current standard in this area in Reunion Island is R577. R583 is susceptible to ratoon stunting disease (RSD).

Ratoon stunting disease is a common sugarcane disease caused by a bacterium, Leifsonia xyli subsp. xyli (Lxx) located in the xylem (Gillaspie and Teakle, 1989). Because symptoms can be attributed to hydric stress, the disease can go unnoticed and can be spread inadvertently (Bailey and Bechet, 1986). Impact on cane yield is well documented (Steindl, 1961; Bailey and Bechet, 1986) but effect on juice composition with the disease is less known.

Disease evaluation of RSD is time-consuming and complex. However, it was decided to evaluate the effects of Lxx infection on the agronomic results of variety R583 in the late breeding stage and on the variety juice composition. The poster presents the results of this preliminary evaluation.

Materials and methods

Breeding field

The field trial is located in Vue-Belle station, representative of the growing area of R583. The field is composed of 5 replications of 24 varieties among which were R583 and the standard R577. It was planted on 1st March 2004. The plant crop was harvested on 25 August 2005, 1st ratoon on 23 August 2006 and 2nd ratoon on 13 September 2007.

The yield was assessed by weighing each plot. The extracted juice was analysed for pol in cane (for sucrose content), fibre and thus extractible sugar according to formulae developed at eRcane:

Fibre %Cane = 0.447 x b x 100 where b = \frac{\text{cake weight}}{\text{pulp weight}}
Extractible Sugar %Cane = Pol%g × ((1–1.24 × Fibre %Cane) × 0.9)−2
With Pol%g = Pol of Extracted juice.
Sugar content %Cane = Extractible Sugar %Cane + 2.8

**Lxx detection**

The cross section of the bottom part of cane stalks was pressed on a sheet of nitrocellulose and used to detect the pathogen in the vascular bundles by tissue blot immunoassay (TBIA) (Harrison and Davis, 1988).

**Plant material for Lxx detection**

Two series of Lxx detection were made in the breeding field trial in 2008 on the third ratoon:

1. In the first series (July 2008), 5 stalks in each plot of the breeding field trial (24 varieties, 5 replicates) were tested on seven-month old canes. The results showed that only R583 was infected by Lxx.
2. Thus, the second series made in September 2008 concerned only R583. One hundred twenty two stalks of twelve months stalks of R583 were sampled in the most infected plots. The purpose was to have as many infected stalks as possible. Then the stalks were numbered and tissue blots were made on each individual stalk.

**Juice collection**

The sampled stalks were individually crushed using a three-roller mill. For the 122 stalks, about 150 to 200 mL of extracted juice was collected and frozen for further analysis.

**Juice analysis**

In order to have sufficient juice for all analysis, juices were pooled according to their percentage of colonised vascular bundles.

Pol and brix were analysed following the non-lead method (ICUMSA Draft Method No. 9, 2007). Conductivity and pH were performed directly in raw juice with a CONSORT C532. Chromatographic analysis of sucrose, glucose, fructose, mannitol, palatinose, isomaltotriose and 1-kestose were performed using dionex high performance anionic exchange chromatography with a pulsed amperometric detector (HPAEC-PAD) following ICUMSA method (GS7/8/4-24, 1998) and with appropriate dilution.

Thirteen amino-acids were quantified using a commercial Waters AccQ.Tag Chemistry Package. Phenols were measured using the reagent Folin-Ciocalteu method (Phenolic compounds determination in cane juice, SPRI).

**Results and discussion**

**Lxx detection results**

**First series**

The first set of analyses showed that none of the stalks of R577 was infected. Presence of the Lxx occurred in 6 of the 25 stalks of R583.

**Second series (on R583)**

Lxx detection revealed that 46 of the 122 stalks (37.70%) were infected by Lxx. For infected stalks, percentage of infected vessels ranged from 3.1 to 93.9% with an average of 54.55%. As mentioned in the materials and methods, juices were pooled into groups presented in Table 1.

The first group included only juice from non-infected stalks. Seventy six of the 122 stalks were not infected by Lxx. Because the number of non-infected stalks was much higher than infected ones, it was decided to analyse only five sub-groups of 5 (total 25) of them.

Ten other groups included all the infected stalks. Range of each group is 9.1% of colonised vascular bundles. When a group is composed of 5 juices or more, two sub-groups are created to maximise the number of analyses.

Infected by RSD, R583 has a higher sugar yield than the healthy standard R577

In Figure 1, R583 is compared to the standard in the area of Vue Belle: R577. According to the first evaluation of RSD infection in this field (series of July), no Lxx was detected for R577; however, R583 was infected. The presented figures apply to the last stage of the breeding process for one plant crop and two ratoons. For R583, cane yield was 26.8% higher than R577 (P < 0.01), sucrose content was comparable to the standard (4.1% higher but not significant) and extractible sugar yield (cane yield × extractible sugar in cane) was 33.4% higher (P < 0.01). R583 can significantly out-yield the standard R577.

Composition of R583 juices

Linear model of each measurement versus percentage of colonised vascular bundles was performed using R software (R Development Core Team, 2009). Results of the linear model analysis presented in Table 2 details the slope of the predicted equation, the determination coefficient (R²) and the associated p-value.

No significant difference in juice was highlighted for the following measured criteria: brix, glucose, pH, phenols, kestose and 7 amino acids: aspartic acid, proline, cysteine, tyrosine, methionine, lysine and phenylalanine.

However, 15 measurements were presenting statistical differences (P value < 0.05). True purity, glucose to fructose ratio and threonine increased significantly with the percentage of colonised vascular bundles.
Significant decreases with percentage of colonised vascular bundles were associated with fructose, reducing sugar, ash, mannitol, palatinose, isomaltotriose, 5 amino-acids (glutamic acid, glycine, arginine, valine and alanine) and total amino-acids content.

**Table 2**—Effect of percentage of colonised vascular bundles on juice composition—results of linear model.

Increase of true purity and decrease of many other components actually improves juice quality. From a sugar mill point of view, differences highlighted in this section should not affect sugar extraction. In this study, amount of most amino acids was lower when the stalk was highly infected. This had never been shown before. This might be related to the physiology of the cane once infected by Lxx.

**Conclusion**

The variety R583 is susceptible to RSD but it has a higher sucrose yield compared to the well-spread standard R577. Decrease of juice quality has not been highlighted. However, it seems that infected canes have a lower content of particular amino acids but this has not been explained so far.

In the west high-altitude dry and non-irrigated area of Reunion Island, R583 can increase growers’ income compared to the standard R577. The spreading of the disease can be controlled by thermotherapy and with appropriate precautions at harvest. Considering the risks of the
susceptibility of R583, the improvement of sugar yield and the results of juice analysis, a decision was taken to distribute the variety with appropriate precautions.

Résumé

La R583 est une variété de canne à sucre adaptée à une altitude élevée et à des conditions sèches de l’ouest de l’île de la Réunion. La variété est sensible à la maladie du rabougrissement (RSD) causée par la bactérie Leifsonia xyli subsp xyli (Lxv). L’objectif de cette étude préliminaire consistait à évaluer les résultats agronomiques et la composition du jus de la R583 infectée par le RSD avant sa distribution. Malgré sa sensibilité au RSD, les essais agronomiques ont montré une augmentation de 33% de sucre à l’hectare en comparaison à la variété R577, largement cultivée. Le jus des cannes infectées de la R583 a été analysé et la différence dans la composition du jus ne devrait pas affecter la performance des usines. En tenant compte de la sensibilité de la R583 au RSD, de l’augmentation de rendement en sucre, et des résultats des analyses du jus, une décision a été prise de distribuer la variété en observant les précautions appropriées.
EVALUACIÓN DE UNA VARIEDAD DE REUNIÓN INFECTADA POR RAQUITISMO DE LA SOCA

PALABRAS CLAVE: RSD, Variedad, Evaluación Agronómica, Calidad de Jugo.

Resumen
R583 ES UNA variedad de caña de azúcar adaptada a condiciones de altas altitudes y clima seco, existentes en la parte oeste de la Isla de la Reunión. R583 es susceptible a la enfermedad raquitismo de la soca (RSD), causada por la bacteria Leifsonia xyli subsp xyli (Lxx). El objetivo de este estudio preliminar fue evaluar los resultados agronómicos y composición de jugos de R583 infectados por RSD, antes de la distribución de la variedad. A pesar de su susceptibilidad al RSD, los ensayos agronómicos mostraron un aumento en 33% las toneladas de azúcar por hectárea, en comparación con R577, variedad ampliamente cultivada en la Isla. Los jugos de tallos infectados fueron analizados. Las diferencias en la calidad de jugos entre sanos y afectados no afectaron negativamente la variedad en su desempeño en los ingenios azucareros. Teniendo en cuenta los riesgos de susceptibilidad de R583 pero su mayor producción de azúcar y los resultados de calidad de jugos, se tomó la decisión de distribuir la variedad, con las precauciones adecuadas.
COGENERATION POTENTIAL IN COLOMBIAN SUGAR MILLS

Abstract
NOWADAYS, the Colombian sugar industry is involved in an expansion process, mainly related to the diversification of final products. In this way, since 2005 five ethanol distilleries are running, covering just 65% of total ethanol demand. Distilleries were designed coupled with a composting plant, based on vinasses and sludges from the sugar plant. Both distilleries and composting plants show many features which make them a special case in the ethanol market, so they produce a maximum of 3 L vinasse/L ethanol. Besides, in all cases, the thermal and electrical power requirements at the ethanol plant are supplied by the sugar plant. In this paper, a brief description of technological features of the typical process configuration followed by the Colombian sugar industry is shown. It comprises the steam consumption distribution by sections, the common configuration of the heat exchanger network (HEN) developed for vegetal steam usage and the role of the energetic self-sufficiency of the factory played by the bagasse quality. A set of possible scenarios for improving energy efficiency in a selected mill which comprises a modified HEN can be formulated, including a revamping of existing boiler and finally a new boiler operating at higher pressure. Based on the previous information, the state of the main Colombian cogeneration projects based on sugar cane and its potential impact on national energy supply is shown. Finally, the paper describes how Colombian governmental requirements for cogeneration plants are trying to establish a legal framework for this novel industrial activity in the country.

Introduction
In Colombia, the sugar sector is one of the most important thermal energy consumers. Steam % cane is an indicator of the quantity of thermal energy used in the process. This index for the Colombian sugar mills ranks between 500 and 680 kg steam/t cane. Besides, the index of electrical energy usage in the process is increasing since the ethanol plants began operation (2005), reaching values of 30 kW-h/t cane.

This paper shows how the configuration of the heat exchanger network (HEN) for different stages in the sugar mill process is useful to improve energy efficiency and to project different cogeneration configurations. Finally, as a result of this analysis, a general review of the present cogeneration projects in the sugar mills is presented, including the Equivalent Electrical Efficiency (EEE) calculated for each of them.

Methodology
First, a detailed characterisation of the production process in a selected sugar mill is required. The mass and energy balance is obtained including an evaluation of the efficiency and fuel waste in the boilers. Thus, the electrical energy generation requirement was obtained for the actual conditions.
Next, alternative cogeneration schemes for the sugar mill are projected, taking into account the implementation of new technologies for improving energy saving. After that, by applying ‘Pinch Technology’ in sections like heating, evaporation and concentration, the potential of saving steam is determined. Finally, for assessing the legal feasibility of several Colombian sugar mills’ cogeneration projects, the Equivalent Electrical Efficiency is calculated.

**Selected sugar mill characterisation**

The selected sugar mill is located in the north zone of the Cauca Valley, Colombia. The total cane crushed during 2007 was 1 260 305 tonnes for 287 working days. In Table 1, a description of principal processes used in the sugar mill is presented. The energy and mass balance for the actual scenario are presented in Figure 1.

The energy incoming with bagasse is taken by the distilleries (17.8%), the turbo generators (38.9%), the process turbines (20.4%) and the remainder is lost in the boilers. The electrical power is supplied by three turbogenerators (18.5 MW in total), which are enough to supply all process requirement. Figure 2 shows the exhaust steam use distribution in the process.

Options for improving energy use

First scenario: Applying HEN

The ‘Pinch Technology’ is a process designed tool which can be used in different sugar processes. So, for the selected sugar mill configuration, a new Heat Exchanger Network (HEN) would save 9 t/h exhaust steam.

In the juice heating station, a new juice heater was proposed, taking advantage of the thermodynamical quality of exhaust steam, saving around 295 kg/h of steam, by decreasing the pinch point from 12.3°C to 9°C.

The new equipment should be installed before the evaporation station. Besides, four new configurations for the juice heating station were proposed in order to save exhausted steam. In Table 2, the four alternatives are presented.

Figure 3 shows the thermal efficiency obtained by each one of these configurations. This index could be increased from 90% to 94%. The total saving in energy potential is around 9 MW.

Second scenario

For the second scenario, increasing boiler operation pressure (from 22 bar to 40 bar) and flow of cane crushed (5% more) were considered. Electrical power motors should be installed for mills and boiler fans and the use of a continuous pan using second effect vegetal vapour from the evaporation station were also considered.

Figure 4 presents this scenario layout. The modification results in saving around 2858 kg/h of steam by the use of continuous pan, and around 1.7% (2.3 MW) from the total bagasse energy is available for selling to the grid. Figure 5 presents the results.
Fig. 3—Evaporation station efficiency for proposed new configurations

Fig. 4—Modifications in the second scenario.

Fig. 5—Sankey diagram for the second scenario
Third scenario:

In this case, a new boiler operating at higher pressure and temperature (65 bar and 480°C) and a new, more efficient extraction–condensation turbo generator (5.4 kg steam / Kw-h) were considered. A 21.5 bar steam extraction is projected from the new turbo generator to supply the evaporation station. The modifications on electrification of mill station and boiler fans and continuous pan implementation from second scenario were conserved. Figure 6 shows this third scenario. In this case, electrical power available for selling to the grid reaches values of 11 MW. In Figure 7, the Sankey diagram about the energy distribution for this case is presented.

Comparisons between the total electrical power generated in each one of the three scenarios are presented in Figure 8.
General overview of colombian cogeneration sugar mill projects:

Actually, seven cogeneration projects in the Colombian sugar mills are in progress. Table 3 presents a review about the main features of them. The total potential electrical power generation is about 145 MW. Colombian governmental requirements for cogeneration plants are trying to establish a legal framework for this novel industrial activity in the country. For this purpose, an efficiency indicator was proposed, called Equivalent Electrical Efficiency (EEE), which can be determined as follow:

$$EEE = \frac{EE}{PE - \frac{UH}{\eta_{ref}}}$$

Where:
- EE = Electrical energy production
- PE = Primary Energy consumption
- UH = Useful Heat produced
- $\eta_{ref}$ = Reference Boiler Efficiency

| Table 3—Cogeneration projects in Colombian sugar mills |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| MILL # 1        | MILL # 2        | MILL # 3        | MILL # 4        | MILL # 5        | MILL # 6        | MILL # 7        |
| Cane crushed (t/h) | 440            | 300            | 270            | 370            | 330            | 580            | 230            |
| Boiler (Pressure- Temp) | 67 (bar) 540 (°C) | 67 (bar) 505 (°C) | 63 (bar) 510 (°C) | 62 (bar) 480 (°C) | 62 (bar) 480 (°C) | 45 (bar) 395 (°C) | 64 (bar) 500 (°C) |
| Turbo generator BP: Back-pressure EC : Extraction - condensation | BP (20 MW) EC (10 MW) | BP (27 MW) EC (10 MW) | BP (25 MW) | BP (20 MW) EC (20 MW) | BP (20 MW) EC (18 MW) | EC (35 MW) | BP (10 MW) EC (10 MW) |
| Power to sell | 20 (MW) | 25 (MW) | 12 (MW) | 21 (MW) | 23 (MW) | 10.5 (MW) | 10 (MW) |
| EEE - $\eta$ Ref: 90% | 23.0% | 25.4% | 27.9% | 22.6% | 22.8% | 22.2% | 23.2% |
| EEE - $\eta$ Ref: 70% | 33.4% | 37.1% | 38.4% | 33.6% | 33.8% | 35.3% | 34.0% |

So, it is proposed that a minimum value of 30% for EEE in cogeneration projects based on sugar biomass is required. For calculating EEE in any cogeneration project, reference efficiency for transformation of chemical energy of the fuel to thermal energy is necessary. The Colombian
government established 90% as a reference efficiency, but boilers using biomass fuel can just reach 70% on average. Figure 9 shows the EEE for a typical sugar mill cogeneration project calculated with 90% and 70% of reference efficiency. Predetermined EEE value of 30% is just reached using 70% of reference efficiency only.

![Graph showing EEE for cogeneration project](image)

**Conclusions**

Cogeneration is a reality for the Colombian sugar industry with seven projects, accounting for a potential sale of electric power of 145 MW, which gives it a more energetic and technological support to the sector. Planning of a cogeneration project must evaluate different scenarios, including those which involve the energy balances of the process, for determining the real potential for cogeneration. This is a vital part of the assessment of project’s feasibility. A draft of the cogeneration of steam at high temperature and high pressure will give a better chance to get the thermal energy for conversion into electricity. The use of comparative indexes for regulating cogeneration projects (as EEE in Colombian national rules) should be done in consideration of the particular conditions of the technology in use, such as in the case of bagasse boilers.
rendent particulières sur le marché de l'éthanol car elles produisent un maximum de 3 L vinasse L⁻¹ d'éthanol. En outre, l'alimentation électrique et thermique de la distillerie est fournie par les sucreries. Dans cette communication, une brève description des caractéristiques technologiques de la configuration de processus typiques de l'industrie sucrière colombienne est présentée. Cela comprend la consommation et la distribution de la vapeur par sections, la configuration du réseau échangeur de chaleur (HEN) développé pour les usages végétaux et le rôle de l'autosuffisance énergétique de l'usine assurée par la qualité de la bagasse. Un ensemble de scénarios pour améliorer l'efficacité énergétique dans une usine donnée comprend une HEN modifiée peut être formulé, y compris une réorganisation des chaudières existantes et enfin, une nouvelle chaudière fonctionnant à pression plus élevée. D'après les informations antérieures, l'état des principaux projets colombiens de cogénération à partir de la canne à sucre et son impact potentiel sur la fourniture énergétique nationale est présenté. Enfin, cette communication décrit comment le gouvernement colombien tente d'établir un cadre juridique pour cette nouvelle activité industrielle dans le pays.

POTENCIAL DE COGENERACIÓN EN INGENIOS ZUCAREROS COLOMBIANOS

Resumen
EN LA ACTUALIDAD la industria azucarera colombiana está envuelta en un proceso de expansión, principalmente de diversificación de los productos finales. Así, desde el 2005 operan cinco (5) destilerías de etanol, que cubren solamente el 65% de la demanda total de etanol. Las destilerías fueron diseñadas acopladas a plantas de ‘compost’, basadas en vinazas y lodos residuales de las plantas de azúcar. Ambas, las destilerías y las plantas de ‘compost’, muestran muchos rasgos que las hacen un caso especial en el mercado de etanol, producen un máximo de 3L de vinazas/L de etanol. Además, en todos los casos, los requerimientos térmicos y de energía eléctrica de la planta de etanol se suministran por la planta de azúcar. En este trabajo se muestra una breve descripción de los rasgos tecnológicos de una configuración típica del proceso seguido por la industria azucarera colombiana. Esto comprende la distribución del consumo de vapor por secciones, la configuración común de la red de intercambiadores de calor (HEN), que se desarrolló para el empleo del vapor vegetal y el papel de la autosuficiencia energética que juega la calidad del bagazo... Se puede formar un juego de escenarios para incrementar la eficiencia energética en un Central seleccionado, que comprende un HEN modificado, incluyendo una reconstrucción de las calderas existentes y finalmente una caldera operando a más altas presiones... Finalmente se muestra, basándonos en la información previa, el estado de los principales proyectos colombianos de cogeneración basados en la caña de azúcar y su potencial impacto en el suministro nacional de energía. Concluyendo el trabajo con una descripción acerca del como los requerimientos gubernamentales colombianos están tratando de establecer un marco legal para esta novedosa actividad industrial en el país.
POTASSIUM REMOVAL FROM DISTILLERY SLOPS BY Candida utilis PROPAGATION

KEYWORDS: Distillery Slops Decontamination, Single Cell Protein, Feed Protein, Potassium Removal.

Abstract

YEASTS accumulate varied amounts of most of the minerals present in their growth media. Much of the 7.5–8.1% ash found in the yeast grown for baking or harvested from beer is potassium phosphate, but yeast has the ability to accumulate other ions provided (but not necessarily needed) in high concentration. Distillery slops still contain about 70% of all potassium contributed to the soil in cane fields as chemical fertiliser, thus fertigation with these wastewaters has to be carefully calculated since otherwise soil salinisation can occur. When grown in a medium composed of distillery slops, nutrient salts (ammonium phosphate and sulfates) and a microbial growth enhancer Candida utilis shows a great resistance to potassium concentration in continuous culture. Yeast cells were propagated under the above conditions with increasing amounts of K2O from 2.5 g/L concentration (distillery slops from molasses fermentation) up to 25 g/L in propagation medium. Specific growth rate (µmax) ranged from 0.32 to 0.28 h⁻¹ for the extreme values mentioned above, while biomass-substrate yield coefficients were 0.23 to 0.18. These results suggest that yeast propagated on supplemented distillery slops could significantly reduce the potassium content of these wastes making them more suitable for irrigation purposes. According to the nutritional assessment reported, the potassium accumulated has no deleterious effect on animal health.

Introduction

Currently, there are 121 sugar-producing, and 57 ethanol-producing countries in the world. Roughly, 72% of the world’s sugar comes from sugarcane, and the rest from sugar beets (2005). For ethanol, 54% comes from grains, and 46% from sugarcane (2005).

Production of ethanol is concentrated mostly in Brazil and the US, which together account for 72% of world’s production in 2005. Although for decades Brazil was unrivalled as the world’s largest biomass ethanol producer, since 2005 the US has overcome Brazil as the largest producer (Nastari, 2006).

Ethanol makes an excellent motor fuel: it has a research octane number (RON) of 109 and a motor octane number (MON) of 90, both of which exceed those of gasoline. Ethanol also has a lower vapour pressure than gasoline which results in lower evaporative emission. On the other hand, anhydrous ethanol has lower and higher heating values of 21.2 mega joules per litre and 23.4 mega joules per litre, respectively; for gasoline the values are 30.1 and 34.9 mega joules per litre.

Ethanol is a fast growing source of vehicle fuel, and it is likely that it will keep on growing in the future, to be extensively blended with gasoline. Environmentalists hope it could be developed as a cleaner source of fuel than oil or natural gas.

Sugarcane agro-industry exhibits a high ecological impact in all tropical and subtropical countries that operate that production. On the other hand, it should be said that the industry
generates many jobs in the Latin American region, as sugarcane is one of the most widespread commercial plants and, at the same time, ranks among the most efficient plants with respect to bioconversion of solar energy into biomass.

Sugar and ethanol are basically the sole physical products that the sugar industry generates and both of them require large amounts of water during processing which led to the evolution of large quantities of liquid wastes (Otero et al., 2008).

Among the most polluting industrial wastes are distillery slops or vinasse from ethanol distillation, due to their content of organic and inorganic substances.

Vinasse is produced at a rate of 10 to 12 cubic metres per cubic metre of distilled ethanol unless special techniques are applied, but all they do is concentrate the same amount of BOD / COD into a smaller volume. Chemical oxygen demand in vinasse is a function of fermentation and distillation efficiencies and ranges from 30 to 85 mg/mL.

To reduce the environmental impact of vinasse disposal, several strategies have been implemented mainly through biotechnological systems in order to match current legal settings.

Among them are fertigation, anaerobic digestion, desalting and concentration, burning and recycling to reduce the amount of dilution waters (Otero et al., 2006; Otero et al., 2008).

However, the upgrading of vinasse through the production of microbial protein makes this wastewater a valuable product that in addition makes an important contribution to the sustainable management of ecosystems (Martinez et al., 2004; Otero et al., 2006).

One of the most aggressive components of vinasse is its inorganic fraction, especially potassium salts that compose the overwhelming majority of ash composition (van Haandel and van Lier, 2006).

Distillery slops still contain about 70% of all potassium contributed to the soil in cane fields, thus fertigation with these wastewaters has to be carefully calculated since otherwise salinisation is a real danger. However, at the same time, potassium is an essential ion for microbial metabolism. The assessment of the removal of potassium content from vinasse by yeast propagation is the main objective of the present paper.

Materials and methods

**Microorganism** Candida utilis NRRL Y-660 was used for propagation in all experiments. Inoculums were prepared from agar-malt slants, grown overnight in a medium at pH 4.5 containing sugarcane molasses at 20 mg/mL of total reducing sugars concentration and nutrient salts (diammonium phosphate and sulfate) to cover cell nutritional requirements using a rotary shaker at 32°C. A 2.5 L Marubishi MD5 fermenter was used to start batch propagation with a medium composed of molasses-based slops from a local distillery at a COD concentration of 60 mg/mL containing nutrient salts (see above) in the corresponding concentration to ensure that COD was the limiting substrate.

A microbial growth enhancer QZ-350 (Quimizuk, Havana, Cuba) was added to supply other micronutrients at a concentration of 0.03 mg/mL. Different amounts of potassium sulfate were added to test cell resistance and kinetic behaviour.

**Chemical analysis** nitrogen was determined according to Kjeldahl (Anon., 1983) in a 1030 Kjeltec Auto System (Tecator AB, Haganas, Sweden). Reducing sugars were estimated by copper reduction (Greenfield and Geronimus, 1985). Dry matter was done by desiccation at 105°C overnight and lipids by extraction with ethyl ether and desiccation until constant weight in a vacuum oven at 60°C.

Ash was determined by incineration at 600°C for 4 hours and referred to dry matter content. Sediment was dissolved in 1N HCl and taken up to 100 mL with distilled water; then the potassium content in ash referred to biomass dry matter was determined by atomic absorption spectrophotometry.
Results and discussion

Alcohol production from sugarcane

Distillery slops or vinasse contains organic matter as well as mineral component. Typical concentration of molasses-based vinasse is about 8–10° bx, while juice-based vinasse hardly reaches 5° bx. Table 1 shows the typical composition of both vinasses.

Table 1—Typical composition of distillery slops (vinasse) from molasses and cane juice ethanol fermentation.

The dominant vinasse ash component is potassium regardless of the original substrate in fermentation. This fact is a consequence of the potassium requirements of sugarcane. It is the most used nutrient and its demand by the plant can reach 800 kg/ha.

A harvest of about 100 tonnes of sugarcane removes from the soil close to 220 kg of K₂O. Around 98% of metallic ions in molasses or juices are K, Ca and Mg. In a typical molasses, potassium content in ash ranges from 70 to 75% of the whole inorganic fraction (Otero et al., 1993).

The use of vinasse for soil fertilisation has evolved from the direct disposal to water streams in the 1970s to the current rational utilisation as fertiliser that prevents, or at least tries to, underground water contamination (Veronez de Sousa, 2008).

However, it has been documented that the main disadvantage of vinasse fertigation lies in the distance from its site of generation to the field. When that distance reaches 50 km, the real cost for irrigation increases far beyond 300 US dollars/ha.

Thus, the area of current disposal of vinasse for this purpose is normally significantly smaller than the original area where cane was harvested with the concomitant accumulation of unused potassium in the soil.

Potassium ions are the most abundant intracellular cations in most types of cells, from yeast to humans. Potassium has been reported to play a crucial role in a variety of cellular processes, including regulation of cell volume, intracellular pH, and protein synthesis, plus the prevention of the deleterious effects of sodium ions (Gomez et al., 1996; Rodriguez-Navarro, 2000; Camacho et al., 2005). Even more, during potassium limitation, ammonium ions become toxic for yeast metabolism (Hess et al., 2006).

The propagation of yeast on vinasse is capable of removing potassium from the growth medium and embodying it in the cell biomass. In doing so, a potentially valuable protein source is also produced.

To assess the inhibition limits of potassium in yeast growth, a set of experiments under different potassium concentrations was done. Table 2 shows yeast kinetic parameters at different potassium concentrations.
Table 2—Growth parameters of *Candida utilis* NRRL Y-660 under different potassium concentrations.

*K⁺ = 5 mg/mL

The table shows the kinetic behaviour of yeast cells under K⁺ concentration between 5 and 30 mg/mL. This concentration is far beyond the normal content in vinasse. Up to 13 mg/mL, there is no significant effect of potassium concentration on specific growth rate, productivity or biomass-substrate yield for *C. utilis*.

The values for μmax are quite similar to those previously reported by the authors of the present paper (Martinez *et al.*, 2004; Otero *et al.*, 2008) for the same medium without potassium addition.

The fact that yeast is capable of growth in high potassium concentration is important but not enough for vinasse decontamination. Yeasts accumulate varied amounts of most of the minerals present in their growth media and have the ability to accumulate other ions provided (but not necessarily needed) in high concentration.

Therefore, the mineral content of cells harvested from a particular propagation medium could be adjusted to be of significance for the removal of undesirable metals in liquid wastes (Duncan *et al.*, 1995; Otero *et al.*, 2000). The last column in Table 2 shows the potassium content accumulated in yeast cells under the different experimental conditions.

In standard vinasse, yeasts remove about 50% of the potassium present in the growth medium. As potassium content in the propagation broth increases, the amount of potassium removed by yeast cells also increases but in a lesser proportion with respect to the amount provided. However, for all practical purposes yeast propagation not only reduces the organic load of vinasse by 60–70% (Otero *et al.*, 2007) but also half of its potassium content.

Reports about vinasse-yeast use in animal nutrition showed no deleterious effect on animal health (Lezcano and Mora, 2008; Llanes-Iglesias *et al.*, 2008; Rodriguez *et al.*, 2008).

**Conclusions**

Yeast propagation offers a unique method for vinasse decontamination, reducing both the organic fraction and the potassium content to a significant extent. According to the results presented above, the propagation of yeast on vinasse medium is an excellent pretreatment for further irrigation. Vinasse with less than 30 mg/mL of COD and potassium content below 2.5 mg/mL offers no ecological impact when used for irrigation of cane fields.

Résumé

LES LEVURES sont connues pour accumuler des montants variés de la plupart des minéraux présents dans leurs milieux de culture. La majeur partie de 7.5-8.1 % de cendres trouvée dans la levure boulangère ou de brasserie est composée de phosphate de potassium, mais les levures ont le moyen d'accumuler d'autres ions qui s'y trouvent en concentration élevée, mais ces ions ce sont pas nécessairement requis. La vinasse de distillerie contient encore environ 70 % de potassium provenant des engrais chimiques utilisés dans les champs de canne à sucre d'où la nécessité d'utiliser ces rejets par fertigation avec précaution afin d'éviter des problèmes de salinité. Lorsqu'elle est cultivée dans un milieu composé de vinasse de distillerie, éléments nutritifs tels (phosphates et sulfates d'ammonium) et un promoteur de croissance, Candida utilis montre une grande résistance à la concentration de potassium en milieu de culture continue. Des cellules de cette levure ont été propagées dans les conditions sus-mentionnées avec des concentration de K2O variant de 2.5 g/L à 25 g/L en prevenance de la vinasse résultant de la fermentation de mélasse. Des taux de croissance spécifique (μmax) allant de 0.32 à 0.28 h⁻¹ pour les valeurs extrêmes sus-mentionnées ont été obtenus, alors que les coefficients de rendement de la biomasse-substrat étaient 0.23 à 0.18. Ces résultats suggèrent que la levure propagée sur des vinasses de distillerie enrichies peut réduire considérablement la teneur en potasse de ces rejets en les rendant plus aptes à des fins d'irrigation. Selon l'évaluation nutritionnelle qui est rapportée, le potassium accumulé n'a aucun effet nuisible sur la santé animale.

PALABRAS CLAVE: Decontaminación, Residuales de Destilería,
Proteína Unicelular, Proteína Alimenticia, Remoción De Potasio.

Resumen

LAS LEVADURAS acumulan diferentes cantidades de la mayoría de los minerales presentes en sus medios de cultivo. La mayor parte del 7,5-8,1% de cenizas encontradas en la levadura de panificación ó cultivada para cervaza está constituida por fosfato de potasio, pero las levaduras tienen la habilidad de acumular, en altas concentraciones otros iones suministrados (pero no requeridos). Los residuales de destilerías contienen todavía cerca del 70% del potasio que se aporta a los suelos cañeros como fertilizante químico, de aquí que la fertirrigación con estas aguas residuales debe ser cuidadosamente calculada, porque de lo contrario puede producirse salinización del suelo. La Candida utilis cuando es cultivada con técnicas de fermentación continua en un medio compuesto por residuales de destilería, sales nutrientes (fosfatos y sulfatos de potasio)y un estimulador del crecimiento microbial, muestra una alta resistencia a las concentraciones de potasio. Se propagaron células de levadura, bajo las condiciones anteriormente descritas, con cantidades crecientes de óxido de potasio desde 2.5g/L (residuales de destilerías que emplean melazas) hasta 25 g/L en los medios de cultivo. La velocidad específica de crecimiento (µ max) osciló entre 0.32 y 0,28 h⁻¹ para los valores extremos referidos anteriormente, obteniéndose también coeficientes de rendimiento biomasa-sustrato de 0.23 a 0.18. Estos resultados sugieren que levaduras propagadas en residuales de destilerías suplementados, pueden reducir significativamente el contenido de potasio de estos residuales, haciéndolos más apropiados para la irrigación. De acuerdo con los resultados nutricionales reportados , el potasio acumulado no tiene ningún efecto negativo en al salud animal.
COMMUNITIES AUTO SUFFICIENT IN FUELS FOR HUMANS, TRANSPORT AND ELECTRIC NEEDS

By

PETER CHARLES JAIS
Sugarsoft Ltda.
peter@sugarsoft.com.br

KEYWORDS: Sugar, Ethanol, Co-generation.

Abstract

In view of the present problems facing the world with respect to fossil fuels (pollution and global warming, availability and price), we studied the possibility of a small community becoming auto sufficient in sugar, automotive fuel (ethanol) and electricity, all from renewable biomass (sugarcane). The study was done, based on a real project that we are presently installing under similar lines. The fuel needs of a community of 100,000 people were quantified in terms of sugar, ethanol, and electricity. A mass and energy balance was calculated to determine the amounts of cane and trash needed to produce the sugar, ethanol and electricity by generation and co-generation. The results showed us that 100 tonnes of cane per hour can supply sufficient sugar and electric energy for a community of 100,000 people and run their cars on 96ºGL ethanol (no mix with gasoline) and still be able to export surplus ethanol. The auto sufficiency is for the whole year and not only the crop period. The overall results showed us that, when compared to the importation of ‘fuels’, the project was positive.

Introduction

The aim of this paper is to show how a relatively small sugar and ethanol factory with cogeneration (and straight generation) can provide all of the energy necessary to ‘fuel’ small communities with:

- Human fuel: sugar.
- Transport fuel: ethanol.
- Lighting and heating fuel: electricity.

The idea is to produce sugar and ethanol from mixed juice from sugarcane. The resulting molasses from the sugar production would go to ethanol production. To produce the electrical energy, we would burn all the bagasse and a part of the cane trash in a high pressure boiler.

To have electrical energy all year round (crop and off-crop), we will show that we can divide the bagasse and trash for crop and off-crop generation.

Communities

To establish the amounts of ‘energies’ needed by the community, we have made the following assumptions in Table 1:

<table>
<thead>
<tr>
<th>Energy</th>
<th>Specific Quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sugar</td>
<td>30 kg per person per year</td>
</tr>
<tr>
<td>Ethanol</td>
<td>1200 litres per vehicle per year</td>
</tr>
<tr>
<td>Electrical energy</td>
<td>200 kWh per home per month</td>
</tr>
</tbody>
</table>
If we assume a community of 100 000 people, and that, on average, there will be one house for every 4 people and 1 vehicle for every house, Table 2 shows the annual quantities:

**Table 2**—Annual quantities required.

<table>
<thead>
<tr>
<th>Energy</th>
<th>Annual quantity</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sugar</td>
<td>30 kg x 100 000 = 3000 tonnes sugar</td>
</tr>
<tr>
<td>Ethanol</td>
<td>25 000 vehicles x 1200 = 30 000 000 L</td>
</tr>
<tr>
<td>Electrical energy</td>
<td>25 000 homes x 200 x 12 = 60 000 MWh</td>
</tr>
</tbody>
</table>

The electricity is the equivalent of ~ 6.9 MW.

**Field and factory**

To be able to take advantage of the trash, the cane cannot be burnt. The cane has to be machine harvested and a part be sent to the factory with the cane. This can be controlled by fans on the harvesters. The tops which will almost surely be green should be left in the field.

The amount of trash sent to the factory should be about 10% of the (clean) cane. That means that a fair amount of trash will still remain on the fields, which is good from the agronomic point of view.

At the factory, a cane/trash separation system must be used on the feed table or preferably on a carrier. The trash is separated by fans, when the cane falls from one carrier to another.

The separated trash will then be cleaned of its dirt (soil and sand) in a dry cleaning system (rotary screen). After cleaning, it must be shredded and sent to join the bagasse at the outlet of the mill.

Ideally, for high extraction and low maintenance costs, a diffuser would be better than mills.

The mixed juice is divided into two streams, one for sugar and the other for ethanol. The amounts of juice for each stream will of course depend on the amounts of sugar and ethanol to be produced.

Ideally, one of the streams would be preset and the other would receive the balance. The quantities for this specific project can be seen on Figure 2.

Preparation of the juice to be used for sugar production will be relatively conventional: clarifier and multiple effect evaporators.

As the amount of muds will be very small, they can be recycled to the diffuser, thus eliminating the filter station, and its associated losses.

In the boiling house, we will use just one boiling as the amount of sugar required will be very small as opposed to ethanol.

This gives us the added advantage of being able to make a very good quality sugar (raw or mill white) as there are no molasses boilings.

We will have a purity drop of about 15 points. All the molasses will go to the distillery with a purity of about 70º.

The second mixed juice stream will go directly to the fermentation without needing clarification. It has, however, to be well screened and heated and then cooled on arriving at the distillery. Diffuser juice is clean enough for fermentation.

Fermentation will take place with a mixture of juice and molasses. The fermented juice ‘must’ (beer/wine) will go on to the distillery where hydrous (96ºGL) ethanol will be produced.

Figure 1 shows the basic flow diagram of the plant.
The bagasse that leaves the mill after the diffuser receives the trash and then goes on to the boiler. At this point, part of the ‘fuel’ (bagasse + trash) can be divided, part being burnt and part stocked for off-crop generation, or all can be burnt, thus generating more energy, but only during the crop.

A high pressure boiler must be used. For this simulation, we are considering a 65 bar pressure and superheated steam temperature of 480°C on arrival at the turbine.

In the case of burning all the fuel, a steam turbine with an exhaust extraction for process and an extraction direct to a condenser can be used. If generation is to be all year round, it would be preferable to have 2 turbines: a back pressure turbine and a condensing turbine.

If we consider:
- live steam at 65 bar and 480°C
- exhaust steam at 2.5 bar
- condenser steam at 0.1 bar

The specific steam consumption will be as follows in Table 3.

<table>
<thead>
<tr>
<th>Steam</th>
<th>Specific steam consumption</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exhaust steam</td>
<td>From 65 bar To 2.5 bar Kg steam/kWh 5.4</td>
</tr>
<tr>
<td>Condenser steam</td>
<td>From 65 bar To 0.1 bar Kg steam/kWh 3.9</td>
</tr>
</tbody>
</table>
The plant will be totally electric. This fact plus the amount of water needed for the TG condenser, its cooling and the energy needed for the trash treatment will give us an electric energy consumption above that of a conventional steam driven factory.

**Balances**

Below are 3 balances (Figures 2, 3 and 4). In Figures 2 and 3 we have used a maximum of 500 kg process steam per tonne cane.

In fact, we know that this figure can come down to the range of 350 to 450, depending on what steam economy techniques are used.

The process steam consumers are the evaporation, diffusion and distillation and boiling. Distillation and boiling can be done with bleeding of first and second vapours. Primary heating of water and or juice can be done with vinasse.

Figure 2 shows a flow diagram and balance of a 100 tch plant burning all its fuel during the crop:

![Diagram showing mass and energy balance](image)

**Fig. 2**—Mass and energy balance of plant burning all its fuel during the crop period.

Figure 3 shows a flow diagram and balance of a 100 tch plant burning the amount of bagasse it needs to generate the steam necessary for the process during the crop, plus a small additional amount to reach the energy export necessity.
Figure 3—Mass and energy balance of plant burning part of its fuel during the crop period.

Figure 4 shows a flow diagram and balance of the same 100 tch plant, during the off-crop, burning the fuel left over from the crop.

It must be remembered that our fuel is bagasse and trash. During the crop, the trash is mixed into the bagasse before it is either burned or stocked.

Therefore, we can assume that during the off crop we will be burning a mixture of bagasse and trash.

It can be seen that the amount of bagasse burnt per hour is less than what was burnt per hour during the crop, but the amount of exportable energy is more.

This is because all the steam goes directly down to condenser pressure (0.1 bar) and thus has a higher enthalpy drop. In this case, we have pure thermo electric generation and not co-generation.

Thus, even though the crop harvest lasts only six months, we are able to generate electricity all year round and in the same quantity.

The overall scheme, operating throughout the year, therefore, produces as presented in Table 4.

**Table 4—Yearly production.**

</tbody>
</table>
Fig. 4—Mass and energy balance of plant burning its stocked fuel during the off-crop period.

It can be seen that we have a 19% excess of sugar and a 14% excess of ethanol. These products can be exported or sold to hotels, hospitals etc.

From these figures, we can now draw up a Table for various sizes of communities (Table 5).

</table>
Conclusion

We have shown two possible scenarios:

- Producing sugar, ethanol and electric energy burning all the fuel (bagasse and trash).
  
  This option would be ideal in places where it is possible to run the plant all year round. An example of this is Peru where, in the absence of rain, they are obliged to irrigate in desert lands. The advantage is that they can operate all year round.

- Producing sugar, ethanol and electric energy burning only part of the fuel during the crop, and the rest during the off crop to continue electric energy production.

  In this case, the exportable electric energy production is about half of that in the first case, but over a longer period [assuming a six month harvest season].

  If we assume an agricultural productivity of 80 tonnes cane per hectare and a harvest period of 180 days, it would be necessary to have:
  
  \[
  100 \times 24 \times 180 = 432\ 000 \text{ tonnes cane}
  \]
  
  \[
  432\ 000 / 80 = 5400 \text{ ha}
  \]

  Assuming a plant crop and 4 ratoons, we need to increase the land by 20%: 6480 ha

  Therefore, with 6480 ha of land and sufficient rainfall, it is possible to supply a community of 100 000 with all their sugar, electricity and automotive fuel (pure hydrous ethanol with no gasoline mixture)

  This industry would create jobs (factory and field) and still save money on imported fuel (oil/gasoline/diesel). This money could be recirculated within the community or used for importation on other needed goods.

  An estimated cost of such an industry of this size (100 tonnes cane/hour) is US$70 000 000 installed. The cost of the field side would depend on other non technical factors, but we could say its cost would be similar to that of the factory. Therefore, such an agro-industry could be implemented for about US$140 000 000.

  Many small countries/islands spend this or more per year importing oil. At US$100/barrel, this is equivalent to a consumption of about 4000 barrels per day.

  Perhaps on a medium to long-term basis the most important message here is that:

  **MOST OR ALL THE CO₂ PRODUCED IS RECYCLED.**
COMMUNAUTÉS AUTOSUFFISANT EN CARBURANT POUR LES BESOINS DE L’HOMME, LE TRANSPORT ET L’ÉNERGIE ÉLECTRIQUE

Par

PETER CHARLES JAIS
Sugarsoft Ltda

MOTS-CLÉS: Sucre, éthanol, Co-generation.

Résumé
COMPTÉ tenu des problèmes actuels auxquels le monde fait face par rapport à des combustibles fossiles (la pollution et le réchauffement planétaire, disponibilité et prix), nous avons étudié la possibilité qu’une petite communauté devienne autosuffisante en sucre, en carburant automobile (éthanol) et en électricité, cela à partir de la biomasse renouvelable (la canne à sucre). L’étude faite, a été basée sur un véritable projet que nous mettons en route actuellement dans un cas similaire. Les besoins en carburant d'une communauté de 100 000 personnes ont été quantifiés en termes de sucre, d'éthanol et d'électricité. Un bilan de masse et de l'énergie a été calculé pour déterminer la quantité de canne à sucre et de pailles nécessaire pour produire le sucre, l'éthanol et l'électricité par cogénération. Les résultats ont démontré que 100 tonnes de canne par heure peuvent fournir suffisamment de sucre et de l'énergie électrique pour une communauté de 100 000 personnes et rouler leurs voitures entièrement sur l’éthanol et de surcroît être en mesure d'exporter un surplus d'éthanol. L’autosuffisance est pour l'ensemble de l'année et pas seulement pendant la période de récolte. Les résultats ont démontré que, par rapport à l'importation de "combustibles", le projet a été positif.

COMUNIDADES AUTO SUFICIENTES EN COMBUSTIBLES PARA LAS NECESIDADES HUMANAS, DE TRANSPORTE Y ELÉCTRICAS

peter@sugarsoft.com.br

PALABRAS CLAVE: Azúcar, Etanol, Cogeneración.

Resumen
EN VISTA de los presentes problemas que el mundo enfrenta en relación con los combustibles fósiles contaminación y calentamiento global, disponibilidad y precios) estudiamos la posibilidad de una pequeña comunidad convertida en autosuficiente en azúcar, combustible automotor (etanol) y electricidad, todo a partir de la biomasa renovable (caña de azúcar). El estudio se realizó en un proyecto real que estamos instalando actualmente bajo similares líneas. El combustible necesario para una comunidad de 100 000 personas se cuantificaron en términos de azúcar, etanol y electricidad. Se calculó un balance de masa y energía para determinar las cantidades de caña y paja necesarias para producir el azúcar, el etanol y la electricidad por generación. Los resultados nos mostraron que 100 toneladas métricas de caña por hora puede suministrar suficiente azúcar y energía eléctrica para una comunidad de 100 000 personas y abastecer sus autos con etanol (sin mezcla) y aún ser capaces de exportar etanol sobreante. La autosuficiencia es para un año completo y no solo para el periodo de zafra. Los resultados totales nos mostraron que cuando se compara con la importación de combustibles era positivo.
IMPROVING PRODUCTIVITY IN SUGAR MILLS BY INTEGRATING CO-PRODUCTS UTILISATION

Abstract

This paper shows an ‘incentive program’ for workers, through one model of development, using mainly co-products of sugarcane; used in different ways in ‘Granja Teresita’, 25 kilometres from the mill. The mill has a plant to hydrolyse bagasse in two batch reactors by a physical process (using steam at 1.4 MPa) and areas for composting residuals (90 days, without enzymatic process), and sell the production to the ranch. For cattle and goats, we use the cane tops with molasses, hydrolysed bagasse, wet fibre cane ‘cush – cush’ separated in clarifier filters, and other agriculture residuals of the region. For pigs, invert ‘B’ molasses and some locally produced complements are used. For sustainable agriculture, organic fertiliser (compost), made from sugar mill products (vacuum filter mud, bagasse, ashes, etc), and worm compost, produced locally, are used with lamb manure. A range of crops is grown including corn and sorghum and horticultural crops, and there is also an aquaculture industry.

Introduction

In order to increase the productivity in the MOTZORONGO sugar group, which includes two mills (El Refugio (syrup) and Motzorongo (sugar & molasses)), the administration has promoted a program based on compensation of workers, giving a box that includes several products obtained by cane diversification processes, with several agro-products which are shown in Figure 1.

Fig. 1—Co-products development into the mills.
Work development

El Refugio Mill

Hydrolysed bagasse production

In the El Refugio Mill, there are two reactors (1.5 m diameter and 4 m high – see Figure 2) fed for 40 min with steam at 1.7 MPa and 573 K; the nominal capacity of each is 750 kg per batch. The total capacity of the plant is 2000 tonnes per crop. The composition of hydrolysed bagasse is presented in Table 1.

Central Motzorongo, S.A. de C.V.

The mill is dedicated to the production of raw and standard sugar, with a daily grinding capacity of 8500 tonnes of cane and a total crop of 1 280 000 tonnes. The co-products produced are shown in Figure 3.
Compost

The production of organic fertiliser ‘compost’ is 3000 tonnes, using 20 000 t of filter mud and 4500 t of bagasse. The materials are sent to special areas forming long piles, and are maintained for 15 days to separate the excess water; after that, the components are mixed weekly and air is introduced for the micro organisms that degrade the organic material (fungus and bacteria) (Figure 4). The chemical composition of the compost is presented in Table 2.

Table 2—Chemical composition of ‘COMPOMOTZ’:

Teresita farm

The farm is located about 25 km from El Refugio, and has a total area of 112 ha; 20 ha for sugarcane, leaving the remaining 92 ha for cattle and fruit production, including 3.50 ha for banana.
(musa ssp), mango (manguifera indica L), and noni (morinda citrifolia) and 2.50 ha for short-cycle vegetables. The other 86 ha are used as pasture and corrals for cattle and sheep, fish tanks and pig breeding places. The farm buys molasses and compost from Motzorongo, hydrolysed bagasse and mud from El Refugio (it only pays the freight of the last) and sells the products to both mills. A flow chart of the incentive program is presented in Figure 5.

![Flow chart of the incentive program.](image)

**Cattle food**
To make balanced diets for the animals, sugarcane (juice and tops) and co-products from the milling process (molasses, hydrolysed bagasse and dry filter mud), as well as cheese whey and other products from the regional agriculture are used.

**Cattle**
Grazing is the basic feed, complemented with sugarcane co-products. The cattle are classified as milking cows, empty cows, calves, and stud bulls.

**Milking cows**
They are given a supplement of 5 kg of concentrate after milking to complement their feed from grazing. The production cost per litre is no more than $1.50 (feeding) and it is sold for $7.00/L. With this regime, there is a reduction from 220 to 120 days from giving birth to getting pregnant again. This way, the productive and reproductive parameters are higher. The composition of food for milking cows is shown in Table 3.

**Table 3—Components for a tonne of food for milking cows.**

**NOTE:** Exchange rate used is $13.50 Mexican Pesos/US$dollar.
The cost of sugarcane is only for manpower. The cost of feeding each cow is $4.45 per day. The cows given this supplement increased their milk production by 3 L/day. That is a daily gain of $21.00.

**Empty cows**

These are cows that are pregnant or empty in preparation to enter into the milk production of the farm. Composition of the supplement given to empty cows is presented in Table 4.

**Table 4**—Ingredients of a tonne of food for empty cows.

Feeding them only with milk will cost $28.00 daily to gain 1 kg of weight; using a diet of 2 L of milk plus 2 kg of supplement will cost $16.24 per day.

**Sheep**

Their feeding should be by grazing, but seeking the highest rate of reproduction, it is convenient to give supplement and chopped sugarcane with urea, which produces good results at low cost. The ingredients in the supplement for sheep are presented in Table 6.

**Table 6**—Ingredients for a tonne of food for sheep.

</table>
The traditional food ration has a cost of $31.50 (7 kg/day) and, with the addition of cane co-products, is reduced to $7.63, saving $23.87 per head.

**Sustainable agriculture**

Fruits and vegetables are fertilised with organic fertiliser bought from CM and produced by the same farm from manure (worm compost) and residuals from a biodigester for the production of methane gas. To control pests and diseases, natural traps and bio products are used.

**Growing vegetables**

**Plot preparation**

The soil is loosened with a pick and shovel to a depth of 30 cm and compost is added to give good conditions for plant development.

Lime is added.

**Buying plants**

The plants that are used have been handled and selected previously for their optimum growing and maturing properties and the size of their fruits. The plants are bought by a filial firm, VITROMOTZ.

**Sowing**

At transplanting, the roots are disinfected with a solution of ‘Bordalese broth’ and are inoculated with mycorrhizae to stimulate root development to improve the growing of the plant.

**Fertilisation**

During the first 10 days of development, foliar applications are made with liquid fertiliser, which gives nutrients and salts needed for an optimum growing and production of a good number of flowers and fruits. As a supplement, the crops are fertilised monthly.

**Biological control of pests**

To control pests, biological methods from plant extracts and infusions, such as garlic, onion, cempasuchil, basil, peppers, rue, chamomille and neem are used. Chemical insecticides are not used.

**Diseases**

When there are fungus problems such as smut, control is effected by applying a solution made of cupper sulfate and lime, called ‘Bordalese broth’. It is made with 1 kg of copper sulfate and 1 kg of hydratated lime dissolved in 100 litres of water.

**Fertigation**

Water from the fish ponds is used for irrigation so that all the nutrients and organic matter are used.

**Costs and Profits**

The costs and profits of growing vegetables are presented in Table 11.

</tr>
</tbody>
</table>

**Price**

Not having intermediaries, all products are sold at the regional market price, which makes the production more profitable.
Analysis of cost-benefit

It is important to emphasise that the biggest profit is for the environment by not using agrochemicals, insecticides, herbicides and pesticides. It favours not only the direct health of consumers, but it also protects land, streams, and aquifers. There is some reduction in yields, but this is justified because it spares the depreciation of the biological capital.

Biogas production

As part of an environmental plan for the pigs and cattle, Teresita Farm has a biodigester, Hindu type, of continuous flow, that permits the use of manure and other organic wastes. The volume of the biodigester is 3 m³ and it is fed daily with 35 kg of fresh manure, mixed with 70 litres of hot water at 45°C.

With the biodigester, methane gas is produced for use at the farm, and its residue is used as fertiliser for the vegetables and to feed the fish. A schematic diagram of the biodigester is presented in Figure 6.

Fish pond

The farm has 4 ponds with a capacity of 2000 fish each. The biofertiliser from the digester is used to initiate the production of algae and this begins a trophic chain to feed the fish.

The residual water is used to irrigate vegetables, giving very good results, due to the fact that this water has a good load of nutrients.

Economical impact

It is possible to deduce from Tables 12 and 13 that, during a crisis period in the Mexican sugar industry, both mills produced good financial results.

MOTS-CLÉS: Productivité, Bagasse Hydrolysée, Compost; Production de Biogaz et ‘Mélasse Riche En Sucre’.

Résumé

CETTE COMMUNICATION décrit un programme incitatif pour les travailleurs par le biais d'un modèle de développement, en ayant recours principalement les co-produits de la canne à sucre; utilisés de différentes façons à 25 kilomètres de l'usine de ‘Granja Teresita’. L'usine a une unité pour l'hydrolyse de la bagasse de la canne à sucre dans deux réacteurs individuels, à l’aide d’un procédé physique (utilisant la vapeur à 1.4 MPa) et les aires de compostage de résidus (90 jours, sans procédé enzymatique). La production est vendue à la ferme. Pour les bovins et caprins, la partie supérieure de la canne est utilisée avec la mélasse, la bagasse hydrolysée, la fibre humide provenant des décanteurs et d’autres résidus agricoles de la région. Pour les porcins, la mélasse ‘B’ invertie et d’autres compléments locaux sont utilisés. Pour l'agriculture durable, les engrais organiques (compost), produits à partir des sous-produits de l’usine (boues, bagasse, cendres, etc...) et vermi compost, produit localement, sont utilisés avec du fumier d’agneau. Toutes une gamme d’espèces est cultivée comprenant le maïs et le sorgho et d’autres espèces horticoles, et il y a également une industrie aquacole.

MEJORANDO LA PRODUCTIVIDAD EN EL CENTRAL AZUCARERO MEDIANTE LA INTEGRACIÓN DE COPRODUCIOS

PALABRAS CLAVE: Productividad, Bagazo Hidrolizado, Compost, Biogás, Mielas Ricas Invertidas.

Resumen

EL ARTÍCULO muestra un ‘Programa Incentivo’ para trabajadores, a través de un modelo de desarrollo, empleando fundamentalmente coproducios de la caña de azúcar, utilizados en diferentes modos en la Granja teresita, a 25 kilómetros del Central. El Central posee una planta de hidrolizar bagazo en dos reactores batch mediante un proceso físico (con vapor a 1,4MPa) y áreas para composteado de residuales (90 días sin proceso enzimático) y vende la producción al rancho. Para vacunos y caprinos, empleamos las ‘puntas’ de caña con melazas, bagazo hidrolizado, fibra húmeda de caña ‘cush-cush’ separadas en los filtros clarificadores y otros residuales agrícolas de la región.
Para cerdos utilizamos mieles B invertidas y complementos producidos localmente. Para agricultura sostenible se aprovechan fertilizantes orgánicos (compost) fabricados a partir de productos del Central (tortas de los filtros al vacío, bagazo, cenizas, etc.) y compost de lombrices, producido localmente, junto con excretas de ovejas. Se cosechan un conjunto de cultivos incluyendo maíz, sorgo y hortalizas, también existe una industria acuícola.
EPA CHALLENGES FOR BAGASSE FIRED POWER STATIONS

By

M.B. INKSON, B.J. MISPLON and E. de VILLIERS

Thermal Energy Systems
mike.i@sucrose.com

KEYWORDS: Cogeneration, Environmental Impact, Emissions.

Abstract

Traditionally, the sugar industry has been treated leniently with respect to emissions standards but, as it focuses more on electricity as a profitable by-product, that is changing even though bagasse is a renewable fuel. Nowhere is that more the case than at US Sugar’s Clewiston factory in Florida: even though it is not a major exporter of electricity, when it installed a new boiler, the factory was obliged to conform with stringent EPA standards. The challenges imposed by the standards are discussed together with the engineering solutions and the results obtained. The outline specification was for a 500 000 lbs/h (~226 800 kg/h) boiler delivering 600 psig, 750°F (~4137 kPa, ~399°C) steam when firing bagasse. The main challenges were seen in obtaining the 0.026 lbs/MMBTU (~24 mg/Nm³) PM10 limit and the original 0.12 lbs/MMBTU (~70 ppmvd) NOX limit without exceeding the 0.38 lbs/MMBTU (~363 ppmvd) CO limit or the 20 ppmvd ammonia slip limit. Continuous monitoring was required. Engineering was supported by fluid dynamic studies, in particular with respect to the NOX and CO profiles in the furnace: i) maximum NOX reduction was required from the urea injection system so location was critical; and ii) engineering down combustion NOX increases CO. In the event, the unit comfortably passed all tests. The variable OFA nozzles which had been installed proved particularly useful in tuning the boiler and the low uncontrolled NOX levels [meaning there will be reduced urea charges] were pleasing to see. While these stringent requirements are unlikely to be applied to other bagasse boilers in the short term, the lessons learned will make it possible to rise to those challenges when they arise.

Introduction

The cane sugar industry has developed export cogeneration gradually over several decades, during which time many of the projects have been treated, from the emissions point of view, as no different to any other sugar industry project.

That has frequently meant a very generous treatment compared to the requirements if, for instance, power utility standards had been applied.

There have been exceptions over the years of course, most notably the stations on the French islands [Bois Rouge, Le Gol and Le Moule] and the Florida Crystals station at Okeelanta in Florida.

However, perhaps as an indication of what is to come, when US Sugar needed a new boiler [Boiler #8] for its factory at Clewiston in Florida, the state authorities tried to apply environmental requirements more strict than those at Okeelanta even though the Clewiston site is only an ad hoc electrical exporter, primarily a sugar producer.

US Sugar has a strong environmental policy so readily agreed to the approach taken but the requirements did pose a challenge to the engineers tasked with the boiler design.
Clewiston Boiler #8

The USSC requirement was for a 500 000 lbs/h [~226 800 kg/h] boiler delivering 600 psig, 750ºF [~4137 kPa, ~399°C] steam when firing bagasse as primary fuel and capable of 60% MCR output when firing oil, as a start-up and supplemental fuel.

The unit was destined to become the workhorse of the site which typically has a 200 day crop period crushing at 38 000 stcd but also operates a nominal 1500 t/d RSO refinery throughout the year.

It therefore had to operate 11 months a year without difficulty, much of that with a high turn-down ratio [capacity as low as 40–50% MCR during off-crop].

A conventional single pass, bi-drum design was adopted from the beginning, but a quick glance at the general arrangement immediately shows some unusual features (Figure 1):

- a continuous ash discharge [CAD] stoker instead of steam cleaned pinhole grate;
- an exceptionally tall furnace for a bagasse fired boiler;
- two stage superheater with inter-stage attemperation;
- flue gas scrubbing and a five field electrostatic precipitator [ESP].
The superheater arrangement is a result of the need for the high turn-down ratio but the others, as discussed later, and other less obvious features are all related to the emissions standards imposed.

The other key aspect was the nature of the bagasse: Clewiston is on far sandier soil than most of the Florida industry so bagasse ash levels can be very high and during certain periods can reach 10%.

**EPA requirements**

In general, the emissions standards in the USA are expressed in terms of pounds weight of a particular emission per million BTUs [lbs/MMBTU] of gross heat input, something which makes it difficult to express them exactly in more conventional terms or to compare them with the standards in other countries which are typically based on emission concentrations per normal cubic metre of flue gas referred to some standard condition.

Another issue is the difference in conditions applied around the world, a value which is critical to normalising for comparison purposes.

The original indications from the authorities were that they would want a NOₓ limit of 0.12 lbs/MMBTU and that was the basis that engineering started with.

However, when the permit was issued some 8 months later, they had agreed that such a level was unrealistic so the permit for Clewiston’s Boiler #8 required the following (Table 1).

* at 7% O₂

The permit enforcement for NOₓ and CO was to be with a Continuous Emissions Monitoring System [CEMS] so there was no question of being out of permit as is often the case elsewhere.

The only concessions were that the limits were on a rolling average basis. It was accepted that no chemical scrubbing would be used and, therefore, that the fuel-related pollutants [SOₓ, heavy metals and HCl] would be whatever they would be.

There was, however, still a need to be sure that the permit levels were not exceeded, so bagasse samples were analysed over an extended period in order to verify this and, coincidentally, to provide design data for the boiler.
Particulate matter limits are very typical of the environmental standards imposed around the world but the permit level at Clewiston is remarkably low (Figure 2).

\[
\text{PM}_{10}, \text{ sometimes referred to as the 'thoracic' limit, refers to particles equal to or smaller than } 10 \, \mu \text{m. The limits shown have all been normalised to } 12\% \, \text{CO}_2 \text{ by volume dry.}
\]

Similarly, the NO\textsubscript{x} limit – not a typical requirement – is remarkably low and lower even than that at Okeelanta, only a few miles south (Figure 3):

The CO limit, on the other hand, was not considered too onerous if taken on its own. The problem is, however, that trying to drive down NO\textsubscript{x} by careful furnace design tends to drive up the CO content of the flue gas.

**Engineering**

USSC wanted a boiler which was efficient [in order to maximise the bagasse available for off-crop use], easy to operate and maintain, able to operate at a high turndown ratio and, of course, be permit compliant under all operating conditions.

Experience at Okeelanta showed that any form of intermittent discharge grate would result in permit excursions during cleaning. The ash content of the bagasse indicated that this would be quite frequent at times. It was, therefore, decided from the outset that the unit would be equipped with a CAD stoker in order to avoid that problem and assist with ease of operation. That decision also gave USSC the option of burning other fibrous fuels during off-crop after the surplus bagasse supply was exhausted.

The Thermal Energy Systems stoker is engineered to minimise maintenance: it has larger diameter shafts than comparable units, very robust catenary tensioned chains and high temperature castings throughout. In order to deliver the 227 t/h of steam, it would have to be one of the largest stokers in the world.
Having established the grate concept, the focus of the engineering for Boiler #8 moved to the furnace and the need to control NO\textsubscript{x}, ammonia slip and CO. Selective Catalytic Reduction [SCR] of NO\textsubscript{x} was considered inappropriate and therefore the only practical alternative, non-catalytic reduction [SNCR], was adopted. The significance of that decision was that SNCR, which involves injecting ammonia or, more conveniently, urea into the furnace in order to reduce the NO\textsubscript{x} content to molecular nitrogen [N\textsubscript{2}], is only 50% effective at best so untreated NO\textsubscript{x} levels had to be no more than 0.28#/MMBTU, a low target.

One of the other issues with SNCR is that it is most effective within tight temperature ranges, so it was necessary to predict the temperature profiles in the furnace for the full range of possible operating conditions and to design the urea injection system to cover that range. In addition, over-treating with urea leads to ‘ammonia slip’: surplus ammonia being released to the atmosphere in one form or another. When SNCR is adopted, a limit on ammonia slip of 20 ppmvd [at 7% O\textsubscript{2}] is imposed.

SNCR is a highly specialised technology so the supplier was selected from an early stage and the furnace engineering developed in conjunction with him. It was clear that computerised fluid dynamics would be needed to determine the shape of the furnace, the optimum way to inject the secondary combustion air to approximate perfect mixing within the furnace volume and the optimum injection points for the urea injection.

For the latter two challenges, the systems had to be capable of working within the full range of possible operating conditions, whether that be steam generating capacity or fuel characteristics.

The boiler was modelled using the ‘Furnace’ computerised fluid dynamics [CFD] code developed in Australia using over ¾ million individual cells. In the end, because of the relationship between NO\textsubscript{x} and CO, it was decided to use CO concentration in addition to gas velocities and particle trajectories to analyse the mixing within the furnace.

The output from the modelling was portrayed as a series of elevation and plan sections showing predicted values for the gas velocity vectors, temperatures, particle trajectories, O\textsubscript{2} concentrations and CO concentrations. Figure 4 shows examples of two such portrayals:

![Fig. 4—Example Portrayals from CFD Analysis.](image-url)
The left hand image shows the predicted gas velocities and directions for a particular configuration. [Dark blue is up to 3 m/s and the green – the highest velocity in this instance – is 12 to 15 m/s.] The right hand image shows the predicted gas temperatures for a different configuration. [Dark blue is up to 100°C and the darkest reds are in excess of 1300°C.] Other portrayals showed the same parameters in plan sections and other parameters included particle tracks, oxygen levels and CO levels.

Once the basic model had been established it was possible to evaluate various configurations, in particular of the overfire air [OFA]: both the percentage of total air applied as OFA and the number and arrangement of OFA nozzles. The ultimate objective was to approximate a perfectly mixed furnace and hence minimum CO production with an understanding of the temperature profile and hence the locations for urea injection under various load conditions.

Part of the solution ultimately adopted was to use variable throat OFA nozzles specifically developed for the project so that the injection profile could be changed during the operation of the boiler and the urea injection optimised for different steam output conditions.

Having finalised the furnace, it was possible to proceed with the remaining thermal design and the design of the boiler ancillaries. Allowance had to be made for the additional gas burden imposed on the system by the injection of the urea solution: the resultant ammonia [and reaction products] plus the carrier water. The aspect relevant to this paper was the flue gas treatment in order to achieve the required particulates levels.

It was clear that an electrostatic precipitator [ESP] was going to be an essential part of the solution required but it would only be part of the total solution. The main issue with ESPs on fibrous fuel boilers is that the discards, containing activated carbon from semi-combusted [in this case] bagasse, are highly flammable so the ESP should be operated under positive pressure to minimise the gas oxygen content and avoid fires.

That places the ID fan before the ESP and hence exposes it to the erosive grit content of the flue gas. In addition, ESPs are not particularly good at collecting carbon particles: there is a tendency for them to break free again from the plates and pass up the stack.

USSC, as part of its ongoing environmental impact abatement policy, had recently retro-fitted one of its existing boilers with a non-saturating scrubber system, the water uptake rate being carefully controlled to avoid saturating the gas which would result in condensation and consequently corrosion within the ESP.

What was not understood at the time was that the ash content of the Clewiston fuel would essentially be calcined in the furnace and form a concrete in such scrubbers.

The system adopted for Boiler #8 was therefore a pair of non-saturating Thermal Energy Systems cyclonic scrubbers before the ID fan, followed by a five field ESP after it. The use of five fields was to ensure that permit levels would still be achieved even when rapping one of the five.

The cyclonic scrubbers use a highly turbulent venturi inlet section where the gas is sprayed, followed by a high-g cyclonic section to separate the water again, together with the scrubbed solids.

**Results**

The engineering of this complex boiler started in March 2003 and commissioning started in late January 2005 when the first oil was fired to warm up and dry out the unit. The formal testing of the unit took place just before Easter in that year, very much towards the end of crop and not long after first firing bagasse.

The environmental tests were conducted by specialist consultants on behalf of Florida State using their own portable instruments which were also used to calibrate the CEMS. The first values, compared to the permit values, are presented in Table 2.

</tbody>
</table>

The measured values were each the average of three runs and the boiler was generating an average of 500 853 lbs/h of steam at the specified conditions. Opacity, an alternative measurement to the PM$_{10}$ was not measured because PM$_{10}$ was. It can be seen that, even at this early stage, the boiler was running well: only the ammonia slip was outside of permit value, something which was put down to incomplete commissioning of the SNCR system. It was soon brought under control and within permit once the SNCR system had been fully commissioned and tuned.

The variable OFA nozzles which had been installed proved particularly useful in tuning the boiler and the low uncontrolled NO$_x$ levels [meaning there will be reduced urea charges] were pleasing to see.

The issue of the formation of a sort of concrete in the scrubbers, as referred to early, was unexpected and caused blockages in the scrubbers’ outlets from time to time. In the end, the factory engineers came up with an ingenious solution by designing and installing macerators in the bases of the scrubbers. These are operated typically once a shift to break up any lumps of this concrete which might have broken lose from the walls so that they are flushed away by the scrubber water.

**Conclusions**

It is accepted that the stringent requirements of the Florida DEP and Federal EPA are unlikely to be applied to other sugar industry boilers in the short term – not even in other states of the USA – but the important point is that, with the lessons learned at Clewiston, it will be possible to rise to those challenges when they arise.
DÉFIS APE POUR LES CENTRALES THERMIQUES UTILISANT LA BAGASSE

Par

M.B. INKSON, B.J. MISPLON et E. de VILLIERS

Thermal Energy Systems

MOTS-CLÉS: Cogénération, l'Impact Environnemental, Émissions.

Résumé

TRADITIONNELLEMENT, l'industrie sucrière a été traitée avec indulgence quant aux normes d'émissions, mais comme elle met l'emphasis de plus en plus sur la production de l'électricité comme sous-produit rentable, cette façon de voir est en train de changer, même si la bagasse est une source renouvelable d'énergie. Cela est le cas de l'usine de « US Sugar’s Clewiston » en Floride: même si elle n'est pas une importante exportatrice de l'électricité, lorsqu'elle avait installé une nouvelle chaudière, l'usine a été contrainte de se conformer aux normes strictes de l’APE. Les défis imposés par les normes sont traités avec les solutions d'ingénierie apportées et les résultats obtenus.

La spécification sommaire a été pour une chaudière de 500 000 lbs/h (~ 226 800 kg/h) produisant de la vapeur à une pression de 600 lbs/psig, 750°F (~ 4137 kPa, ~ 399 °C) quand la bagasse est utilisée comme combustible. Les principaux défis étaient d'obtenir la limite de 0.026 lbs/MMBTU (~ 24 mg/Nm³) limite PM10 et l'initial de 0,12 lbs/MMBTU [ppmvd ~ 70] NOX sans dépasser la limite de CO de 0.38 lbs/MMBTU [ppmvd ~ 363] où la limite d'ammoniac de 20 ppmvd. Il était nécessaire d’avoir une surveillance continue. L’ingénierie avait l’apport des études dynamiques des fluides en particulier par rapport aux profiles de NOx et CO dans les chaudières : i) une réduction maximale de NOx était requise du système d'injection de l'urée, donc son emplacement était critique ; et ii) en manœuvrant afin de réduire le NOx de combustion, le CO augmente. Dans ce cas, l'unité a satisfait avec une marge confortable tous les tests. Les buses OFA variables qui avaient été installées se sont avérées particulièrement utiles dans le réglage de la chaudière et il était agréable d’observer les faibles niveaux de NOx incontrôlées [indiquant qu’il y aurait une charge réduite d’urée]. Alors qu’il est peu probable que les exigences strictes seraient appliquées aux autres chaudières à bagasse à court terme, les leçons apprises permettront de relever ces défis lorsqu'ils surviennent.

LOSS RETOS DE LA ADMINISTRACIÓN DE PROTECCIÓN AMBIENTAL (EPA) PARA LAS ESTACIONES DE FUERZA ALIMENTADAS CON BAGAZO

Resumen

TRADICIONALMENTE la industria azucarera ha sido tratada benignamente con respecto a los estándares de emisiones, pero en cuanto esta se enfoca, cada vez más, hacia la generación de electricidad como un subproducto rentable, esto va cambiando, aunque el bagazo es un combustible renovable. Ningún caso mejor que el acontecido con la fábrica de azúcar estadounidense en Clewiston, Florida, que a pesar de no ser una importante “exportadora” de electricidad, cuando instaló una caldera, la fábrica fue obligada a ajustarse a los estrictos estándares de la EPA. Se discuten los retos impuestos por los estándares, junto con las soluciones ingenieriles y los resultados obtenidos.. Las especificaciones fueron una caldera de una capacidad de 500 000 lbs/h (= 226 800 kg/h), generando vapor a 600 psig, 750° F (=4137 kPa a 399° C) cuando quemaba bagazo.

8
El principal reto lo constituyó el obtener el límite de 0,026 lbs/MMBTU (224 mg/Nm³) PM y el límite original de 0,12 lbs/MMBTU (= 70 ppmvd) NOx, sin exceder el límite de 0,38 lbs/MMBTU (= 363ppmvd) CO ó el límite de los 20 ppmvd de desprendimiento de amonía. Se requiere un monitoreo continuo. La ingenierización se apoyó en estudios de dinámica de fluidos, en particular con respecto a los perfiles de NOx y CO en hornos; I) se requería una reducción máxima de NOx del área del sistema de inyección de urea, de aquí que la ubicación fuera crítica, y II) ingeniarizar la caída de NOx de la combustión que aumenta el CO. Afortunadamente, la unidad pasó todas las pruebas cómodamente. La variable de las toberas OFA que fueron instaladas probó ser especialmente útil para ajustar la caldera y los incontrolables bajos niveles de NOx (significando que habrá reducidas cargas de urea), algo muy agradable de apreciar. No obstante el hecho de que estos exigentes requerimientos son poco probables de ser aplicados a otras calderas de bagazo, la lección aprendida hará posible erguirse ante estos retos cuando aparezcan.
BUTANOL PRODUCTION FROM SUGARCANE JUICES

By

M. KIM and D.F. DAY

KEYWORDS: Butanol, Fermentation, Sugar Juices, Biomass.

Abstract

BUTANOL is an aliphatic saturated alcohol with the molecular formula of C₅H₁₀OH, which can be used as a transportation fuel, an intermediate and a solvent for a wide variety of chemical applications. The acetone-butanol fermentation was the standard for industrial production of solvents until the 1950s. Modern microbiological techniques have improved the original organism such that it produces high levels of butanol rather than mixed solvents. Butanol has many advantages as an alternative fuel source; 1) a higher energy content, 2) usable in existing pipelines, 3) easy to blend with gasoline. Butanol can be produced from sugarcane juice, molasses or sugars from bagasse hydrolysates using a strain of Clostridium beijerinckii. Sugarcane juice and molasses ferment directly to butanol. The yield of butanol was 0.30 g/g sugar from molasses and 0.34 g/g sugar from juice whereas equivalent sucrose concentrations produced 0.27 g butanol per g sugar. Details of the economics for a viable production of butanol from sugarcane products are presented.

Introduction

The acetone butanol ethanol (ABE) fermentation by Clostridium acetobutylicum is one of the oldest known industrial fermentations. It was ranked second only to ethanol fermentation by yeast in its scale of production, and is one of the largest biotechnological processes ever known. Prior to the 1950s, the industrial solvents acetone, n-butanol and isopropanol (generically referred to as butanol and propanol in this discussion) were produced by fermentation (Figure 1).

Fig. 1—Acetone-butanol plant, pre 1950, 600 000 gallon fermentation capacity, Terre Haute, Ind.
Historically, two clostridial species, *Clostridium acetobutylicum* or *Clostridium butylicum* were the fermentation organisms of choice. In a typical ABE fermentation by *C. acetobutylicum*, butyric, propionic, lactic and acetic acids are produced first, the culture pH drops, and the culture undergoes a metabolic ‘butterfly’ shift, then butanol, acetone, isopropanol and ethanol are formed (Zheng et al., 2009).

The butanol yield from glucose is low, typically around 15 percent and rarely exceeds 25%. The production of butanol is limited by severe product inhibition. Butanol at a concentration of 1 percent inhibits cell growth and fermentation by 20% while 1.6% inhibits growth 100%. The butanol concentration in the broth in conventional ABE fermentations is usually less than 1.3 percent (Jones and Woods, 1986).

The push for renewable fuels has re-ignited the interest in butanol production by fermentation. Butanol is both an important industrial solvent and potentially a better fuel than ethanol (Table 1).

| Table 1—Properties of Alternative Fuels (Ramey, 2007). |
|-----------------|---------------------------------------------------|-----------------|
|                 | Ethanol              | Butanol     | Gasoline     |
| BTU/ gal(gross caloric value) | 84k                    | 110k        | 115k          |
| Octane(RON)     | 92                    | 94          | 96            |
| Air fuel ratio(mass of air to mass of fuel) | 9                      | 11–12       | 12–15         |
| Vapour pressure psi@100F  | 2                      | 0.33        | 4.5           |

BTU=1.05 x10³ J; psi= 6.9 x 10³ Pa

Butanol has many advantages as an alternative fuel source; 1) a higher energy content, 2) usable in existing pipelines, 3) easy to blend with gasoline. Because of its low solubility, butanol is less likely to separate from a fuel blend in the presence of water than is ethanol.

The production of butanol from sugars goes by the biochemical route where acetoacetyl-CoA is produced from glucose and then simultaneously split to acetone and butyrate followed by the conversion of butyrate to butanol and, depending on the organism strain, the conversion of the acetone to propanol. There have been numerous attempts to manipulate the genetics of these organisms to separate acetone production from butanol production. This has not been completely successful as both acetone and butanol share a common intermediate (Figure 2). Attempts to block acetone production to favour butanol production usually result in a loss of butanol yield.

![Biochemical pathway leading to butanol and acetone](image)
In the past twenty or so years, there have been numerous engineering attempts to improve butanol production in the ABE fermentation, including cell recycling and cell immobilisation to increase cell density and reactor productivity, and use of extractive fermentation to minimise product inhibition. The yields for ABE fermentations are still less than 2 percent in butanol concentration, 4.46 g/L/h productivity, and a yield of around 25 percent from glucose (Ezeji et al., 2007).

Optimisation of the ABE fermentation process has long been a goal of industry. As with any biofuel, the viability of the ABE fermentation will depend on feedstock cost and microbial productivity. The market demand for butanol is expected to increase dramatically if green butanol can be produced economically from low cost sugars (i.e. biomass derived). Recent research has focused on utilisation of sugars from lignocellulose conversion, with butanol being an alternative to ethanol production (Qureshi et al., 2007).

There is little published information on the conversion of ‘traditional’ feedstocks available from the cane sugar industry to butanol. This study was conducted due to our interest in bringing biofuel production to the Louisiana sugar industry.

**Materials and methods**

**Microorganism and inoculum preparation**

A strain of *Clostridium beijerinckii* (obtained from the Centraalbureaus voor Scimmelecultures in the Netherlands) was used in this research. Bacterial spores (200 μL) were heat shocked for 10 min at 80°C followed by cooling in ice, then inoculated into 27 mL tryptone-glucose-yeast extract (TGY) medium in 30 mL screw capped Pyrex tubes and incubated anaerobically for 12–16 h at 34°C (Qureshi et al., 2008).

**Carbon source**

Different carbon sources were used: sucrose (laboratory grade sucrose, Sigma Chemical co., St. Louis Mo.), blackstrap molasses (containing of 33.4% sucrose, 5.4% glucose, 7.3% fructose, 16.5% ash [conductivity ash] as % total solids 41.9% true purity), raw juice (12.35% sucrose, 0.38% glucose, 0.74% fructose, ash content not determined, values on juice volume), and glucose derived from corn starch for comparison. Glucose was prepared by hydrolysis of corn starch derived malto-oligosaccharide syrups using amyloglucosidase. Enzymatic conversion was allowed to proceed until in excess of 95% of the starch was glucose.

**Batch fermentations**

Fermentation studies were conducted initially in 125 mL screw capped bottles containing 120 mL of medium, at 34°C without agitation, gas flow, or pH control. The medium contained either sucrose (5.0% in a total medium), molasses (5.9% sugars), juice (4.9% sugars), or 5% glucose for carbon source, supplemented with 1 g/L yeast extract. After sterilisation, filter-sterilised stock solutions containing (buffer: KH₂PO₄, 50 g/L; K₂HPO₄, 50 g/L; ammonium acetate, 220 g/L), (vitamins: para-amino-benzoic acid, 0.1g/L; thiamin, 0.1 g/L; biotin, 0.001 g/L), and (minerals: MgSO₄·7H₂O, 20 g/L; MnSO₄·H₂O, 1 g/L; FeSO₄·7H₂O, 1 g/L; NaCl, 1 g/L)] (Qureshi and Blaschek, 1999) were added (1 mL each). The media was then inoculated with highly motile cells of *C. beijerinckii* (6 mL cell suspension in 114 mL medium). During the course of fermentations, 4 mL samples were collected at intervals for absorbance, pH, solvents, organic acid, and sugar analysis.

**Analytical procedures**

Cell concentration was estimated from the absorbance at 600 nm. The solvents, butanol, acetone, ethanol were measured using gas chromatography on a wax column (Phenomenex ZP Wax plus). Organic acids, acetic and butyric were determined by high performance liquid chromatography (HPLC) using an anion exchange column (Dionex Ionpac AS-11). Sugars were analysed by HPLC using a K column (Biorad HPS87K).
Results and discussion

The growth curves for *C. beijerinckii* were similar for all carbon sources, achieving late exponential phase of growth around 30 h and maximum growth after 49.5 h (data not shown). The media pH in either sucrose or glucose media decreased until late exponential phase, and then rebounded (data not shown). This is a typical growth pattern for *C. beijerinckii* (Parekh *et al*., 1998; Jones and Woods, 1986) and reflects the production and then utilisation of organic acids. In most ABE fermentations, butanol production starts after the stationary phase begins. Throughout our fermentations, low levels of acetone and ethanol were continuously present and, except for the molasses fermentations, butanol concentrations increased throughout the growth phase. This pattern is indicative of continuous, efficient butanol production by *C. beijerinckii* (Jones and Woods, 1986) (Figure 3). Cultures containing molasses were acidogenic because molasses feed has high levels of acetic acid (0.65% on Brix), which slowed the start of butanol production compared to the other carbon sources. Butanol production increased rapidly after the stationary phase was achieved. Sugar juices showed rapid increases in butanol production between 12 and 49.5 h of fermentation.

![Production of acetone-butanol from individual carbon substrates by C. beijerinckii. Propanol is indicated by the ( ) symbol, butanol by ( ) symbol and total solvent by the ( ) symbol. The glucose was that obtained from corn starch hydrolysis.](image)

Juice (containing 4.9% sugars) and molasses (5.9% sugars) were the preferred substrates for butanol production by this strain (Figure 4). Higher concentrations of molasses repressed growth, probably due to osmotic effects (data not shown). In all cases 2-propanol was the largest secondary product. This product pattern is very similar to that produced by *C. butylicum*. Small amounts of ethanol were found in all samples. No differences were observed between glucose and sucrose fed
cultures in the production of butanol. These fermentations were not optimised for carbon utilisation. In all cases, residual sugars remained at the conclusion of the fermentations.

The productivity of this culture was higher on juice and molasses than on sucrose or glucose. In these, non-optimised, fermentations there were 1.6 to 1.7 times more solvent in the fermentation broth with molasses or juice as feedstock than with sugars.

On a carbon source utilised, yield to product produced (Table 2), there was about 1.3 times more solvent produced using sugarcane feedstocks than with either pure sugar or corn hydrolysate.

*weight % of product on carbon source utilised
The differences in solvent yields, as a function of feedstock, is significant. In comparing butanol production with the alternative (ethanol), it should be kept in mind that ethanolic (yeast) fermentations have a theoretical maximum yield of 51% and take 1.65 kg of sugar to produce a litre of ethanol. The amount of sugar used and relative feedstock costs (in the US) to produce butanol are given in Table 4.

*Price in US dollars for American market
** Molasses estimated at 49% fermentable sugars, $70.00/tonne.

Even though the conversion of sugar(s) to butanol/propanol is lower than conversion to ethanol, the higher BTU values for butanol and reduced fuel transport handling problems make this fermentation worth considering for fuel production. (Qureshi and Blaschek, 2000). Butanol fuel made directly from sugar juice is probably competitive with corn ethanol and that from molasses is cheaper. Improvements in yields can be expected as further efforts are made in strain improvement and as the technology matures to the equivalent of fuel ethanol production technology.

Résumé

Le butanol est un alcool aliphatique saturé avec la formule moléculaire de C₄H₉OH, qui peut être utilisé comme un combustible de transport, un intermédiaire et un solvant pour une grande variété d'applications chimiques. La fermentation acétone-butanol était la norme pour la production industrielle de solvants jusqu'aux années 1950. Les techniques microbiologiques modernes ont amélioré le micro-organisme d'origine pour qu’il produce des niveaux élevés de butanol plutôt que de solvants mixtes. Le butanol présente de nombreux avantages comme une source de carburant de remplacement. 1) Un contenu énergétique plus élevé; 2) Une utilisation dans les pipelines existants; 3) Un mélange plus évident avec l'essence. Le butanol peut être produit à partir de jus de canne à sucre, de mélasse ou des sucres issus des hydrolysats bagasse à l'aide d'une souche de Clostridium beijerinckii. Le jus de canne et la mélasse fermentent directement en butanol. Le rendement de butanol était 0.30 g/g sucre à partir de mélasse et de 0.34 g/g à partir de jus que canne alors qu’une concentration équivalent en saccharose produit 0.27 g butanol par g de sucre. Les détails d’ordre économique pour une production viable de butanol à partir de produits émanant de la canne à sucre sont présentés.

PRODUCCIÓN DE BUTANOL DE JUGOS

Resumen

El butanol es un alcohol alifático saturado con la fórmula molecular de C₄H₂OH, que puede ser usado como combustible de transporte, como intermediario y como solvente para una amplia variedad de aplicaciones químicas. La fermentación acetona-butanol fue el estándar para la producción industrial de solventes hasta los años 1950. Modernas técnicas microbiológicas han mejorado el microorganismo original en un modo tal que produce elevadas cantidades de butanol en lugar de la mezcla de solventes. El butanol tiene ventajas como fuente alternativa de combustible: 1) mayor contenido energético, 2) posible de emplear en instalaciones actuales, 3) fácil de mezclar con gasolina. El butanol puede producirse del jugo de caña de azúcar, de melazas ó de azúcares de los hidrolizados de bagazo, empleando una cepa de Clostridium beijerinckii. Los jugos de caña y las melazas se fermentan directamente a butanol. El rendimiento de butanol fue de 0.30 g/g de azúcar de melazas y 0.34 g/g de azúcares de jugos, mientras concentraciones equivalentes de sacarosa produjeron 0.27 g de butanol por gramo de azúcar. Se presentan detalles acerca de la economía para una producción viable de butanol.
SUSTAINABLE ENERGY FOR ETHANOL DISTILLERIES

KEYWORDS: Vinasse Treatment, Biogas Production, Biogas from Vinasse.

Abstract
The production of ethanol from the sugar containing feedstock generates waste waters coming from the bottom of distillation towers, well-known as vinasse. These constitute the biggest load pollutant. Using a group of parameters found in a wide list of international references, the present paper shows energy balances (of steam and electricity) using Excel, to demonstrate that biogas produced from the anaerobic digestion of this polluting load, besides degrading the vinasse, can contribute to the supply of energy demand to an ethanol distillery. The results are presented for medium, low and high values of pollutant concentration. It is intended also to use this energy to feed gas burners at conventional steam generators, removing the H₂S that contains the biogas in a process called desulfurisation. At the end, the main methods for desulfurisation for this combustible gas are recommended.

Introduction
The production of ethanol from the sugar industry generates waste waters coming from the bottom of distillation towers, well-known as vinasse. These constitute the biggest load pollutant. The biogas production is one of several alternatives frequently used internationally for degradation of this polluting load.

There are reliable references about significant energy advantages that this alternative offers such as in Godbole (2002).

The target of the present paper is to show that biogas which can be generated from anaerobic digestion of vinasse in an ethanol distillery, besides degrading the vinasse, can contribute to a high percent of its energy demand.

Pollutant loads
Vinasse is defined as a solution of substances and mineral and organic salts with relative value and with potential for diverse uses. COD (Chemical Oxygen Demand) measures the value of the contamination present in vinasse.

Factor selected for this calculation
The values of load pollutant selected for this work will be those proposed by Estévez (2007a) that are shown in the Table 1.

Table 1—COD characterisation of vinasse from the cane sugar industry (Estévez, 2007a)

<table>

<th>Non-harvest season</th>
<th>Harvest season</th>
</tr>
</thead>
<tbody>
<tr>
<td>COD (kg/m³)</td>
<td>60–80</td>
<td>30–40</td>
</tr>
</tbody>
</table>
As may be observed in Table 1, there are differences in COD vinasse composition generated in the harvest season period compared to those generated in the non-harvest season. This is due to a fundamental difference in the preparation of the substrate.

**Harvest season period**

To prepare the substrate, filter juices previously subjected to a purification process in the sugar factory are used. These juices can be blended with molasses B or may be added directly to reactors, as required.

**Non-harvest season: Molasses ‘B’ or second crystallisation is used.**

As the critical period for the energy demand of a distillery is the non-harvest period, because the energy from bagasse is not available, this paper will use the values of the range of the COD presented in Table 1 for this scenario. The volume of vinasse of 17.4 L vinasse/L ethanol is the value considered by this paper such as in Estévez (2007a).

**Removing polluting load and conversion to fuel (methanisation)**

Not all the COD becomes biogas. Five references are presented in Table 2 related to removal percent.

### Table 2—COD removed by anaerobic digestion.

The biogas is a mixture of fuels, and methane is the one that gives the energy qualities. 

**Steam and electricity balances for a typical ethanol distillery of 50 000 L/day**

Table 5 shows results of energy calculations, made by a calculation table using Excel from Microsoft Office, where the indicators and parameters discussed in Tables 1, 2, 3, and 4 are used. The steam and electricity balances for the distillery example of 50 000 L/day are shown.

The values of load pollutant are those that were presented in Table 1 and the rest of the calculations will be carried out in a range with a medium value and their two extreme values (low and high), using the previously analysed data.

Table 5 shows figures of equivalent fuel oil obtained by biogas production. Further on will be determined what this biogas represents in energy availability with regard to steam and electricity demands for a distillery example.

The steam and electricity generation have a first and fundamental dependence on steam parameters. For this calculation, two levels will be considered: saturated steam at 11.35 bar abs and superheated steam at 18.25 bar abs and 330ºC.

A boiler efficiency of 88% with regard to the low heating value of the fuel is assumed.

A value of 100ºC water temperature for feeding the boiler is also assumed. Such water temperature value can be assumed when the vinasse is cooled using this water, a practice used in several factories of Torula yeast in Cuba according to Doménech (2008b).

**Steam balance with saturated steam at 11.35 bar abs**

In Table 6A, the steam balance carried out for the selected distillery is presented.

**Table 6A—Steam balance with saturated steam at 11.35 bar abs.**

</tbody>
</table>
Table 6A shows results of steam generation by biogas in this steam variant. They are significant, even in the low extreme value (69.34%) with regard to steam demanded by the distillery. This confirms the benefit of using biogas. For the medium value analysed (131.33 %), the steam demand for the distillery is totally covered, which eliminates the necessity to use other fuels in the non-harvest season period.

Electricity balance with saturated steam at 11.35 bar abs

Table 7A shows the results of the electricity generation by biogas in a turbo-generator which uses direct steam from a boiler considering some data presented in Table 6A. In the worst variant from the low value using biogas, more than half of the electricity (56.02%) is produced with regard to electricity demanded by the distillery.

In this case, for the medium value of electricity produced by biogas (106.11%), there is enough to cover the electricity demand by the distillery.

### Steam balance with superheated steam at 18.25 bar abs and 330ºC

For this steam parameters level, more fuel by unit of mass will be necessary for generating the available steam from biogas. Table 6B shows that less quantity of steam will be available in this variant than in the previous one analysed.

Nevertheless, a significant 61.16% steam generation by biogas with regard to steam demand of the distillery is provided with the low value, and a large surplus in the medium (116.84%) and high values (200.16%) is achieved.

### Table 6B—Steam balance with superheated steam at 18.25 bar abs and 330ºC.

Electricity balance with superheated steam at 18.25 bar abs and 330°C

Table 7B shows that the steam rate of the Turbo-Generator can diminish significantly with regard to Table 7A. As a consequence of this, the available electricity from biogas will be considerably higher in all cases, with regard to the variants previously analysed for saturated steam. In the low value, a good electricity generation by biogas (86.62%) and surpluses in the medium (164.05%) and high (283.48%) values are achieved.

</tbody>
</table>

It can be concluded that steam and electricity generation by biogas could be significantly beneficial for both levels of steam parameters studied, with the characteristic that there will be more steam generation by biogas in the variant at 11.35 bar abs (saturated steam) than at 18.25 bar abs and 330ºC (superheated steam). However, in this last alternative, there is more electricity generation by biogas than the first one. A particular study would help to decide the selected alternative. It is necessary to point out that steam generation in excess of the distillery demand has no practical sense in the analysed conditions. In this circumstance, biogas could be stored.

Elimination of hydrogen sulfide H$_2$S from biogas (Desulphurisation)

As was shown in Table 4, there is always significant sulfur content in the form of H$_2$S in produced biogas. The use of biogas directly as a fuel in steam boilers without purification has resulted in serious corrosion problems, which have led to failures such as in eco-efficiency for Australian dairy processors (2004). Therefore, in order to be able to use the biogas as fuel in steam boilers, it is necessary to carry out a desulphurisation process.

The commonly used desulphurisation processes, in general, can be classified in two categories, that is: (A) Desulphurisation in dry and (B) Desulphurisation in liquid phase.

(A) Dry Desulphurisation as in Kapdi (2004) is often used in homemade productions. This paper is related only to industrial productions.

(B) Desulphurisation in liquid phase.

One solution for H$_2$S removal in liquid phase is a commercial technology called Greenlane of FLOTECH as in www.flotech.com (2006). The raw biogas under pressure enters a scrubber through the bottom, making contact with water in a counter flow process, and the clean gas goes to an outlet at the top part. The CO$_2$ and H$_2$S are absorbed by the water.

Other processes frequently used for removal of H$_2$S consist of scrubbing of biogas with an alkaline solution. In the references are:

- The use of hydrated lime as in Marchaim (1992) in solid or liquid form. This substance has not been applied on a great scale for a long time, because of the big quantity of residuals with bad smell that occur and that cannot be eliminated satisfactorily. Big concentrations of CO$_2$ that are present in biogas composition make
the satisfactory removal of H$_2$S difficult, since the CO$_2$ also reacts with the live or hydrated lime. Of course, the elimination of CO$_2$ is also convenient for using biogas as fuel. For this reason, this desulphurisation process could be considered if:

- Limestone is available in the market.
- When the residuals destination from the process is very secure.

- *Use of NaOH.* In a commercial system called THIOPAQ as in www.sta-at.com, NaOH is described as a washer or scrubber for biogas desulphurisation. The NaOH consumed in absorption of H$_2$S is continually regenerated in a bioreactor (biological method). The absorption of H$_2$S inside the scrubber is given under basic conditions. The washer liquid that contains the extracted sulfur of H$_2$S is transferred to the bioreactor where this sulfur is oxidised to elementary sulfur by use of a series of bacteria.

- *Using ferric solutions or ferric salts as ferric chloride.* There is a commercial system from Eco-Tec as in www.eco-tec.com BgPurTM or cleanser of the biogas, which is based on a high effectiveness device of contact gas-liquid. The scrubber or cleanser removes the H$_2$S from a current of gas using a purifying solution that uses a very well-known ferric chemical reducer. The vessel for regeneration of the polluted purifying solution uses atmospheric oxygen to convert H$_2$S to elementary sulfur. The regenerated solution, now free of H$_2$S, is returned to the cleanser vessel. The catalyst, the products of the reaction, and the preservative buffer are all acceptable environmentally.

- *Novel patent of Habets (1999).* The natural alkalinity generated during aerobic biological processes for purification of waste waters, i.e. a biomass carrier, can be used as washer instead of adding some alkaline chemical products. The aerobic treatment of the waste waters, which has an acquired alkalinity in a natural way, contacts the biogas that contains H$_2$S. The H$_2$S will be absorbed from the biogas in a water phase. The advantage of this treatment is that some chemical product is not added; therefore, the operational costs are low. An additional advantage is that the washer liquid which, at the end of process, contains the absorbed H$_2$S, can be recycled toward the aerobic treatment without difficulty and without some additional treatment. The scrubbing liquid that contains the extracted sulfur of the hydrogen sulfide is transferred to a bioreactor, where this sulfur is oxidised until elementary sulfur due to a series of bacteria.

**Conclusions**

**Steam and electricity generation with the biogas production**

The non-harvest season period was analysed because of the non-availability of bagasse as fuel. The generated energy by biogas was calculated by a program using Excel applied to a distillery example of 50 000 L/d. Steam and electricity balances were carried out for two levels of steam generation parameters: 11.35 bar abs saturated steam and 18.25 bar abs and 330ºC superheated steam. It was calculated for a medium value and extreme high and low values.

**Steam generation**

For the generation at 11.35 bar abs (steam saturated), the steam available is highly significant since, in the low value, there was an important steam generation by biogas of 69.34% of steam demanded and a wide surplus for the medium (131%) and high values (226.94%).

For 18.25 bar abs and 330ºC, an important steam generation by biogas of 61.16% for the low value with regard to steam demanded by the distillery and a large surplus in the medium (115.84%) and high (200.16%) values, although not as high as the previous case of saturated steam.
Electricity generation

For generation at 11.35 bar abs (steam saturated), the available electricity was significant since, for the low value, there was an electricity production by biogas of 56.02% of the demand and a large surplus in the medium (106.11%) and high (183.3%) values.

For 18.25 bar abs and 330ºC, more electricity was produced by biogas. In the low value, there was a good electricity generation by biogas (86.62%) and surpluses in the medium (164.05%) and high (283.48%) values.

It can be concluded that steam and electricity generation by biogas could be significantly beneficial for both levels of steam parameters studied, with the characteristic that there will be more steam generation by biogas in the variant at 11.35 bar abs (saturated steam) than at 18.25 bar abs and 330ºC (superheated steam) although, in this last alternative, there is more electricity generation by biogas than the first one.

Biogas desulfurisation systems that would be of use in ethanol distilleries offered for industrial scale presented here:

This system uses under pressure biogas at counter flow with water (It does not use chemical products) with a later recovery system for the same water using atmospheric air.

**Use of hydrated lime as in Marchaim (1992)**

This is in solid, or in liquid form. This means besides the H₂S, the CO₂ is also eliminated in biogas which is also convenient, provided that limestone is available and there are reliable means of disposing of the residuals with bad smell.

**System THIOPAQ of STA-AT as in [www.sta-at.com](http://www.sta-at.com)**

The biogas enters in a washer with a liquid that contains caustic soda that absorbs H₂S. For regeneration of the scrubber liquid, this is transferred to a bioreactor, where the sulfur is oxidised thanks to a series of bacteria.

**System BgPurTM of Echo-Tec as in [www.eco-tec.com](http://www.eco-tec.com)**

The washer removes the H₂S using a watery solution for scrubbing with a very well-known ferric reducing substance. For regeneration of the washer solution, atmospheric oxygen is used which converts H₂S to elementary sulfur.

**Novel patent of Habets (1999)**

The natural alkalinity generated during an aerobic biological process for purification of waste waters; carrier of biomass, can be used as washer instead of addition of alkaline chemical products; therefore operational costs are low. Washer liquid, the one that contain the absorbed H₂S, can be recycled toward the aerobic treatment without difficulty and without some additional treatment.

MOTS-CLÉS: Traitement de Vinassee, Production de Biogaz, Biogaz de Vinassee.

Résumé
LA PRODUCTION d'éthanol à partir des substrats contenant du sucre génère des eaux usées provenant de la partie inférieure de tours de distillation, connues comme la vinasse. Celle-ci constitue le plus fort polluant du procédé industriel. À l'aide d'un groupe de paramètres sélectionnés dans une large gamme de références internationales, le présent document comporte des bilans d'énergie (vapeur et électricité) pour démontrer à l'aide d'Excel que du biogaz produit à partir de la digestion anaérobie de ce polluant, en outre de la dégradation de la vinasse, peut contribuer à satisfaire la demande d'énergie d'une distillerie d'éthanol. Les résultats sont présentés pour des concentrations de vinasse à taux faible, moyen et élevé. L'étude vise également à utiliser cette énergie pour alimenter les chaudières conventionnelles à vapeur, tout en supprimant le sulfite d’hydrogène contenu dans le biogaz par un procédé appelé desulfurisation. À cette fin, les meilleures méthodes pour desulfurer ce gaz combustible, sont recommandées.

ENERGÉTICA SOSTENIBLE PARA DESTILERÍAS DE ETANOL

Resumen
LA PRODUCCIÓN de etanol a partir de materias primas azucaradas genera aguas residuales del fondo de las columnas de destilación, bien conocidas como vinazas. Éstas constituyen la mayor carga contaminante. El presente trabajo, empleando un grupo de parámetros hallados en la larga lista de referencias internacionales, muestra balances de energía (de vapor y electricidad) empleando Excel, para demostrar que el biogas producido de la digestión anaeróbica de esta carga contaminante, además de degradar las vinazas puede contribuir a abastecer las demandas de energía de una destilería de etanol. Los resultados se presentan para medianos, bajos y altos niveles valores de concentración de polutante. Se intenta, igualmente, emplear la energía para alimentar quemadores de gas en calderas de vapor convencionales, removiendo el H2S que contiene el biogas, por un proceso denominado desulfurización. Finalmente se recomiendan los mejores métodos para desulfurar este gas combustible.
THE COLOMBIAN EXPERIENCE IN THE PRODUCTION OF BIOETHANOL FOR TRANSPORT USE

By

Abstract

THE NATIONAL Colombian Program for promoting the use of oxygenated gasoline for transport purposes started in 2001 with the implementation of the governmental tax incentives and the definition of the required technical framework for blending and fuel quality. The maximum level of blend for ethanol and gasoline was determined to be 10% v/v and the minimum concentration of dehydrated ethanol 99.5% v/v. Since 2005, five ethanol plants, using sugarcane feedstocks, are operating in the country with an overall production of 1 050 000 litres/day. The technological configuration of all plants is alike, mainly conformed by a continuous fermentation section and a continuous ethanol dehydration section. This paper describes some specific features derived from the commencement of the plants and some problems found in the normal operation of the fermentation. These troubles are mainly related to persistent microbial contamination in the fermentors, which reduces ethanol production efficiency and causes an overproduction of toxic and inhibitor organic compounds like acetic acid and lactic acid, among others. From a monitoring campaign, it was established that each plant had to develop its own adaptation process, such as the usage of different feedstock blending relationships, and to follow different learning curves despite the common technology used.

Introduction

In the past 5 to 6 years, the acknowledgment and acceptance of ethanol as an oxygenating additive for fuels commonly used in automobiles have extended beyond the United States and Brazil, the countries with the highest production and consumption. As a result, different evaluative, legislative, economic, and research activities have been conducted in several countries of Asia, Africa, Europe, and Latin America, as well as Australia, to promote and expand the use of ethanol as a fuel (Shete, 2003).

The production of ethanol and the establishment of new alcohol production plants, or the expansion of existing plants, are important issues for the sugar and sucro-chemical sectors of the department of Valle del Cauca, Colombia, to satisfy the needs for oxygenating compounds or gasoline additives.

Plans, therefore, include the study and search for strategies that reduce the environmental impact of sugar industry effluents, commonly known as vinasses, the main by-product of the alcohol-chemical industry. It is therefore indispensable to have a good diagnosis and characterisation of vinasses in our national scenario.

In the Colombian alcohol-chemical industry, sugarcane molasses is currently used as the substratum and the yeast Saccharomyces cerevisae as the biological catalyst. Vinasse is a high-volume by-product, generated at a ratio of 14 litres per litre alcohol produced.
During production, vinasse is characterised by its high temperature, low pH (4.2–4.6), and high content of suspended, dissolved organic matter. Vinasse also contains a considerable number of inorganic salts (sulfates, phosphates, etc.), calcium, potassium, sodium, magnesium (0.1%–4.4% in concentrated vinasse), and other elements in smaller amounts (6–300 ppm) (Briceño, 2006).

Vinasse has been broadly used in agriculture because it improves almost all soil fertility factors. In Brazil, because of prevailing soil conditions, vinasse is used as an organic fertiliser either alone or mixed with other products, depending on the specific characteristics of each region. In Colombia, however, rates above 50 m³ per hectare are not applied. Although the high organic matter content of vinasse justifies its use as fertiliser, this characteristic should be given special attention when considering new uses of this byproduct. The possibility of extracting organic compounds of high added value should also be studied (Graca, 2002).

In Colombia, ethanol production for transport started in October 2005. Table 1 summarises the capacities and starting date of each Colombian plant. By July 2009, the demand coverage of ethanol reached 85% to supply the biofuel just to the northern portion of the country.

Bioethanol projects and investments in Colombia

Over the last decade, technical, economic, and environmental studies have been conducted in Colombia to determine the feasibility of the country entering the ‘bioethanol era’. As a result, several requests for clarification on legal and commercial issues have been presented before the national and departmental governments. The national program that has been established offers the opportunity to address the following sectors and topics:

- Farmers growing cane, maize, cassava, sweet sorghum, potato, and beet.
- Engineering and construction firms, installers, environmentalists, and transporters.
- Effective reduction of CO₂ emissions.
- Opening to biofuels and alcohol chemistry.
- Legal precautions for private investors.
- Sound legislation and regulations in related technical and environmental issues and regarding prices.
- Tax-related incentives (VAT, tax on gross revenue, and surcharge).

Colombia’s national fuel alcohol program aims to produce ethanol from sugarcane and other agricultural inputs to improve the quality of gasoline. Legislation favouring this undertaking includes the following:

- Law 788 of 2002 exempts fuel alcohol from the payment of taxes normally charged on gasoline such as the tax on gross revenue, VAT, and surcharge (Articles 31 and 88).
- The Ministry of Environment, Housing, and Territorial Development, together with the Ministry of Mines and Energy, passed Resolution 0447 of 2003 to regulate quality characteristics of alcohol and oxygenated gasoline and to establish the minimum percentage of anhydrous alcohol (99.5%).
- The Ministry of Mines and Energy, by Resolution 181710 of 23 December 2003, established that the ceiling price would be established and then adjusted annually as follows: 70% based on the variation of the Producer Price Index (PPI) and the remaining 30% based on the annual devaluation.
In Colombia, the main clients of oil refineries are large distributors that store and re-distribute fuels (petroleum derivatives) to smaller suppliers or clients, who, in turn, sell the product to typical users (citizens). This scheme will continue in the case of alcohol and gasoline mixtures. Each country must not only establish its own product specifications but also define how and where the mixtures are prepared, and how they are dispatched and received. The safety controls to minimise risks, ensure quality, and prevent losses or alterations vary depending on the methods and technologies involved. Figures 1 and 2 present a summarised scheme of the main factors related to important clients of distilleries (Calero et al., 2003).

![Diagram showing factors associated with the reception, mixture, and distribution of gasoline and alcohol that affect the businesses of important clients or distributors.](image)

**Fig. 1**—Factors associated with the reception, mixture, and distribution of gasoline and alcohol that affect the businesses of important clients or distributors.

Figure 2 schematically shows the system of preparing and distributing gasoline-fuel alcohol mixture (10%), adopted in Colombia.

![Diagram of the system of mixing and distributing gasoline-fuel alcohol mixture (10%) in Colombia.](image)

**Fig. 2**—System of mixing and distributing gasoline-alcohol fuel (10%) mixtures in Colombia.

**Bioethanol projects and investments in Colombia**

The production of bioethanol as an oxygenating additive for gasoline began in Colombia in October 2005 and, to date, there are five distilleries adjunct to sugar refineries (Table 1).
The building and putting into operation of these new processing plants in the geographical valley of the Cauca River implied the compliance of numerous environmental, technical, legal, commercial, and financial requirements. The factors found to have greater impact on ethanol production projects were the raw material and its permanent availability, the technology used (fermentation, dehydration, effluent concentration and treatment, etc), the effluents produced, energy requirements, automation, and capital costs.

The investors in new alcohol production plants should assess the opportunities that will arise with the increasing demand for the product worldwide as well as the competition between technologies, raw materials, effluent treatments, development of derivatives/byproducts and reduced investment costs, processes and quality.

In Colombia, the five recently established distilleries are adjunct to cane sugar mills and use technology of Praj and Delta T, with vinasse concentration and its subsequent use to obtain compost (see text boxes 1 and 2, Figures 3 and 4).
Fig. 3—Typical milling flow chart for sugar production in Colombia. Source: Vivas, A.L. (2006).

ATR = Azúcar Total Recuperable (as original) (Total Recoverable Sugar).

Fig. 4—Typical flow chart for ethanol production in Colombia.
Relevant features of the actual Colombian technology

The distilleries coupled to sugarcane mills in general use molasses B, with a recirculation system for vinasse. All plants are operating with continuous fermentation, distillation and dehydration process.

The distillation step has two units. From the first one, ethanol at 45% is obtained and from the second, ethanol at 95% is produced followed by the dehydration step. All bioethanol plants are using a strain from the yeast *Saccharomyces cerevisae* as the biological catalyst, provided by Praj - Delta T Company.

To establish some indicators or parameters which can indicate the performance of the whole fermentation stage, a monitoring campaign was conducted for determining glycerol and organic acids concentration levels (lactic, acetic and butyric) during a steady state operation period of the plant. Then, during an abnormal and atypical operational condition of the fermentors, the same concentration levels were measured, in order to establish any possible relationship between microbial contamination and inhibitors formation. Other operational conditions at the fermentors such as temperature and pH were kept constant. It must be noted that an abnormal condition situation was promoted by the continuous operation of the plant with no scheduled addition of any microbiological or chemical agent.

The plant uses two continuous fermentors with 8-hours-retention-time each one. Vinasse was recycled to first and second fermentor. Samples for analytical chemical and microbiological tests were collected from global entering and exiting streams from both fermentors. Additional samples were collected too from the wine tank. Determinations of selected organic compounds were carried out at Cenicãña’s lab using HPLC technique. Microbiological analysis uses plate count method. Each monitoring record included three samples of each location.

It was found during the stable or normal operation of the fermentation, that concentration levels of organic compounds were on average lower than 0.6% w/w, while during the atypical stages those reached in average 0.75% w/w (Figures 5 and 6). So, an important increase of 33% of total organic acids content during periods of higher microbial contamination can be reported, which can affect the fermentation process and ethanol production. Also, for glycerol, increases of 3 to 11% were found in its w/w concentration during atypical operation. Population of Lactic Acid Bacteria (LAB) was higher during the atypical operation (> 2x10⁶ CFU/mL) compared with the levels observed for stable operation (< 8x10⁵ CFU/mL).

![Fig. 5—Organic acids content in a fermentation stage during two different reactor conditions (lactic, acetic and butyric acids).](image-url)
In a parallel way, a second monitoring campaign was conducted in a different distillery for assessing the mass and energy balance of the whole plant. It was observed that the ethanol plant produces different vinasse-ethanol ratios mainly explained for the quality of the substrate mixtures supplied to the fermenter. So, it can be established that the mixture of clarified juice-molasses B used as feedstock to the fermenter produced less volume of vinasse per ethanol volume (Figure 7).

**Figure 6**—Glycerol content in a fermentation stage during two different reactor conditions.

**Figure 7**—Vinasse volume per anhydride ethanol produced for several substrates employed during continuous fermentation. (MB = Molasses B; S/MB = Syrup/Molasses B relationship).

It can be noted that some comments on the performance of the selected technological scheme for ethanol plants in Colombia are focused on often recurrent operational problems caused by microbiological contamination by wild yeast and other micro-organisms, such as lactobacillus. In order to establish a biological control for wild yeast or other kinds of micro-organism, further studies are underway which include a biological characterisation of the different strains which might affect ethanol production.

**Conclusions**

- In medium-term investments, the producer of fuel alcohol should consider aspects ranging from environmental permits granted by the State to commitments with companies responsible for the gasoline mixtures.
• The main use of bioethanol in Colombia is currently as a fuel oxygenating additive; however, a very broad range of derivatives or byproducts exists, all with significant market demand.

• The periodic evaluation of organic acids and glycerol concentration levels can be useful for getting a potential biochemical marker which can be a performance index of the fermentation process.

• Some operational problems arise during the production of bioethanol in Colombia, mainly related with microbiological contamination with wild yeast, causing the need for a new operational approach to the sugar plant.

Resumen
EL PROGRAMA Nacional Colombiano para promover el empleo de gasolinas oxigenadas para propósitos de transporte comenzó en el 2001 con la implementación de incentivos gubernamentales de impuestos y la definición del marco técnico requerido para la mezcla y calidad de los combustibles. El máximo nivel de mezcla etanol - gasolina se determinó que era 10% v/v y la mínima concentración de etanol deshidratado 99.5%. Desde el 2005 operan en el país cinco plantas de etanol, empleando caña de azúcar como materia prima, con una producción total de 1 050 000 litros/día. La configuración tecnológica de todas las plantas son similares, conformada básicamente por una sección de fermentación continua y una sección continua de deshidratación de etanol. Este trabajo describe algunos aspectos específicos derivados de la arrancada de las plantas y algunos problemas encontrados en la operación normal de la fermentación. Estos problemas están básicamente relacionados con una contaminación persistente en los fermentadores, que reducen la eficiencia de la producción de etanol y causan sobreproducción de componentes orgánicos tóxicos e inhibidores, tales como los ácidos acético y láctico, entre otros. A partir de una campaña de monitoreo, se estableció que cada planta debe elaborar su propio proceso de adaptación, tales como el empleo de diferentes relaciones de mezcla de materias primas y seguir diferentes perfiles de desarrollo y adaptación con independencia de la tecnología común empleada.
TECHNO-ECONOMIC INDICATORS FOR THE THERMOCHEMICAL AND BIOCHEMICAL ROUTES FOR BIOFUELS PRODUCTION USING SUGARCANE BAGASSE AS FEEDSTOCK

By

D.S. OBANDO, M.A GUALDRÓN, M.L.G. RENO and E.E.S. LORA

Excellence Group in Thermal Power and Distributed Generation, Federal University of Itajubá, Brazil
electo@unifei.edu.br

KEYWORDS: Second Generation Biofuels, Sugarcane Bagasse, Biochemical Route, Thermochemical Route.

Abstract

The main goal of the paper is to compare the biochemical and thermochemical routes for second generation biofuels production performance, using efficiency and economic indicators. In both cases, the feedstock used is bagasse. Calculations are carried out for a biofuel plant having a bagasse consumption of 1772 t/day of dry matter, equivalent to 400 MW of thermal energy. By-products utilisation, such as lignin in the biochemical route, and bagasse for steam and electricity self sufficiency through cogeneration were considered also. The high production cost of bioethanol obtained through the biochemical route (21.32 to 22.7 US$/GJ$_{ETOH}$) is strongly influenced by the enzyme costs. The biomethanol production cost by the thermochemical route (15.82 US$/GJ$_{MeOH}$) is mainly influenced by the high equipment cost.

Introduction

Biofuels derived from lignocellulosic biomass can be produced through two conversion routes: the biochemical and thermochemical ones, and are classified as second generation biofuels to differentiate them from the conventional first generation ones.

The production of ethanol through pre-treatment, hydrolysis and fermentation from the sugars resulting from lignocellulosic materials conversion corresponds to the biochemical conversion route. On the other side, the obtainment of biofuels derived from biomass gasification synthesis gas conversion (Fischer-Tropsch liquids, methanol synthetic natural gas – SNG, and other hydrocarbons) corresponds to the thermochemical conversion route Schwietzke et al. (2008).

Presently, the bioethanol production cost from lignocellulose is high, and this is the main reason it has not reached the market commercialisation stage. Sassner et al. (2008) presented the results of the techno-economic evaluation of bioethanol production from three types of lignocellulosic materials, and showed production costs in the range from 0.66 to 0.87 US$/L, depending of the feedstock used. Finally, according to a study carried out by the United States Energy Department (DOE, 2008), the bioethanol cost can be reduced to the range 0.3–0.4 US$/L in the future.

Regarding methanol, although great environmental restrictions exist regarding its utilisation due to the mainly fossil origin, a considerable number of techno-economic evaluations based on its production through renewable non-commercial technologies have been reported. The use of the renewable methanol could increase the sustainability of biodiesel production considerably, raising the output/input relation (renewable to fossil energy relation) of this process from 5 to 8, reaching the same value as for conventional ethanol, as reported by Angarita et al. (2009).
According to Hamelick and Faaij (2001), the average biomethanol production cost varies between US$9 – 12/GJ for a plant with a processing capacity of 400 MW (biomass feedstock cost is 2 US$/GJ).

Lower production costs, of about 8.04 US$/GJ also for a 400 MW plant (biomass feedstock cost of 2 US$/GJ), can be reached when the technology LPMeOH™ (Liquid Phase Methanol) is used, as work of Sørensen (2005).

In this paper, the biochemical and thermochemical routes for the production of second generation biofuels (bioethanol and biomethanol respectively), using sugarcane bagasse as feedstock are compared using different techno-economic indicators.

Feedstock

Lignocellulosic biomass is composed mainly of carbohydrates (cellulose and hemicelluloses), lignin and a small fraction of extractives, acids, salts and minerals, as reported by Hamelinck et al. (2005) and Mosier et al. (2005).

Sugarcane bagasse and trash are co-products of the sugar and ethanol industry. In the harvest 2007/2008, the Brazilian sugar and alcohol agro-industry, having approximately 300 mills, processed 4.32x10^8 tonnes of cane for the production of 2.0x10^7 m³ of ethanol. The quantity of sugarcane processed generated about 1.2x10^8 tonnes of bagasse (UDOP, 2009).

Therefore, a wide recognition exists that the annual production of cane bagasse reaches huge figures and that the efficient use of this residue is an urgent necessity, with wide potential for the development of more profitable activities than direct combustion or gasification for electricity generation, and biofuels production, as discussed by Pitarelo (2007). It is assumed that both the bioethanol and biomethanol plants are located in Brazil, are autonomous, and have a processing capacity of 400 MWth (1772 t/day of dry biomass). Bagasse is acquired from nearby sugar and alcohol mills at market prices.

Biochemical platform

Process description

The process of bioethanol production starting from lignocellulosic materials has the following stages: pre-treatment of the raw material, hydrolysis, fermentation and distillation (Figure 1). Also, a stage of steam and power generation by using the solid residues of the process as fuel should be considered.

![Flowchart of bioethanol from biomass production (Hamelinck et al., 2005).](image-url)

In the bioethanol plant, bagasse does not require previous grinding due to its small size distribution, and it is assumed to have 50% moisture. The bagasse is imbued with gaseous SO₂ that functions as a catalyst for the pre-treatment process (Sendelius, 2005). The bagasse pre-treatment is carried out in a reactor, where steam with a pressure of 400 kPa is injected. A sudden system decompression is carried out and the slurry is collected in an expansion tank.
After this, comes the proper hydrolysis process using enzymes, where two types of sugar are produced: C6 (glucose) and C5 (non-glucose-xylose). It must be taken into account that conventional yeast can not ferment C5 sugars. Before the hydrolysis, the pH of the pretreated bagasse should be adjusted by the addition of sodium hydroxide.

For sugars fermentation, two technologies are considered: the simultaneous saccharification and fermentation (SSF) and the simultaneous saccharification and co-fermentation (SSCF). In the case of the SSF hydrolysis (Table 1), only the fermentation of C6 sugars is considered. It is assumed that conventional *Saccharomyces cerevisiae* yeasts are used and that these are produced *in situ*, while enzymes are acquired from specialised suppliers.

In the case of SSCF hydrolysis, it is assumed that the yeasts used are genetically modified and they are capable of fermenting both C6 and C5 sugars (Table 1). However, presently, these yeasts do not reach yields shown in Table 1, and they are being used only in laboratory scale (Öhgren, *et al.*, 2006).

<sup>a</sup> Macedo, 2008.
<sup>b</sup> Sendelius, 2005. FPU (Filter Paper Units)
<sup>c</sup> Hamelinck *et al.*, 2005.
<sup>d</sup> The required power for different process stages was estimated according to Wooley *et al.* (1999).

In the hydrolysis stage, 96.3% of the cellulose is recovered. A performance of bioethanol production of 76.89% of the theoretical value is assumed to be achieved starting from glucose (Sendelius, 2005).

The bioethanol is concentrated up to 92.5% on a distillation stage that consists of two columns, the first being an exhaustion column, and the second a rectification one, and operating on different pressures. After this, the bioethanol is concentrated up to 99.5% of purity through a molecular sieve process. A scrubber is used to minimise the bioethanol losses with the CO<sub>2</sub> vent from fermentation.
From the bottom of the rectification column, the co-products of the distillation stage mixed with the residual lignin are recovered. Lignin is separated by centrifugation and dried in a steam dryer up to moisture of 48%, before being supplied to the boiler, to be used as fuel for cogeneration.

The recovered lignin is burned in a boiler that produces 127.08 t/h of steam for electricity production in steam turbines. The isentropic efficiency of the turbine was assumed to be 0.85, while the generator efficiency was 0.925. The lignin low heating value (LHV) in dry basis was considered to be 17.5 MJ/kg (Bensen et al., 2006).

Thermochemical platform

Process description

In Figure 2, the general outline of the evaluated process is shown. For this case study, a pressurised bubbling fluidised bed gasifier, that uses a mixture of oxygen and steam as the gasification agent, was chosen. In Table 2, the main gasifier parameters are shown (Tijmensen, 2000).

Once the cane bagasse arrives at the plant with moisture of 50%, it is necessary to dry it until it reaches the specifications requested by the gasification process, about 20% (Tijmensen, 2000).

*Hamelinck and Faaij, 2001*

The gas produced contains tar, dust, alkalis and halogens that can affect the catalysts used in downstream processes. Particles removal from the gas is carried out using cyclones, fabric filters and scrubbers. A HRSG (heat recovery steam generator) is used for gas cooling.

The gas produced has a considerable amount of methane and other light hydrocarbons. A steam reforming stage is included to maximise the concentration of CO and H\textsubscript{2} by the conversion of CH\textsubscript{4} and C\textsubscript{2}H\textsubscript{6}. The H\textsubscript{2}/CO relation of the syngas is adjusted through the gas-water shift reaction (WGS). The synthesis gas passes through a CO\textsubscript{2} removal stage and enters the reactor of methanol synthesis. Finally, the raw gas obtained from the synthesis goes through a purification stage to obtain the biomethanol with the necessary purity (Ohlström, et al., 2001).

The total capital investment, or TCI, is calculated using an estimated scale factor based on known costs for major equipment as found in literature and/or given by experts (Tables 4 and 5). Operational costs (maintenance, labour, consumables, residual streams disposal) are taken as a single overall percentage (4%) of the total investment.

Techno-economic performance

For the ethanol production plant using SSF and SSCF enzymatic hydrolysis, the enzyme costs represent 66 and 70% of the total biofuel production costs, respectively. The costs of the cane bagasse, investment, M&O (maintenance and operation) and electricity commercialisation revenues, represented 21 and 17%; 17 and 15%; 3 and 3%; –7 and -6%, respectively. The electricity generated in co-generation systems has negative revenue, which results in biofuels production cost decrease.

Out of the sensitivity analysis, when varying the enzyme costs ±55%, a sharp reduction is observed in the production cost of bioethanol down to 0.48 US$/L. Other parameter variations do not affect the production costs significantly (Figure 3).

Fig. 3—Sensitivity analysis of the bioethanol SSF enzymatic hydrolysis.
The behaviour of the production costs for the SSCF case is very similar to SSF. A reduction of 55% in the cost of the enzymes results in an ethanol production cost of 0.314 US$/L. Significant changes in the production costs are not observed for variations in the other economical parameters.

Although the bioethanol production cost through SSF technology is larger than the production cost by the SSCF method (0.48 and 0.45 US$/L of bioethanol, respectively), these costs are still are very high when compared with the costs of ethanol starting from sugarcane juice and from corn, as shown in Figure 4.

The cost of the enzymes used in this work was taken from information published in the news section of the Ministry of External Relations of Brazil related to NovoEnzymes data (0.32 US$/L bioethanol). The enzyme manufacturing companies are focused on reducing these prices by several times, which would make the process profitable (Ministry of External Relations of Brazil, 2008).

The biofuel production cost was calculated for different scenarios, as presented in Figure 5. Scenario 2 corresponds to the more optimistic one, with an enzyme cost of 0.05 US$ per litre of produced bioethanol (Novozymes, 2008; Bon, 2007). Scenario 1 is more pessimistic with a cost of 2 US$/L bioethanol (Bon, 2007). Scenario 3 was the one considered in this research.

![Fig. 4—Comparison of ethanol production costs from bioethanol starting from enzymatic hydrolysis (SSCF and SSF) and the conventional processes from sugarcane and corn.](image1)

![Fig. 5—Comparison of the costs of the bioethanol produced from enzymatic hydrolysis for different scenarios.](image2)
Different from the case of the biochemical platform, in the thermochemical one the largest percentage of the biofuel production cost corresponds to investment with 65%, followed by the fixed costs of M&O, cost of sugarcane bagasse and electricity commercialisation revenues with 22%, 18% and –4%, respectively.

Making a sensitivity analysis, varying the costs ±55%, it is observed that the production cost is strongly influenced by the investment and, consequently, for the fixed costs of M&O. The fluctuation of the bagasse costs between –55 and +55% leads to biomethanol costs of 0.23 and 0.27 US$/LMeOH, respectively, as shown in Figure 6.

![Fig. 6—Sensitivity analysis of the biomethanol production costs starting from biomass gasification.](image)

In Figure 7, the cost of production of the methanol obtained from biomass is shown compared with the production cost starting from natural gas. It is observed that the production cost of methanol obtained through the first technology is greater than the second one with 0.25 US$/L and 0.11 US$/L, respectively.

![Fig. 7—Methanol production costs when using biomass and natural gas as feedstock.](image)
Seeking the comparison of the biochemical and thermochemical routes, as is shown in Figure 8, the biofuel production cost in US$/GJ\text{HHV}. It is observed that, in spite of the total investment cost of the biomethanol plant being much higher than for the bioethanol plants, the cost of production of the bioethanol starting from the enzymatic hydrolysis is higher than the cost of production of the biomethanol This is due mainly to the high annual total costs involved in the biochemical platform.

![Figure 8](image)

Fig. 8—Total investment costs (bars, left axis) and biofuels production cost (points, right axis) for the biochemical and thermochemical platforms for obtaining second generation biofuels.

A similar behaviour is observed when the biofuel production for plant capacity of 400 MW\text{th} and the production costs are compared (Figure 9).

![Figure 9](image)

Fig. 9—Annual total production (bars, left axis) and second generation biofuels production cost (points, right axis) for the biochemical and thermochemical platforms.
Another scenario comes when the most optimistic case for the biochemical platform is considered. In this case, it is possible to reach ethanol production costs greater than biomethanol ones, that are 13.68 and 11.73 US$/GJ respectively, as shown in Figure 10.

It is also observed that, for the more optimistic scenario of the biochemical platform, the ethanol production cost becomes competitive when compared with the production costs of the sugarcane juice ethanol.

Considering the process energy efficiency (GJ product / GJ required), the biomethanol production starting from biomass presents a greater value, of 45.3%, than ethanol production through enzymatic hydrolysis types, both SSCF and SSF, that have an efficiency of 34.08 and 25.78%, respectively. It should be pointed out that energy efficiencies were calculated taking into account only the energy content of biofuel.

The estimated efficiencies in this study don't differ too much from efficiencies found in the literature. According to Hamelinck et al. (2005), for the process of ethanol production starting from enzymatic hydrolysis, the efficiency varies in the range from 30 to 40%. For the biomethanol process starting from biomass gasification, they are around 50% (Hamelinck and Faaij, 2001; Cardenas, 2006).

Discussion and conclusions

Production costs of 22.7 and 21.32 US$/GJ_{ETOH} were obtained from the economic analysis of the processes of ethanol production through SSF and SSCF enzymatic hydrolysis, respectively. These costs are not competitive when compared with the costs of the conventional processes for ethanol production starting from sugarcane juice and corn.

The high current production costs that characterise the biochemical route are strongly influenced by the costs of the enzymes (0.32US$/L_{ETOH}), that represent from 66 to 70% of the annual total costs. The implementation of the enzymes production ‘in situ’ could reduce costs, and lead to the economical feasibility of the process.
A reduction of the enzyme costs down to 0.05 US$/L$_{ETOH}$ would make the lignocellulosic ethanol production process competitive when compared with the conventional routes of ethanol production. Besides, it would lead to lower production costs than in the case of the thermochemical platform.

For the thermochemical platform, the estimated methanol production cost is 15.82 US$/GJ$_{MeOH}$, significantly less than for the biochemical platform. However, the cost of production of the methanol from biomass is higher than from natural gas (6.96 US$/GJ$_{MeOH}$).

Bagasse de Anne à Sucre, Procédé Biochimique, Procédé Thermochemique.

Résumé

L'OBJECTIF PRINCIPAL de cette communication est de comparer les itinéraires biochimique et thermochemique pour la production de biocarburants de deuxième génération à l'aide des indicateurs deficiencies et d’ordre économique. Dans les deux cas, la matière première utilisée est la bagasse de canne à sucre. Les prévisions ont été effectuées pour une usine de biocarburants ayant une consommation de bagasse de canne à sucre de 1772 tonnes jour⁻¹ en matière sèche, équivalent à 400 MW d'énergie thermique. L'utilisation de sous-produits, comme la lignine dans la voie biochimique et de la bagasse de canne à sucre pour attendre l’auto suffisance en vapeur et en électricité par cogénération ont été également prise en considération. Le coût élevé de production de bioéthanol obtenu par le procédé biochimique (US $ 21.32 à 22,7/GJETOH) est fortement influencé par le coût élevé de l'enzyme. Le coût de production de biométhanol par la procédé thermochemique (15.82 $ US/GJMeOH) est principalement influencé par le coût élevé des équipements.
INDICADORES TÉCNICO-ECONÓMICOS PARA LAS VÍAS TERMOQUÍMICA Y BIQUÍMICA PARA LA PRODUCCIÓN DE BIOCOMBUSTIBLES, EMPLEANDO BAGAZO DE LA CANA DE AZÚCAR COMO MATERIA PRIMA

PALABRAS CLAVE: Biocombustibles de Segunda Generación, Bagazo de Caña de Azúcar, Vía Bioquímica, Vía Termoquímica.

Resumen

El principal objetivo de este trabajo es comparar las vías bioquímica y termoquímica en el comportamiento de la producción de biocombustibles de segunda generación, empleando indicadores económicos y de eficiencia. En ambos casos a partir de bagazo. Los cálculos se realizaron para una planta de biocombustible con un consumo de bagazo de 1772 t/día base seca, equivalente a 400 MW de energía térmica. Se consideró, así mismo, el empleo de subproductos tales como la lignina en la vía bioquímica y el bagazo para la autosuficiencia de vapor y electricidad a través de la cogeneración. El alto costo de producción del etanol obtenido por la vía bioquímica (21.32 a 22.7 US$/GJ etoh) está influido por el costo de la enzima. El costo de producción del biometanol por la vía termoquímica (15.82 US$/GJ meoh) está influido por el elevado costo del equipamiento.
THE BIOLOGICAL UTILISATION OF BAGASSE: A SOUTH AFRICAN PERSPECTIVE

By

S.N. WALFORD
Sugar Milling Research Institute, c/o University of KwaZulu-Natal, Durban, South Africa
swalford@smri.org

KEYWORDS: Bagasse, Collaborative Research, Enzymatic Ethanol, Economic Drivers.

Abstract

In the early 1980s, the Sugar Milling Research Institute was part of a national collaborative program entitled ‘The Biological Utilisation of Bagasse’. The aim was to develop and evaluate the expertise and technology required to provide biomass fermentation substrates (specifically from sugarcane bagasse) for ethanol, single cell protein and other industrial products. A number of processes were successfully developed on a pilot scale including acid hydrolysis, direct fermentation of the hydrolysate, production of single cell protein, hydrolysed fibre preparation for enzymatic hydrolysis using attritor milling and the production of very high activity cellulase. The processes were developed on a sufficiently large scale to allow for economic evaluation. Given the current interest in cellulosic fuels, the proposed use of sugarcane biomass feedstock for value-added addition and the possibility of sustaining ailing sugar industries, this paper highlights the processes that made the program successful, compares the historical and current economic and technical drives and comments on some current thinking in this field.

Introduction

In the early 1980s, the Sugar Milling Research Institute (SMRI) was part of a national collaborative research program entitled ‘The Biological Utilisation of Bagasse’.

The aim of this program was to develop and evaluate the expertise and technology required to provide biomass fermentation substrates (specifically from sugarcane bagasse) for the production of ethanol, single cell protein and other industrial products.

This paper serves to highlight the diverse socio-, economic and technological drivers of that period that impacted on the program, explain the program and the outcomes achieved, reasons for its success and finally draws parallels to current drivers.

Economic drivers

During the 1970s, the world economy was stressed by two oil crises: in 1973, when Middle Eastern oil producing nations proclaimed an oil embargo in response to the U.S. decision to re-supply the Israeli military during the Yom Kippur war; and in 1979, in the wake of the Iranian Revolution.

Crude oil prices went as high as $100 / barrel (expressed in 2009 dollars) (Figure 1). The major producers of the time were the United States, Russia, Saudi Arabia and Iran.

The South African economy was, in addition to the international crude oil crises, being challenged by the start of selected economic sanctions.

Most of the country’s crude oil was being sourced from Iran until the fall of the Shah in 1978.
In 1955, a South African company called South African Synthetic Oil Limited (SASOL) started producing petrol, liquefied petroleum gas and other chemicals from coal using the Fischer-Tropsch process at Sasolburg (Collings, 2007).

Together with Total SA and the National Iranian Oil Company, a refinery (NATREF) was established in 1967 based on Iranian crude. Because of the 1973 oil crises, a second oil-from-coal complex was established (SASOL II), coming on-line in 1980. As a consequence of the Iranian Revolution and drying up of supplies from that country, a third SASOL complex was built adjacent to the SASOL II complex, coming on stream in the mid 1980s.

The three plants supplied approximately half of the country’s liquid fuel requirements at the time. (This has declined over time as Sasol currently supplies approximately 36% of the country’s fuel requirements (Anon., 2009a)).

Technological drivers

The 1970s witnessed an upsurge in technological advances that aided scientists. Examples include the adoption of liquid chromatography as a routine analytical technique due to advances in instruments and column packing material synthesis. These advances had a direct effect on the biological sciences with advances in molecular biology, bacteriology and genetics laying the foundations for the modern forms of these disciplines.

In 1973, Stanley Cohen and Herbert Boyer pioneered the techniques to create recombinant DNA (Anon, 2009b). This technology became the beginning of the biotechnology industry. Genetech was founded in 1976 with the aim to produce materials from the emerging technology. This set the stage for the investigation and use of biotechnology in the lignocellulosic field.

The program and its outcomes

During the 1970s, the Council for Scientific and Industrial Research (CSIR) funded stand-alone research at a number of different centres into the utilisation of lignocelluloses. In 1979, this research was consolidated into a goal-orientated, cooperative program to focus the effort on a single
lignocellulosic material, to produce a single product and a single conversion process. The goal of the program was the development of a technically and commercially viable process to convert bagasse to ethanol (Paterson-Jones, 1989). Liquid fuel production was perceived as important at the time due to the drivers already mentioned.

Although several lignocellulosic resources were potentially available, bagasse was chosen because it was already being collected at a central location (the mill), it could be produced in excess of the mill’s energy requirements and the mill could provide an established industrial infrastructure for a bagasse processing plant. Ethanol was chosen as the preferred end product because it had potential for use as both a liquid fuel and as a chemical feedstock. An enzymatic saccharification process for cellulose hydrolysis cellulose was chosen because it held the promise of providing a high yield under mild conditions. It was also viewed that the enzyme process held the potential for improvement through research. The sponsors accepted that the program was a high risk venture but that it held potential benefits to South Africa. These included the development of a process which could be applied to other lignocellulosic wastes (with minor modifications) and produce a range of products including ethanol.

Eleven institutions throughout South Africa collaborated in the program. A total of fourteen research groups with a range of expertise in enzymology, microbiology, genetics and engineering were involved over the nine year period (Anon, 1989). The program was managed with a coordinator at both the scientific and administrative level and made extensive use of a steering committee. SMRI played a pivotal role as a contact point between the researchers in the program and the sugar industry. The Institute also hosted and was responsible for running the process development unit that ran for more than two years. The results from the development unit were used for subsequent economic modelling.

The program achieved successful outcomes in both the technical and human capital development arenas. Technically these included:

- The development of an acid-based extraction and hydrolysis of hemicellulose to xylose and other monomeric sugars using dilute acid.
- Direct fermentation to alcohol of the sugars in the hemicellulose hydrolysate.
- Production of single cell protein from the hemicellulose hydrolysate.
- Treatment of acid-extracted bagasse by attritor milling.
- Simultaneous enzymatic hydrolysis of the cellulose in acid-extracted, attritor milled bagasse and its fermentation to ethanol.
- Production of very high activity cellulase enzyme (57 IU/mL).

Human capital development within the program was evidenced by the awarding of 13 MScs, 5 PhDs, 47 papers in international peer reviewed journals, 33 conference papers and local expertise developed in fermentation research and technology and associated fields.

During the course of the program (1979 to 1987), a number of significant changes occurred within the drivers which had been present at the beginning of the program. The most significant globally was the decline in crude oil prices back to levels approaching the early 1970s (Figure 1).

The second significant change within the South African context was the coming on-line of the SASOL II and III plants (Collings, 2007). A by-product of the synthesis processes being used at that time was ethanol, which directly affected the potential development of a fuel alcohol industry. Throughout the duration of the program, the economic potential of not only ethanol but other products was investigated as the economic background changed. Potential products investigated included acetone, n-butanol, acetic acid, butane-2,3-diol, xylose, furfural, butadiene, sugar alcohols (mannitol, xylitol, etc), organic acids (citric, tartaric, lactic, etc) and amino acids.
Based on the processes developed and optimised using the process development plant, an economic evaluation showed that (Purchase, 1989):

- the production of ethanol from enzymic hydrolysed bagasse was not economically promising due to the high cost of enzyme;
- the production of single cell protein from hemicellulose hydrolysate was possible;
- the production of ethanol from hemicellulose hydrolysate was marginal.

**Parallels to the present and future potential**

On an international scale, some of the current economic drivers have parallels to those that were present in the late 1970s in South Africa and have to be considered when reviewing participation in renewable cellulosic feedstock research and developing related economic models. These include the fluctuating crude oil prices (such as the highs of 2008 which have subsequently declined in a similar fashion to the early 1980s (Figure 1)), the increasing supply of internationally traded fuel alcohol (particularly from Brazil which supplies more than 50% of global alcohol), the cost of finance (Tuxen, 2009) and the next step in the evolution of analytical instrumentation.

The sensitivity and types of instruments currently available provide the researcher with the ability to understand reactions and interactions at a molecular level which again promises to build a platform to make rapid progress in the enzyme field. However, although much progress has been reportedly achieved in enzyme efficiencies and reducing costs of production, enzyme costs are still considered to be inhibiting factors to the adoption of the technology (Tuxen, 2009).

In addition, a number of new economic drivers that were not present in the 1980s now have to be considered when venturing into renewable biomass research. These include global warming, land use change policies (Anon, 2009c), government policies relating to carbon credits and carbon tax (Winkler and Marquard, 2009), the United States Renewable Fuel Standard Program (Anon, 2009d) and similar programs which may include subsidies (Askew, 2003; Tuxen, 2009). The inclusion of these drivers in economic models for renewable energy makes long-term forecasting more difficult than 25 years ago.

From a sugar industry perspective, the use of sugarcane as a biomass source has many advantages including the plant being one of the most efficient utilisers of the sun’s energy and collection of the biomass at central locations. These advantages often encourage a perception among researchers outside the industry to view bagasse as an almost limitless resource freely available for enzymic conversion to fuel alcohol. Sugar mills are generally not energy efficient but rather energy sufficient: the energy produced from bagasse matches the desired configuration and operation of the plant and any other ancillary factories.

Large quantities of the raw material are therefore not necessarily available. Purchase and Wienese (2004) reviewed co-generation using bagasse and fuel alcohol from molasses, sugar and biomass hydrolysis. The authors estimated that, in the South African context, about one third of all bagasse is available for cellulosic ethanol production. This would contribute less than 1% of the current annual fuel requirements of the country (Anon, 2009a). It was concluded that the use of bagasse for co-generation is a better option than ethanol from cellulosic hydrolysis.

**Conclusion**

The biological utilisation of bagasse program was successful in both its technological and socio-economic outputs even though it did not create a new industry. There are lessons that can be learnt for any consortium planning an integrated approach to research.

The success was founded in well defined, achievable goals and appointing one leader responsible for co-ordination and overseeing the whole project. The outputs of the research were continually tested against the economic drivers within the context of the overall program goals.
Although there are many parallels between the current divers and those present in the 1980s, additional policies now make biomass derived renewable energy economically attractive. However, the widespread adoption of cellulosic enzymatically derived biofuels from sugarcane bagasse still has many barriers to overcome when compared to adoption of co-generation.

Résumé

AU DÉBUT des années 1980, le Sugar Milling Research Institute faisait partie d'un programme de collaboration national intitulé "L'utilisation Biologique de la Bagasse". L'objectif était de développer et d'évaluer l'expertise et la technologie nécessaires pour fournir des substrats de fermentation de biomasse (plus précisément à partir de la bagasse de cannes à sucre) pour la production d'éthanol, la protéine unicellulaire et d'autres produits industriels. Un certain nombre de procédés ont été développés avec succès à l'échelle pilote, y compris l'hydrolyse en milieu acide, la fermentation directe de l'hydrolysat, la production de protéines unicellulaires, la préparation de la fibre par l'hydrolyse enzymatique à l'aide d'un défibreur et de la production de cellulase à très forte activité. Les procédés ont été développés sur une échelle suffisamment grande pour permettre une évaluation économique. Compte tenu de l'intérêt actuel pour des combustibles à base de cellulose, l'utilisation proposée de la biomasse de la canne à sucre pour des produits à forte valeur ajoutée et la possibilité de venir en aide à des industries sucrières en difficulté, cette communication met en exergue les procédés qui ont fait le succès du programme, fait la comparaison entre les aspects historiques et courants des motivations économiques et techniques et offre des commentaires sur la reflexion actuelle dans ce domaine.

LA UTILIZACIÓN BIOLÓGICA DEL BAGAZO: UNA PERSPECTIVA SURAFRICANA

Resumen

A INICIOS de los 1980s, el Sugar Milling Research Institute era parte de un programa nacional colaborativo denominado ‘La utilización biológica del Bagazo’. El objetivo era desarrollar y evaluar el nivel de especialización y la tecnología requerida para proveer un sustrato fermentable basado en biomasa (específicamente a partir de bagazo de caña de azúcar) para etanol, proteína unicelular y otros productos industriales. Se desarrollaron exitosamente un grupo de procesos a escala piloto, incluyendo hidrólisis ácida, fermentación directa de los hidrolizados, producción de proteína unicelular, preparados de fibras hidrolizadas para la hidrólisis enzimática empleando molinos de atrición y la producción de una celulasa muy activa...los procesos se desarrollaron a una escala suficientemente grande que permitía su evaluación económica. En razón del actual interés en combustibles celulósicos, la propuesta de empleo de alimentos de la biomasa de la caña de azúcar para generar valor agregado y la posibilidad de una industria azucarera sostenible, este trabajo destaca los procesos que hicieron exitoso el programa, compara los promotores económicos históricos y actuales, así como los tecnológicos y comenta sobre algunas consideraciones actuales en este campo.

KEYWORDS: Lignolytic Fungi and Bacteria, Biotechnological Production of Cellulose, Sugarcane Bagasse.

Abstract

Actual chemical processes able to obtain cellulose from sugarcane bagasse are very toxic and pollutant. The objective of this work was to find native microorganisms able to delignify bagasse helping to raise its cellulose content, without affecting actual fibres, in order to obtain higher quality paper. Advantages of biological delignification compared to chemical methods are: softer reaction conditions, higher product yields and less energy consumption. Another advantage is the improvement in the paper’s mechanical properties such as tensile strength. For isolation and identification of the microorganisms, such as bacteria and fungi, sugarcane bagasse was used as the only substrate, which was obtained from a Mexican sugar mill. The plate dilution and enrichment culture techniques were applied. Six native strains of fungi and four of bacteria have been isolated, some of them with potential capacity to degrade the lignin which is due to lignolytic extracellular enzyme production, yielding laccases and peroxidases. Obtained results indicate that biotechnological lignin degradation is possible using native microorganisms from sugarcane bagasse thus eliminating chemical processes. The biological delignification of the sugarcane bagasse for obtaining cellulose could be considered as a sustainable process not only because of the recycling of this by-product but also because it is environmentally friendly.

Introduction

Sugarcane bagasse is a by-product of the sugar industry consisting principally of cellulose, hemicellulose and lignin. It is the fibrous residue of sugarcane after the juice has been extracted. In Mexico, more than 95% of the bagasse is used by the sugar factories as fuel for the boilers. In recent years, alternative and more profitable uses of bagasse are being investigated.

Bagasse has been used for the production of enzymes, amino acids, drugs, ethanol, and single-cell protein as animal feed after treating it with a large variety of microorganisms including bacteria, yeasts, and fungi, among which Basidiomycetes are preferred (Eriksson, 1990). However, such bio-processes require only small quantities of substrate and would not utilise all available bagasse (Xin et al., 2002).

Due to increasing restraints on forest harvesting, the use of agro-based residues for pulp and paper production has been steadily increasing in recent years (Bustamante et al., 1999). The sugarcane bagasse is a biomass that can be used as raw material for pulp and paper production, which in turn yields new paper, dissolvable pulp and cellulose-based filter paper for soft drinks and other liquids (Valdes, 2007).
Lignin is the most abundant renewable source of aromatic polymers in nature, and its degradation is therefore of general significance for the global carbon cycle. It is chemically recalcitrant to breakdown by most organisms because of the complex, heterogeneous structure. The most efficient and most investigated lignin-degrading microorganisms are the wood-decaying Basidiomycetes causing white-rot. They contain the extracellular oxidative enzymes laccases and peroxidases (Gao et al., 1997).

The major groups of lignolytic enzymes include lignin peroxidases, manganese peroxidases, versatile peroxidases, and laccases. The peroxidases are heme-containing enzymes with catalytic cycles that involve the activation by H₂O₂ and substrate reduction of compound I and compound II intermediates. Lignin peroxidases have the unique ability to catalyse oxidative cleavage of C–C bonds and ether (C–O–C) bonds in non-phenolic aromatic substrates of high redox potential. Manganese peroxidases oxidise Mn(II) to Mn(III), which facilitates the degradation of phenolic compounds or, in turn, oxidises a second mediator for the breakdown of non-phenolic compounds. Versatile peroxidases are hybrids of lignin peroxidase and manganese peroxidase with a bifunctional characteristic. Laccases are multi-copper-containing proteins that catalyse the oxidation of phenolic substrates with concomitant reduction of molecular oxygen to water (Wong, 2009).

Breccia et al. (1997) screened several white-rot fungi to degrade long-fibre bagasse aiming at bio-pulping and found that about 16% of the lignin was removed. Biological pulping has the potential to reduce energy costs and environmental impact compared to traditional pulping operations (Breen and Singleton, 1999).

The objective of this work was isolating and identifying the strains of native microorganisms which assist in delignifying bagasse and as a result raise its cellulose content. The enrichment culturing technique was used. Thus, cellulose would become a by-product of the cane sugar industry. The present study describes a simple system for isolating and screening of microorganisms, either fungi or bacteria, which have lignolytic activities.

Materials and methods

Sample source

The sugarcane bagasse samples were provided by Ingenio San José de Abajo, from Veracruz, México.

Culture media

- Saline medium for enrichment cultures. Composition in g/L: KNO₃ 1.0; FeCl₃ 0.02; MgSO₄ 0.2; NaCl 0.1; CaCl₂ 0.1; K₂HPO₄ 1.0 and yeast extract 0.05. The pH of the medium was adjusted to 6.3 with a 0.1 N HCl solution.
- Saline Agar. This medium contains the same components as the saline medium, but is complemented with 1.5% (w/v) bacteriological agar. The pH of the medium was also adjusted to 6.3 with a 0.1 N HCl solution.
- Malt Extract Agar. Malt extract Agar (Difco). Sabouraud Dextrose Agar (BD Bioxon), and Nutritive Agar (BD Bioxon).

Microorganisms isolation

The isolation of the microorganisms, bacteria as well as fungi, was done from sugarcane bagasse applying enrichment culturing.

Sugarcane bagasse was washed with water at 60°C in order to remove the sugar. It was used as the only substrate. Then, 1.0 g of this bagasse was added into a 250 mL Erlenmeyer flask which contained 125.0 mL of the saline medium. It was cultured by shaking for three days at 25°C and 180 rpm. After being incubated for three days, 12.0 mL of the supernatant was transferred to an Erlenmeyer flask of 250 mL containing 125 mL of fresh medium, which was cultured at the same above described conditions. This process was repeated three times.
Isolation and identification of microorganisms

After three transfers, 0.1 mL of sample from the recuperated medium was spread on saline agar plates and incubated at 26°C for 24 hours. For isolation, the obtained colonies were inoculated on to nutritive agar plates if they were bacteria or on malt extract agar and Sabouraud dextrose agar if they were fungi. The plates were incubated for another 24 h at 35°C and for 72 h at 26°C, respectively.

The fungi were primarily identified based on their characteristics of colonial morphology and structure. For the structure identification, a micro-culture from each isolated colony was prepared, which was incubated at 26°C until sporulation. Final fungi identification was done after staining with lactophenol-cotton blue and observation under the microscope. Photos were taken.

Bacteria could be identified based on their colonial morphology and biological characteristics, and physiological and biochemical tests including Gram reaction (Buchanan and Gibbons, 1974).

Results

The results show ten strains of microorganisms, which were obtained by the enrichment culture technique using sugarcane bagasse as the only source of carbon and energy. Of the ten strains isolated, six were fungi, which are named F-1 through F-6; the others were bacteria and are named B-1 through B-4. Figure 1 shows the macroscopic and microscopic characteristics of isolated fungi and their corresponding identification. The morphology and Gram reaction of the isolated bacteria are shown in Figure 2. Table 1 shows the physiological and biochemical characteristics of strains of isolated bacteria.

Conclusions

There are reports in the literature on several identified lignolytic fungi and bacteria suitable for biotechnological processes on bagasse permitting diversification of the sugar industry (Meza *et al*., 2006; Ramos *et al*., 2001; Viñals Verde *et al*., 2006; Xin *et al*., 2002).

In this study, six different native strains of fungi were isolated and identified: *Penicillium sp.* (two strains), *Fusarium sp.*, *Cladosporium sp.*, *Mucor sp.* and *Geotrichum sp.*; also four bacteria, all of the gender *Bacillus*. The production of lignolytic enzymes by these microorganisms will be tested later with liquid cultures.

It is also intended continuing this work to isolate fungi of the *Basidiomycetes* group, which are reported as having higher lignolytic capacity.

MOTS-CLÉS: Champignons et Bactéries Lignolytiques, Production Biotechnologique de Cellulose, Bagasses de la Canne à Sucre, Canne à Sucre.

Résumé

Les processus chimiques courants, capables d'obtenir la cellulose à partir de la bagasse de canne à sucre sont très toxiques et polluants. L'objectif de ce travail était de trouver des micro-organismes natifs capables de delignify bagasse contribuant à augmenter son contenu de cellulose, sans affecter les fibres réelles, afin d'obtenir des papiers de qualité supérieure. Les avantages de la délignification biologique par rapport aux méthodes chimiques sont : conditions de réaction plus douces, hausse des rendements de produit et moins de consommation d'énergie. Un avantage supplémentaire est l'amélioration des propriétés mécaniques du papier telle que la traction. Pour l'isolement et identification des micro-organismes, comme les bactéries et champignons, seule la bagasse de canne à sucre a été utilisée comme unique substrat, obtenu à partir d'une sucrerie mexicaine. Les techniques de culture de dilution et d'enrichissement de plaque ont été appliquées. Six souches de champignons et quatre de bactéries à l’état naturel ont été isolées, certaines d'entre elles avec une capacité potentielle de dégrader la lignine de la cellulose qui est due à la production d'enzymes extracellulaires lignolytiques, produisant des laccases et peroxidases. Les résultats obtenus indiquent que la dégradation de la lignine par biotechnologie est possible à l'aide de micro-organismes trouvés de la bagasse de canne à sucre éliminant ainsi les processus chimiques. La délignification biologique de la bagasse de canne à sucre pour l'obtention de cellulose pourrait être considérée comme un processus durable non seulement en raison du recyclage de ce sous-produit mais aussi parce qu'il est plus respectueux de l'environnement.
AISLAR Y SELECCIONAR MICROORGANISMOS PARA OBTENER CELULOSA SOSTENIBLE

PALABRAS CLAVE: Hongos y Bacterias Lignolíticas,
Producción Biotecnológica de Celulosa,
Bagazo de la Caña de Azúcar.

Resumen

Los procesos existentes capaces de obtener celulosa del bagazo de la caña de azúcar son muy tóxicos y contaminantes. El objetivo de este trabajo fue encontrar nativos microorganismos capaces de delignify bagazo ayudando a elevar su contenido de celulosa, sin que ello afecte a fibras reales, con el fin de obtener mayor papel de calidad. Las ventajas de la delignificación biológica en comparación con los métodos químicos son condiciones de reacción más suaves, mayores rendimientos de productos y menores consumos de energía. Otra ventaja es el mejoramiento de las propiedades mecánicas del papel, tales como la fuerza tensil. Para el aislamiento y el identificación de los microorganismos, tales como bacterias y hongos se empleó el bagazo de caña como único sustrato, el que se obtuvo de un Central mexicano. Se emplearon las técnicas de dilución en placas y de cultivos enriquecidos. Se aislaron seis (6) razas nativas de hongos y cuatro (4) de bacterias, algunas de ellas con capacidad de degradar la lignina a celulosa debido a la producción de una enzima lignolítica extracelular, rindiendo laca y peroxidasas; los resultados obtenidos indican que la degradación biotecnológica de la lignina es posible empleando microorganismos nativos del bagazo de la caña y así eliminar los procesos químicos. La delignificación biológica del bagazo de la caña de azúcar para obtener celulosa puede considerarse un proceso sostenible, no sólo por el reciclado de este coproducto, sino también porque es amigable con el medio ambiente.
A SOFTWARE FOR SIMULATION OF FERMENTATION PROCESSES

KEYWORDS: Fermentation Processes, Mathematical Modelling,
Ethanol Production, Software Simulation.

Abstract

Fermentation is a key process stage in ethanol production and has a high incidence in the overall process efficiency in distillery. For improving this efficiency, a rigorous analysis for defining the best choice in operation variables is needed. Simulation of the process is a recognised way for doing such an analysis. In this paper, the software tool FERMENTA® for simulation of fermentation processes is presented. This software tool allows simulation of continuous and discontinuous modes of fermentation. In the continuous mode of operation, several stages can be considered. In the batch mode, alternatives for feeding (batch, fed batch with different politics) can be analysed. The mathematical model includes non-stationary balances for biomass, substrate, ethanol, oxygen, energy. The kinetic expression can be selected by the user among more than 30 possibilities, taking or not into account inhibition factors in the process. Parameters in this equation can be estimated from experimental data. The result is a useful software tool that can be used for analysis of fermentation processes in industry and also for academic purposes. In this paper, the software is described and some case studies used for showing its possibilities.

Introduction

The technology of ethanol production by anaerobic fermentation of sugarcane molasses is well known. This process, used initially in the production of alcoholic drinks, reached high generalisation grade during the Second World War with the purpose of having an alternative source of fuel. Nowadays, ethanol with different purity grades is still produced from molasses and sugar juices. Their uses go from the pharmaceutical and cosmetics industry to the production of alcohol used as fuels by vehicles.

Keeping in mind the multiple uses of ethanol, there is an intensified interest in the study of all steps involved in ethanol production in order to reduce costs. Mathematical modelling reduces research costs by eliminating part of the experimental work, because it allows the study of process parameter interactions through simulation. Besides, it provides understanding of the process, which is helpful for operational policy definitions and can be applied for later optimisation and control.

In this paper, the mathematical model of alcohol fermentation process and FERMENTA 4.0 software, designed for simulating this process, is presented. This software could be useful in other fermentative processes because it reduces costs by eliminating part of the experimental work and allows the study of process parameter interactions through simulation.

Finally, we present a case study where the influence of some operational conditions on the yield and productivity of fermentation processes was assessed. We compare the simulation results with typical industrial data.
Process description

The conversion of sugar to ethanol is an anaerobic biological reaction by *Saccharomyces cerevisiae* yeast cells. This yeast is used commercially and classified as heterotrophics, the necessities of coal and energy are satisfied by monosaccharides (simple sugars) like glucose. Disaccharides like sucrose can also be used after the hydrolysis of the yeast in fructose and glucose (inverted sugar).

Raw materials used for ethanol production include sugary ones: juices of different fruits, beet juices, juices of cane sugar, intermediate streams of the process like molasses, etc. Sugarcane is a raw material of easy transformation and the agronomic aspects of cultivation do not present limitations, and has been cultivated for centuries. For this reason, it is the most economical raw material.

Ethanol production is divided into two phases: respiration (yeast propagation under aerobic conditions) and ethanol fermentation under anaerobic conditions. You can calculate the theoretical yield of glucose conversion to ethanol in the fermentation stage using the Gay Lussac equation, including an estimate of the heat evolved ($Q$) during the reaction.

**Respiration**

**Aerobic conditions**

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$$

**Anaerobic conditions**

Glucose $\rightarrow$ Carbon Dioxide + Ethanol

$$C_6H_{12}O_6 \rightarrow 2CO_2 + 2C_2H_5OH + Q$$

$$100 \text{ g} \quad \rightarrow \quad 49 \text{ g} \quad + \quad 51 \text{ g} \quad - \quad 23.7\text{Kcal}$$

Beginning with equation (2), the theoretical yields of ethanol and $CO_2$ can be calculated.

$$y_{\text{ethanol}} = 0.51 \quad \text{g ethanol/ g glucose}$$

$$y_{\text{CO}_2} = 0.49 \quad \text{g CO}_2 / \text{g glucose}$$

The real yields, however, are smaller because part of the glucose is used in the biomass generation and maintenance energy.

There are different operating fermentation modes. The first one is the batch mode where the fermenter is inoculated and fed with substrate until its working volume is reached and the process is carried out until the biotechnological conversion of sugars to ethanol finishes. Second one is the fed-batch mode with any number of feeding streams and the last is continuous fermentation, with continuous feed of fresh medium and continuous extraction of fermented medium; the fermentation can last stably for weeks and months.

**Mathematical modelling**

Mathematical models have been used to predict the influence of operating parameters on cell concentration, substrate utilisation rate and ethanol production rate (Sabadí *et al*., 1990, Rosso *et al*., 1995, Corsano *et al*., 2004, Rivera *et al*., 2006 and Ribas *et al*., 2006). These models may lead to the development of better strategies for the optimisation of the fermentation process to ensure its economic viability.

**Microbial growth**

The growth of microorganisms can be best imagined as the increase of cell material expressed in terms of mass (or cell numbers). It is the result of a highly coordinated series of
enzymatically catalysed biological steps. Optimal expression of growth kinetics depends on optimal maintenance of the transport of the necessary nutrients in the medium to cell surface, rate of mass transfer from the medium into the cells, and environmental parameters (such as temperature and pH).

In technical literature, different models describing the growth kinetics of cells are reported. The Monod (1942) model, based on Michaelis-Menten kinetics, describes the relationship between the specific growth rate ($\mu$) and the substrate concentration limit ($S$).

$$
\mu = \mu_{\text{max}} \frac{s}{k_s + s}
$$

where:
- $\mu$: specific cell growth rate ($h^{-1}$)
- $\mu_{\text{max}}$: maximum specific cell growth rate ($h^{-1}$)
- $k_s$: saturation parameter ($g/L$). Maximum substrate concentration that can use the cells for their growth. It is defined as the substrate concentration at half the maximum specific cell growth rate.
- $S$: Substrate concentration ($g/L$)

A high substrate concentration inhibits cell growth due to the effect of osmotic pressure. The model of Andrews (1968) takes this effect into consideration.

$$
\mu = \mu_{\text{max}} \frac{s}{k_s + s + \frac{s^2}{k_{is}}}
$$

$k_{is} > \left( \frac{s^2}{2k_s} \right)$: substrate inhibition parameter ($g/L$)

Microorganisms have a certain tolerance to the concentration of alcohol in the growth medium. Increasing alcohol concentration will gradually retard microbial growth and may finally completely inhibit it. This phenomenon is included in the Levenspiel (1980) model.

$$
\mu = \mu_{\text{max}} \frac{s}{k_s + s} \left( 1 - \frac{P}{P_{\text{max}}} \right)^n
$$

Parameter value $n \in [0.3; 2.0]$

Maiorella (1984) developed a model that describes the specific production rate of ethanol and biomass considering the yeast *Saccharomyces cerevisiae*, very often used in ethanol production.

$$
\mu_p = \left[ \mu_{p_{\text{max}}} \frac{s}{k_s + s} \right] \left[ 1 - \frac{P}{P_{\text{max}}} \right]^n
$$

where:
- $\mu_p$: Specific ethanol production rate. ($g$ ethanol/ g cell h)
- $\mu_{p_{\text{max}}}$: Maximum specific ethanol production rate. ($g$ ethanol/ g cell h)
- $K_s$: Saturation parameter. ($g/L$)
- $P_{\text{max}}$: Ethanol inhibition term. ($g/L$)

The specific cell growth rate can be calculated as:

$$
\mu = E \cdot \mu_p
$$
where:

\( E \): Efficiency in the use of sugar for the cells production. (g. cell / g sugar).

Wijtzes et al. (1993) and Ratkowsky et al. (1982) develop a model with environmental parameters such as temperature \( (T) \) and \( (pH) \).

\[
\mu_{\text{max}} = \mu_{\text{opt}} * f(pH) * g(T)
\]

\( \mu_{\text{opt}} \): Value of \( \mu_{\text{max}} \) under optimal conditions \( (pH_{\text{opt}}, T_{\text{opt}}) \).

In software FERMENTA 4.0, more than 30 kinetics growth models are implemented among which are the previous ones. These models are classified in four categories:

- Models without substrate inhibition.
- Models with substrate inhibition.
- Models with ethanol inhibition.
- Models with mixed inhibition.

A fermentation system, in a general way, can be represented schematically as Figure 1. Starting from here, it is possible to write the mass balance and determine how cells, substrate and ethanol concentrations change over time.

![Fig. 1— Schematic representation of ethanol fermentation system.](image)

Cell concentration \( (g / L) \)

\( S \): Substrate concentration \( (g / L) \)

\( P \): Ethanol Concentration \( (g / L) \)

\( V \): Fermentation Volume \( (L) \)

\( F \): Flow rate \( (L / h) \)

Indices: \( e \): input. \( s \): output

**Total balance**

The mass balance equation depends on operation mode. In batch fermentation, there are no inlet and outlet flows in the fermenter and the volume remains constant. In the case of a semi-continuous fermentation, an inlet flow exists to the fermenter that can be operated in different ways.

- Feeding flow for stages: The fermenter is partially fed until sugar is exhausted. It is fed again and so forth until the vessel is filled.
• Constant feeding flow.

\[ \frac{dV}{dt} = F \]  \hspace{2cm} (10) 

• Incremental feeding.

\[ \frac{dV}{dt} = F_0e^{kt} \hspace{0.5cm} k > 0 \]  \hspace{2cm} (11) 

\[ \frac{dV}{dt} = F_0e^{kt} \hspace{0.5cm} k < 0 \]  \hspace{2cm} (12)

Lastly, in continuous fermentation, there are inlet and outlet flows.

\[ \frac{dV}{dt} = F_e - F_s \]  \hspace{2cm} (13)

**Cell mass**

Keeping in mind the same considerations mentioned, a cell mass balance can be written as follows:

\[ \frac{d(xV)}{dt} = F_e x_e - F_s x_s + V(u-k_d)x \]  \hspace{2cm} (14)

\[ \mu : \text{ Specific growth rate (1/h)} \]

\[ k_d : \text{ Specific death rate (1/h)} \]

**Substrate**

A substrate mass balance can be written as follows:

\[ \frac{d(sV)}{dt} = F_e s_e - F_s s_s - V \left[ \frac{\mu x}{Y_{x/s}} + \frac{r_p}{Y_{p/s}} + mx \right] \]  \hspace{2cm} (15)

where:

\[ Y_{x/s} : \text{ Growth yield coefficient (g cells / g substrate).} \]

\[ Y_{p/s} : \text{ Product yield coefficient (g product formed / g substrate).} \]

\[ m : \text{ Maintenance coefficient (g substrate/g cells per h).} \]

\[ r_p = \frac{dp}{dt} \text{ Product formation rate.} \]

**Product formation**

The product may be obtained from the beginning of process fermentation, together with cell growth. It can also begin to be formed during the stationary phase or begin in the growth stage and
continue in the stationary phase. In dependence of this, the kinetics of product formation is defined like:

- Product associated with growth
  \[ r_p = Y_{p/x} \mu x = \alpha \mu x \]  
  \((16)\)
  
  \(Y_{p/x} = \alpha\): Product yield coefficient (g product formed / g cells)

- Product not associated with growth
  \[ r_p = \beta x \]  
  \((17)\)

- Product partially associated with growth
  \[ r_p = \alpha \mu x + \beta x \]  
  \((18)\)

\[
\frac{d(pV)}{dt} = F_e p_e - F_s p_s + V(r_p - k_{dp} p) 
\]  
\((19)\)

\(k_{dp}\): Specific product degraded rate \((1/h)\)

**Energy balance**

An energy balance for the fermentation process can be written as follows:

\[
\frac{dQ}{dt} = Q^E - Q^S + Q_g - Q_{transf}
\]  
\((20)\)

where:

- \(Q\): Heat accumulation rate. \((\text{Kcal/h})\)
- \(Q^E\): Total heat accumulated by the inlet flow until time \(t\). \((\text{Kcal})\)
- \(Q^S\): Total heat in outlet flow until time \(t\). \((\text{Kcal})\)
- \(Q_g\): Total heat evolved by the process during the reaction. \((\text{Kcal})\)
- \(Q_{transf}\): Heat transfer by the wall. \((\text{Kcal})\)

The set of coupled relationship equations 15, 16, 20 and 21, describing the fermentation kinetics, together with equations of microbial growth, was solved numerically by employing Runge Kutta method of five order with variable step (Dormand et al., 1980). This algorithm was included in FERMENTA 4.0 software.

**Software FERMENTA 4.0**

The software FERMENTA 4.0 has been designed and implemented to be used on Microsoft Windows platforms. It has a friendly user interface and a great variety of graphical reports. The main menu of the system is shown in Figure 2, representing the fermentation process according to the configuration analysed by the end user.

The system is configurable to simulate different types of fermentation (batch, fed-batch, continuous with tanks connected in series and recycling cells with one or two stages).

For simulating the process, it is necessary to input data related to the initial conditions and several parameters of yields previously adjusted if necessary to match given fermentation results.
In Figure 2, a simulation of an alcohol fermentation is shown, operated in batch mode with a fermenter capacity of 150 m³ and biomass recycle. The initial conditions of this fermentation are typical of most industrial alcohol fermentation.

- Initial substrate concentration 150 g/L
- Initial ethanol concentration 2.32 g/L
- Initial biomass concentration 1.43 g/L

The software also allows simulating the biomass recycle by the Mellé-Boinot batch process. To do this, it is necessary to give the information about the centrifuges used, number of nozzles and the efficiency (Figure 3).
The fundamental characteristics of most used centrifuges in the ethanol industry are in a database. The calculations are carried out to obtain yeast with 92% dry matter, considering the drying efficiency in the balance.

Another important step before the simulation is to select the kinetics growth equation (Figure 4). You can see the equation of the selected growth model.

In Figure 5, you can appreciate the kinetic behaviour of the fermentation. The results predict a fermentation time of 22 hours; in industrial alcohol fermentation, this parameter is estimated to be from 20 hours to 25 hours as mean. The concentration of substrate decreased from 150 g/L to less than 3 g/L. This value is very close to the final condition of many industrial alcohol fermentations. On the other hand, the ethanol concentration increased from 2.32 g/L to 62.5 g/L, which represents an ethanol content of wine equal to 8.06° GL. This parameter varies between 8°GL and 8.5° GL in real processes. The ethanol yields were 84.06% of the theoretical values and present a good productivity of 3.34 L/m³h.
The results of the yeast recovery scheme (Figure 6) indicate that a quantity of 4105.6 kg of yeast is produced by fermentation, recovering as product around 81%. The total power consumption of centrifuges was 8.7 HP.

![Batch fermentation results, table.](image)

**Fig. 6—Batch fermentation results, table.**

**Sensitivity analysis.**

With the help of FERMENTA 4.0 software, we decided to carry out an experimental factorial design with two controllable factors, the initial concentration of substrate ($S_0$) at three levels and the fermentation temperature ($T$) at two levels. The results are given in Table 1.

**Table 1—Sensitivity analysis results.**

The sensitivity analysis shows the effect of the initial concentration of substrate on the productivity of the fermentation. When the initial substrate concentration decreased from 150 g/L to 110 g/L, the process productivity (Prod.), the ethanol content of wine (Ethanol content) and the necessary area heat transfer ($A$) decreased, too.

The industrial fermentations are very sensitive to the variation of media composition, presenting a similar tendency to the one described by the simulation.
Conclusions

Dynamic models for simulation of fermentation processes were developed and implemented in FERMENTA 4.0 software, which includes different equations representing cell growth rate. They are sufficiently general and can be applied to different practical scenarios.

FERMENTA 4.0 software allows process engineers and managers to perform different analyses, in order to select the best alternatives to operate the fermentation process.

In the case study, the sensitivity analysis option allowed studying the effect of initial substrate concentration variations on the efficiency, productivity and final alcoholic grade, as well as the temperature of fermentation on the necessary area of heat exchange.

The simulation results agree closely with typical data obtained on an industrial scale.

Résumé
LA FERMENTATION est une étape clé dans la production d'éthanol et a une incidence élevée dans
l'efficacité du processus de la distillerie. Pour améliorer cette efficacité, une analyse rigoureuse
pour définir le meilleur choix dans les variables de l'opération est indispensable. La simulation du
processus est un moyen reconnu pour faire une telle analyse. Dans cette étude, le logiciel
FERMENTA ® pour la simulation des procédés de fermentation est présenté. Ce logiciel permet la
simulation des modes de fermentation continus et discontinus. Dans le mode de fonctionnement
continu, plusieurs étapes peuvent être considérées. Dans le mode de traitement discontinu, des
solutions alternatives d'alimentation peuvent être étudiées (batch, alimentation par batch selon
différents protocoles). Le modèle mathématique comporte des équilibres transitoires pour la
biomasse, le substrat, l'éthanol, l'oxygène et l'énergie. L'expression cinétique peut être sélectionnée
par l'utilisateur parmi plus de 30 possibilités, en prenant ou pas en compte les facteurs d'inhibition
dans le processus. Les paramètres dans cette équation peuvent être estimés à partir des données
expérimentales. Le résultat est un logiciel utile qui peut être utilisé pour l'analyse de processus de
fermentation de l'industrie et également à des fins académiques. Dans cette communication, le
logiciel est décrit et certaines études de cas utilisées pour démontrer ses possibilités.

Producción de Etanol, Software de Simulación.

Resumen

LA FERMENTACIÓN es la etapa clave en la producción de etanol y tiene una alta incidencia en la eficiencia total del proceso de la destilería. Para mejorar esta eficiencia se precisa un riguroso análisis para definir la mejor selección de las variables de operación. La simulación del proceso es una vía reconocida para realizar este análisis. En este trabajo se presenta la herramienta software FERMENTA® para simular el proceso de fermentación. Este software herramienta permite simular modos continuos y discontinuos de fermentación. En el modo continuo de operación se pueden considerar varias etapas. En el modo discontinuo se pueden analizar alternativas de alimentación (batch, batch incrementado con diferentes políticas). El modelo matemático incluye balances no-estacionarios para biomasa, sustrato, etanol, oxígeno, energía. La expresión cinética puede seleccionarse por el usuario entre más de 30 posibilidades, tomando ó no en cuenta factores inhibidores en el proceso. Los parámetros en esta ecuación pueden estimarse de los datos experimentales. El resultado es un útil ‘software herramienta’ que puede utilizarse para analizar el proceso de fermentación en la industria y también para propósitos académicos. En este artículo se describe el software y se emplean algunos estudios para mostrar sus posibilidades.
ECO-FRIENDLY COOKING GAS FROM SUGAR MILL WASTE

By
P. THANGAMUTHU
Karnataka Sugar Institute, NH4A, Belgaum-Khanapur Road, Zadshahpur, Belgaum–590 014, Karnataka, India
thangamuthu_p@yahoo.co.in

KEYWORDS: Filter Cake, Digester, Organic Matter, Methanisation, Biogas.

Abstract
IT WAS FOUND that biogas or cooking gas can be produced successfully from sugarcane filter cake. It contains a considerable amount of organic matter in the range of 73% to 77% including 1.8% to 3.0% sugar. After analysing the constituents of the filter cake and after finding its suitability, a laboratory scale study was conducted. As a result it was established that maximum biogas can be produced using filter cake as a feed stock when the concentration of its solids is 6% to 8%; beyond which the production rate decreases. It was also established that average biogas of 0.39 L/d was higher at 8% concentration than with other feed concentrations. After optimising the results, a pilot scale study was conducted during which it was established that the filter cake gives a biogas production of 65% to 75% instead of 50%–52% in the case of cow dung which requires 1:1 dilution to make a slurry for feeding. The filter cake requires 1:1.25 dilution as it contains 26% to 32% dry matter. Recommendations for biogas plant selection and installation are given. The increase in fertiliser value of digested filter cake, power generation, indirect way of helping afforestation, and environmental protection are discussed.

Introduction
About half of the world’s population depends on fire wood for cooking purposes. Water-containing materials from plants and animals contribute to bio-fuels. Such materials should be utilised to keep pace with the growth of biomass, since excessive cutting of woods leads to deforestation and also direct combustion leads to excessive smoke causing air pollution. The gasification is done in two ways. The first is by bio-degradation in which a large amount of biogas is obtained.

The second is thermo-chemical conversion or pyrolysis which yields producer gas comprising carbon monoxide and hydrogen (CO, H₂). The development and utilisation of renewable sources of energy along with conventional sources is essential to meet the growing demand for energy in the world. In particular, among the non-conventional energy sources is ‘biogas’.

In India there are about 500 working sugar mills, crushing about 300 million tonnes of sugarcane, producing about 12 million tonnes of filter cake which is one of the by-products of the sugar industry. This filter cake is being used as fertiliser in and around the sugar mill areas. In some factories, the cane growers do not want to use it as a manure. In such areas it is a great problem for the sugar mills to dispose of the filter cake.

The factory has to spend a large amount for the disposal by engaging lorries or tractors. If it is dumped on public lands, it will affect the environment and the surrounding village people may object to it. If it is not removed from the filter cake yard, the accumulation may sometimes affect the rate of crushing or will lead to stoppage of crushing if the area required for storage is insufficient. If the filter cake produced is not taken by cane growers, the factory has to spend extra money for the disposal and thereby increases the cost of production. In each sugar mill, a canteen is
provided for the employees. The canteen will run around the clock during the crushing season. In the off-season also the canteen has to operate for the preparation of meals, ‘tiffin’, tea, coffee etc.

Fire wood is used as a fuel. A 2500 t cane/d plant utilises about 150–200 t of fire wood per annum. In money value, it will be about $8500. So, to avoid the deforestation for fire-wood, a study on filter cake utilisation for the production of biogas and to increase the fertilising value of filter cake was carried out.

Generally in India, in rural areas, the people cannot rely on LPG (liquefied petroleum gas) for cooking purposes as the availability is very unreliable, Hobson et al. (1981). Only the urban area people are enjoying this benefit. The rural area people in addition cannot afford to use it, because its cost is higher compared to fire wood.

Additionally, firewood is easily available due to deforestation. To some extent, the biogas acts as an eco-friendly bio fuel in rural areas. Biogas can be generated using cow dung in general in rural areas. However, the maintenance cost for cattle has caused the people to abandon it. That is why a number of ‘gobar’ (cow dung) gas plants in the rural areas are not functioning and have been left abandoned.

The outcome of the research resulted in the identification of sugarcane filter cake as a potential alternative source for biogas generation to utilise it in sugar factory canteens as well as in rural areas. Additionally, the fertilising value of digested filter cake improves.

**Filter cake as a feedstock**

Filter cake is a solid residue which is a by-product of sugar industry, Balasubrammaniam and Kasturei Bai (1988). The filter cake has essential nutrients besides containing a considerable amount of organic matter Nunez et al. (1985) and sugar Paturau (1982).

Experimental aspects Lakshmanam et al. (1990)

Volume of biogas
The generated biogas was measured at a fixed time by an electronic gas meter.

Moisture and total solids
By evaporating the moisture of a known weight of sample in an air-oven at 105°C, the loss of weight of sample was calculated as moisture and the remaining as solid concentration.

Ash and volatile solids
By ignition of a known quantity of sample in a muffle furnace at 550°C for one hour, the ash and volatile solids were determined.

Protein
Protein was estimated by Kjeldahl’s nitrogen analysis multiplying total nitrogen by a factor of 6.25.

pH
By using a digital type pH meter.
Determination of methane
By gas chromatography (porapak-Q column) with hydrogen as a carrier.

Biogas production from filter cake

Procedure
Cattle dung and water in the ratio of 1:1 are first mixed in a tank and then the mixture
(slurry) is allowed to pass through the inlet into the digester. A strainer (sand catcher) has been
provided to prevent the sand particles from entering the digester. The slurry ferments and produced
biogas collects in the gas holder or in the gas storage dome, depending on the design of the plant.
Biogas is drawn from the plant through a pipeline directly to the points of use. To drain out the
condensed water in the pipeline, a drain valve has been provided. Daily, after the gas has been used,
the digester is freshly filled with slurry, taking care that an equal amount of digested slurry comes
out from the digester.

Results and discussions
Tables 1 and 2 summarise the chemical composition of the used filter cake.
It should be pointed out that the dry substance of filter cake is 26%–32% higher than that of
cow dung (18%) requiring dilution for efficient biogas production.
Table 3 indicates that the biogas production increases from 4% to 8% dry substance,
culminating at 6% with 22.40 L biogas. Beyond 8% solids, the biogas production decreases.
However, during the first week of operations, the highest biogas production was achieved with feed
of 4% solids, which gradually changed during the following weeks (2 to 6) in favour of 6% and 8%
feed solids.
The average biogas production of 0.39 L/d was reached at 8% feed concentration. Highest
methane production was observed at 8% solids. The above results indicate the potential of filter
cake as feed stock for biogas generation.

Pilot scale studies
In the pilot scale studies, a 4 cubic metre capacity digester was used. Initially, the seed
development was done by charging cow dung slurry (by mixing one part of cow dung with one part
of water) to build the essential population of methanogenic bacteria. After the stabilisation of the
methanogenic operation, the bacterial population was adequate as indicated by the sufficient
methane production. Filter cake slurry prepared by mixing one part of filter cake with 2.5 parts of
water was added. Biogas production was found to be 0.7–0.8 m³/d with about 50%–52% methane
during the first week of initial feeding with cow dung slurry. The gas production increased to a
steady level of 2 m³/d after a week of feeding with filter cake. After three months of continuous
feeding with filter cake, biogas production increased to 2.4–2.6 m³/d. It was observed that, after
charging with filter cake, the methane content of biogas gradually increased from 50%–52% with
cow dung to 65%–75% with filter cake slurry.
Initially, the Karnataka Sugar Institute, Belgaum has commenced a trial with a 4 m³ gobar
gas plant in a near-by sugar mill. After successful completion of the trial, it recommended to all the
cooperative and public sector sugar mills to put up a biogas plant with capacities varying from
60–75 m³/d for canteen cooking purposes.
Similarly, the Institute has helped the cane growers in and around the mills in the
cooperative as well as public sector sugar mills. In addition, it has helped to set-up 3–4 m³/d
capacity small plants in the rural areas. Now, there are about 100 industrial type biogas plants with
a capacity of 60 m³/d in 100 sugar mills including cooperative, public and private sector sugar mills
in India. About 200 of 4 m³/d capacity domestic type biogas plants are now operating near sugar
mills in India utilising filter cake as a feedstock for the production of biogas. Thus the sugar mills in
India are helping the rural people to enjoy the benefit of biogas for safe cooking by avoiding the use
of firewood.
**Tips for biogas plant installation**

1. Select an elevated dry and open area exposed to sunshine for a greater part of the day.
2. It should be near the kitchen.
3. The ground water level should be minimum 2 metres.
4. There should not be any drinking water well or hand pump within the range of 15 metres from the gas plant.

**Capacity**

1. Each kg of filter cake produces 0.05–0.06 m³ of bio gas.
2. The gas required for cooking per day per person is estimated to be 0.3 m³.
3. For a sugar factory canteen, the gas requirement for some 250 persons is 75 m³.

**Selection of bio-gas plants** Malik et al. (1995).

1. Floating gas holder, commonly called KVIC type (Khadi & Village Industries Commission).
2. Fixed dome called Janatha type.
3. Pragati model.
4. Modified fixed dome called Deenabandhu model.
5. KVIC type plant having digester made of angle iron and polyethylene sheet called Ganesh model.
6. KVIC type plant having digester made of pre-fabricated ferro-cement segments.
7. KVIC type plant made with fibre glass, reinforced plastic.
8. The floating type drum was found to be more efficient compared to other types. The floating drum should be rotated once or twice a day so that a stirring effect will be created. If the plant is in regular use, 1:1 ratio of urea and di-ammonium phosphate added once in a fortnight will enhance the growth of the methanogenic bacteria. Diluted molasses or effluent can also be used to enhance gas production. Generally, the retention time varies from 30–50 days. Instead of mild steel, fibre glass can also be used for the drums to avoid corrosion. If a stirring arrangement is provided, the retention time is reduced. The retention time may vary from digester to digester. If a higher production rate is required, the rate of feeding may be increased. Generally, feeding should be in the morning.
9. The fixed dome plant should strictly be made by well-trained master masons who have the experience of constructing such plants; material quality is of importance (bricks, cement) for avoiding cracking and gas leaks Malik et al. (1997).

**Components of a plant**

A biogas Plant consists of the following parts:

1. Mixing tank and inlet.
2. Digester.
3. Gas holder or gas storage dome.
4. Outlet and compost pit.
5. Gas main outlet and valve, pipelines, water fittings, gas stove lamp and similar appliances suitable for biogas.

**Selection of depth of digester**

The depth or volume of the digester is determined by the retention period which depends upon the average ambient temperature of the area. Commonly these are:

1. Plants based on 30 days retention period.
2. Plants based on 55 days retention period.
Cost of the plant
Cost of installation varies according to the type and size of the plant. On average, a FRP model is 5% more and a ferro-cement digester model is 10% less than the KVIC model.

The cost of the plant will vary depending on location. In India, the cost of the floating drum type model with 60 m³ capacity about $6000–7000.

Facilities provided by the State and Central Government of India

The State Energy Development Corporation under the control of State Governments and the Ministry of Non-Conventional Energy Sources, Government of India are providing facilities for promotion, construction, after sales services and repairs. It also provides subsidy facilities.

The State Government and KVIC (Kadhi and Village Industries Commission) have created biogas cells at the state and district level for providing technical guidance, supervision in the construction, maintenance of plant and arrangement, inputs like cement, steel and institutional finances providing post installation servicing facilities etc.

Power from biogas

One cubic metre of biogas produces 250 watts of electricity (with the aid of oil engine and generator). It has increased thermal efficiency and calorific value as compared to biogas from cow dung. The biogas can effectively be used for cooking, running farm machinery and also for lighting farm houses.

Fertilising values

The digested filter cake which leaves the digester is rich in nitrogen, phosphorus and potassium. Field trials with sugarcane comparing raw filter cake vs. digested filter cake showed increased yields from digested filter cake.

There is also no wax and sulfur in digested filter cake. It was also discovered that digested filter cake acts as a weedicide. When using digested filter cake for wetting agricultural wastes in bio-manuring, the methanogenic bacteria act as catalysts in decomposing the organic residue. The digestion period is also reduced by about 40%.

Conclusion

Biogas from filter cake is a clean and cheap gaseous fuel. It contains 65%–75% methane which is combustible and it is produced by digestion. The fertilising value of the filter cake does not diminish but rather enhances during the digestion process.

Thus, the filter cake converts by digestion to two useful products, fuel and fertiliser. It should be handled with care (fire hazard) and it saves on cooking time.

It is a non-conventional energy source. The Central and State Governments are encouraging this program.

Biogas is an eco-friendly, non-fossil fuel replacing firewood for cooking, thus helping to prevent deforestation for the benefit of the environment.

Acknowledgement

The author expresses his heartfelt thanks to both the chairman and the director of the Karnataka Sugar Institute, Belgaum for their encouragement in conducting the research and permission for publication of this paper. He also wants to thank all his colleagues and staffs of KSI who assisted and contributed.

MOTS-CLÉS: Ecumes, Digesteur, Matiere Organique, Methanisation, Biogaz.

Resumé
Il a été constaté que du biogaz ou gaz de cuisson peut être produit avec succès à partir des écumes produites dans les usines sucrières. Elles contiennent une quantité considérable de matière organique de 73 à 77% y compris le sucre de 1.8 à 3.0%. Après l'analyse des constituants des écumes et l'identification de leur utilité possible, une étude à échelle de laboratoire a été effectuée. Il a été ainsi établi qu’un taux maximal de biogaz peut être produit à partir des écumes quand la concentration des solides est de 6 à 8%. Après ce seuil le taux de production diminue. Il a également été établi qu’une production de biogaz de 0.39 L/jour était supérieur à 8% de concentration qu’aux autres taux utilisés. Après optimisation des résultats, une étude pilote a été menée au cours de laquelle il a été établi que les écumes donne une production de biogaz de 65 à 75% au lieu de 50–52% dans le cas de fumier de vache qui nécessite une dilution de 1:1 pour faire une boue pour l'alimentation. Les écumes nécessitent une dilution de 1:1.25 car elles contiennent 26 à 32% de matière sèche. Des recommandations pour la sélection d'usine de production de biogaz et les installations connexes sont énoncées. L'augmentation de la valeur en termes d'engrais des écumes fermentées, la production d'énergie, le moyen indirect d'aider le boisement et la protection de l'environnement sont abordés.
GAS PARA COCINAR ECOAMIGABLE A PARTIR DE RESIDUOS DE INGENIOS AZUCAREROS

PALABRAS CLAVE: Torta de Filtros, Digestor, Materia Orgánica, Metanización, Biogás.

Resumen

Se encontró que el biogás ó gas para cocinar puede ser producido exitosamente a partir de tortas de los filtros de la cana de azúcar. Contienen una cantidad considerable de materia orgánica, en el rango de 73 a 77%, incluyendo de 1.8 a 3.0% de azúcar. Después de analizar los constituyentes de las tortas de los filtros y después de encontrar su conveniencia, se realizó un estudio a escala de laboratorio. Como resultado se estableció que un máximo de biogás puede producirse empleando torta de los filtros como materia prima, cuando la concentración de los sólidos es de 6–8%, más allá de estos valores decrece la producción. Se estableció, así mismo, que el promedio de biogás de 0.39 L/d era mayor a8% de concentración que a cualquier otro valor. Después de optimizados los resultados, se realizó un estudio a escala piloto, en el cual se comprobó que la torta de filtros rinde una producción de biogás de 65% a 75% en lugar de 50–52% que se obtiene con excretas de vacas, que requieren una dilución 1:1 para lograr la consistencia del fango de alimentación. La torta de los filtros requiere una dilución de 1:1.25 ya que contiene 26 a 32% de materia seca. Se brindan recomendaciones para la selección e instalación de las plantas de biogás. Se discute en el valor fertilizador de la torta de los filtros digerida, la generación de energía, vías indirectas de forestación y la protección ambiental.
AN UP-DATE OF COGENERATION EFFICIENCY AND ECONOMIC INDICATORS USING MODERN COMMERCIAL TECHNOLOGIES

By

NEST – Excellence Group in Thermal Power and Distributed Generation, Mechanical Engineering Institute, Universidade Federal de Itajubá, Brazil
electo@unifei.edu.br

KEYWORDS: Ethanol, Cogeneration, Production Cost.

Abstract

A SCENARIO considering capacity, parameters and commercialisation prices for cogeneration systems equipment was carried out, different Brazilian manufacturing costs were considered, and related data presented in tables and figures. Using the Gate-Cycle software, cogeneration plant schemes were modelled for different ethanol distillery capacities. Using energy balances and equipment cost data, the electricity generation cost was calculated for each of the evaluated scenarios. As a result of the evaluated scenarios, indicators such as: surplus electricity index, energy utilisation factor and exergy efficiency are presented. Recommendations are presented about the most profitable scenarios considering present electricity commercialisation prices of about 56.52 US$/MWh and two ethanol market price levels: 0.30 and 0.17 USD$/L.

Introduction

According to the Ministry of Agriculture, Livestock and Supply (MAPA), a government agency responsible for the registration of the mills and distilleries installed in Brazil, 434 plants crushing 495 million tonnes of sugarcane per year were in operation in the 2007/2008 harvest. Sixteen were used for sugar production only, 167 for ethanol production and the 251 remaining plants produced both sugar and ethanol (MAPA, 2009). Most of the large plants are located in the state of São Paulo, where almost two-thirds of the Brazilian ethanol is being produced (Goldemberg, 2008).

Until 1980, sugar and ethanol plants in the state of São Paulo were using boilers with pressure between 1.2 and 2.2 MPa and were purchasing 40% of the electric power they consumed. By 1990, with the replacement of old boilers and turbines, the average steam pressure in these plants had reached 2.2 MPa, with temperatures of 300°C, levels which made the plants self-sufficient with regard to their electric power needs, and in some cases produced a small surplus for sale.

Today, these boilers are being substituted by high-pressure boilers operating in the range of 6 up to 12 MPa and, in some cases, the plant capacity is increased; as a result, energy efficiency is being increased and there is in fact a large electricity surplus that is supplied to the grid. Presently, it is assessed as approximately 1400 MW, with a forecast for 2020 of 14 400 MW (Unica, 2009).

Therefore, research about how these changes affect the production costs of the final products obtained in the distilleries (electricity surplus and ethanol) and what will be the resulting efficiency increase for the whole plant is an important aspect. By carrying out simulations using commercial software and thermodynamic tools, this study intends to determine the available surplus electricity, the global efficiency and the final production cost of the main products of an autonomous distillery, considering increases in the plant mill capacity and steam parameters. It also evaluates, from an economic point of view, each one of the alternatives proposed, considering the investment values, the operational and maintenance costs, and the revenues from hydrated ethanol and electricity commercialisation.
Finally, an analysis is carried out for the determination of the specific investment required per tonne of crushed cane, the electricity generation cost, and the NPV obtained as a function of the plant capacity and steam parameters utilised, as well as for different hydrated ethanol and electricity commercialisation prices.

**General aspects**

Bioethanol producers establish the minimum price for their product considering two conditions: a) to cover the production costs, which obviously include raw material and plant operational costs, as well as capital costs corresponding to production investments; and b) be equal to, or higher than the price that could be obtained if the raw materials were used in the best manufacturing alternative. Sugar and molasses are among the alternative products that can be obtained from sugarcane. The second one is a by-product of the sugarcane industry that has value as an industrial input or as animal feed (BNDES and CGEE, 2008).

Indeed, the estimation of the ethanol production costs in Brazil is quite a difficult task. First, it is important to mention that this cost varies significantly in different production regions, due to the differences in productivity and cost of sugarcane production. Not only does the productivity vary, but also the cost of sugarcane production changes according to the harvest and transportation technologies. Second, estimating the cost of the sugarcane is crucial to the ethanol cost estimation. Most studies regarding Brazilian ethanol have estimated sugarcane production cost at $10 dollars per tonne, which gives a cost of roughly $0.10 per litre of ethanol. However, this cost is considered by De Almeida et al. (2007) to be underestimated.

Figure 1 shows the rise of hydrated ethanol production in Brazil between 2003 and 2008 and the corresponding prices for producers (excluding taxes).

![Fig. 1—Brazilian hydrated ethanol production and average prices for producer excluding taxes (UDOP, 2009 and CEPEA, 2009).](image)

Having in mind the previously mentioned aspects, the estimation of the real ethanol production cost for the different installed plants is a very important aspect in the modernisation and expansion of the ethanol industry.

Equally, the prospect of selling electric power to public utility concessionaires requires knowledge of the real electricity production cost to calculate the economic impact of surplus electricity commercialisation in the economic balance of the distillery plant.

**Process description**

During ethanol production from sugarcane in an autonomous distillery (i.e., not annexed to a sugar mill), the feedstock is washed, crushed and milled to extract the sugarcane juice and in doing so a co-product is generated (bagasse). The sugarcane juice is transformed into ethanol according to
the following stages: juice treatment, concentration and sterilisation; fermentation; distillation and dehydration. The sugarcane bagasse (50% moisture) is burnt in boilers for generation of thermal and electrical energy demanded by the whole plant (see Figure 2).

![Diagram](image)

**Fig. 2—Physical structure of autonomous distillery (Adapted from Higa, 2003).**

**Evaluated alternatives**

Considering the great diversity of autonomous distilleries that exist in Brazil in relation to their milling capacity and the level of technological development of their cogeneration systems, five different autonomous distilleries with different steam parameters and capacities were considered. Their simulation was carried out, considering the parameters presented in Table 1, using the Gate-Cycle software.

*Based on LHV of mill wet bagasse
**Calculated for each case using the modelling software Gate-Cycle.
With respect to the electric power consumed by the different process stages (juice treatment, concentration, illumination, etc.), there are slight distinctions between processes, but all of them are around 12 kWh per tonne of processed sugarcane (BNDES and CGEE, 2008). This index was complemented with the electric power consumption of pumps and auxiliary equipments in the cogeneration systems, calculated using the Gate-Cycle software.

**Performance indexes**

**Thermodynamic assessment**

Some thermodynamic performance indexes presented by Horlock (1987) and Lora et al. (2006) (Eqs. (1), (2), (3) and (4)) have been considered and calculated for the different alternatives analysed in this paper. The calculated values are shown in Table 2.

**Energy fuel utilisation (EUF)**

This index is based on the first law of thermodynamics and allows calculating the energy efficiency of a cogeneration plant.

\[
EUF = \frac{W_e + Q_u}{m_f \cdot LHV}
\]

where \( W_e \) is the net electricity power output, \( Q_u \) is the useful heat rate delivered to the process and \( E_f \) is the fuel energy consumed, calculated as the product of bagasse mass flow (\( m_f \)) and its low heating value (LHV).

**Exergetic efficiency (\( \eta_{ex} \))**

This index allows calculating the cogeneration efficiency based on the second law of thermodynamics, using exergy as a measure of the ‘real’ value, i.e., availability of an energy stream. Instead of using the process heat, this index uses the process consumed exergy, and the fuel energy is also substituted by its exergy.

\[
\eta_{ex} = \frac{W_e + B_p}{B_f}
\]

where \( B_p \) is the exergy of the heat delivered to the process (as steam) and \( B_f \) is the exergy of the consumed fuel (bagasse).

**Global exergetic efficiency (\( \eta_g \))**

This indicator is obtained by dividing the sum of the exergy of the hydrated ethanol and the surplus electricity, by the exergy contained in the sugarcane (Eq. 4). It is a measure of the level of utilisation of the energy contained in the sugarcane.

\[
\eta_g = \frac{E_{HE} + E_{el.ex}}{E_c}
\]

where \( E_{HE} \) is the exergy content of hydrated ethanol; \( E_{el.ex} \) the surplus of electricity and \( E_c \) the sugarcane exergy.

The sugarcane exergy content (\( E_c \)) is calculated by the Eq. 4.

\[
E_C = E_B + E_{BC}
\]

where \( E_B \) is the bagasse exergy content and \( E_{BC} \) the sugarcane juice exergy content.
Thermodynamic evaluation results

Figure 3 shows that, for each mill capacity, when the steam parameters are increased from 4.2 up to 12 MPa the surplus electricity per tonne of sugarcane crushed is increased by approximately 46%, while the exergetic efficiency of the plant is increased by 17%. It also shows the influence of the steam parameters and the distillery capacity in global exergetic efficiency of the plant. When these two factors are increased, this index is increased by approximately 3% as a consequence of the better use of the sugarcane energy content. To accomplish the necessary process steam consumption for each evaluated capacity scenario, it was necessary to consider the utilisation of turbines with different sizes and extraction/steam flow ratios. As a consequence, different values of surplus electricity per tonne of crushed cane were obtained, showing no logical tendencies. So, this is the reason why, for crushing rates of 180 tc/h, the index of electricity surplus is higher than for plants with capacities of 580 tc/h.

For steam parameters of 12 MPa, an increase of 5, 8, 9 and 11% in the global exergetic efficiency of the plant is obtained, respectively of the considered plant capacity levels.

From a thermodynamic point of view, Figure 3 shows that the better alternative, to be considered as a first option, is a distillery with steam parameter of 12 MPa/520°C and a plant capacity of 580 tc/h. A distillery with steam parameters of 8 MPa/510°C and a plant capacity of 580 tc/h can be considered as a second alternative. However, to validate the obtained result, it is necessary to carry out the economic evaluation of these alternatives.

Economic assessment

Considering that in the autonomous distillery, analysed multiple products with aggregated value (Electricity and Ethanol) are obtained, it is necessary to distribute the total costs of the plant and of the sugarcane in a rational way among them, as they will influence directly on each final product cost.

Therefore, to obtain the final production cost of electricity and ethanol, it is necessary to select the more rational cost allocation method for the products. The allocation method must generate product costs that reflect the real costs involved in its production, without overcharging
one of the products (Escobar et al., 2009). In this work, the cost allocation method applied is based on the Second Law of Thermodynamics, using the so-called thermo-economic analysis, an approach that combines the exergy concept with economics, seeking for cost distribution (Lora et al., 2008). This methodology allows allocation of the input costs, as well as the investment, operation and maintenance costs of the equipment for ethanol and electricity production in dependence of the consumed exergy for its production. Figure 4 shows a schematic representation of the methodology employed for the thermo-economic assessment.

![Thermo-economic assessment methodology flow scheme.](image)

**Cost formation**

The distillery system can be considered as a system or a set of subsystems, that exchange flows (mass and energy) among themselves and between them and the environment. This information can be converted into financial or cost flow (C). The cost composition in the distillery system can be generally represented by equation (5), where the units are expressed in financial units per unit of time ($/h). In Eq. (5) the first member is the sum of input flows and the second member the outputs flow.

\[
C_c + Z_{pp} = C_{\text{ethanol}} + C_{\text{electricity}}
\]  

(5)

The input costs of the plants are the cost of sugarcane (\(C_c\)) and the fraction referred to depreciation, operations and maintenance costs of the equipment that compose the global plant (\(Z_{pp}\)). The products or output of the equation are the cost allocated to ethanol (\(C_{\text{ethanol}}\)) and the electric power (\(C_{\text{electricity}}\)). For computing the unitary costs of electricity production (\(c_{\text{electricity}}\)) and ethanol (\(c_{\text{ethanol}}\)), that are expressed in $/kWh and $/L, it is necessary to write the Eq. (5) in the form of Eq. (6).

\[
C_c + Z_{pp} = c_{\text{ethanol}} V_{\text{ethanol}} + c_{\text{electricity}} P_{\text{electric}}
\]

(6)

where \(V_{\text{ethanol}}\) is the hourly produced hydrated ethanol and \(P_{\text{electric}}\) is the net electric power expressed in L/h and kW, respectively.

The equipment costs that compose the plants in the different analysed scenarios were obtained from national equipment manufacturers and adapted to necessary capacities using a scaling factor. During the determination of the investment costs, some of the items necessary for the economic analysis couldn’t be determined. So it was necessary to set percentages in relation to the acquisition price of different equipment (Table 2).

**Table 2**—Percentage values used of equipment costs used for auxiliaries, installation, civil construction and O&M during investment cost calculation (Barreda, 1999).

The autonomous distilleries specific investments for different steam parameters and plant capacities are presented in Figure 5.

![Figure 5](image)

Fig. 5—Specific investment required for ethanol distilleries as a function of steam parameters and plant capacity.

With the values obtained from Figure 5, it’s possible to calculate the production cost for the electricity and ethanol in different distilleries, in accordance with the productive purpose of each subsystem that comprises the global plant and the consumed and/or produced exergy in each stage. A schematic representation of the formation and cost sharing process in a distillery is shown in Figure 6.

![Figure 6](image)

Fig. 6—Cost splitting and allocation scheme in a distillery system.

The subsystem 1 (Sub1) of Figure 6 represents all the components of the plant that supply exergy to the cogeneration cycle (pumps, boilers, deaerator, etc.), while the subsystem 2 (Sub2) represents the components that consume exergy (turbogenerators, condensers, mechanical drives). The subsystem 3 (Sub3) represents the ethanol production stages (heating, evaporation, cooling, fermentation and distillation). This allows one to follow the costs formation process of the main products of the plant (ethanol and electricity).

The Eq. (6) shows that, in a multiproduct plant, the main product costs are depending one of the other; therefore, it is necessary to allocate the sugarcane cost in a proportional way for the global system, avoiding overcharging the cost of one of the obtained products. When the bagasse cost is considered zero in the cogeneration systems, as is usually done due to its byproduct nature, the sugarcane cost will be charged fully to the sugarcane juice obtained in the mills, having as a consequence that the ethanol cost will be higher, while the electricity cost will be lower than the real cost.

Figure 7 shows the dependence of the unitary economic cost for electricity and hydrated ethanol calculated for a distillery with steam parameters of 8 MPa/510°C and a capacity of 480 tc/h.
This means that, when the market price of the ethanol grows, this can economically compensate the decrease in the commercialisation price of surplus electricity, a phenomenon known as internal cost allocation. To calculate the cost of the generated electricity, it is necessary to estimate in advance the hydrated ethanol production cost, as this is the main distillery product. The average unit cost calculated for hydrated ethanol in the different plant capacities was 0.18 USD$/l. Electricity production costs for all the evaluated scenarios starting from this average ethanol cost are presented in Figure 8.

Figure 8 shows that the highest values of electricity cost production are obtained for steam parameters of 4.2 MPa/420°C with values of 52.60, 49.56, 43.53, 38.74 and 33.03 USD$/MWh for each one of the considered plant capacities.

However, it’s possible to obtain a reduction of these values by approximately 13% through the increase in the steam parameters from 4.2 MPa up to 6 MPa, and a reduction of 6% by the implementation of steam parameters of 8MPa instead of 6.0 MPa.

When the steam parameters are increased from 8 up to 12 MPa, the electricity generation cost increases by approximately 8%, due to the higher investment in some plant components. In this case, the boiler cost increases approximately 31%.

When steam parameters are increased from 4.2 up to 6 MPa, the boiler costs increase by 22% and, in the case when passing from 6 up to 8 MPa, this cost increases is 9%, approximately.

It is observed in Figure 8 that, from an economic point of view, the steam parameters of 12 MPa do not represent significant advantages for the electricity cost generation, different from the results obtained when using only the thermodynamic analysis.
Finally, as a complement of the obtained results, cash flow analyses were performed for the determination of the economic attractiveness of the considered scenarios. The Net Present Value (NPV) was used as an economic feasibility indicator. For calculation, an IRR of 15% was assumed representing the minimum attractiveness rate, a value assumed by investors based on market conditions. With the increase in the IRR value, the economic attractiveness of some of the evaluated scenarios could be reduced, especially the ones, shown in Figure 10, with lower ethanol market prices.

Taxes and discount rates adopted for this work during cash flow analysis are presented in the Table 3.

Figure 9 shows the main NPV obtained in the different evaluated scenarios. It is observed that, for fixed market prices of ethanol and electricity of 0.30 USD$/l and 56.56 USD$/MWh, the attractiveness of the investment increases when the steam parameters go from 4.2 up to 8 MPa and the plant capacity is in the range of 380–580 tc/h.

Fig. 9—Specific Net Present Value for a distillery as a function of steam parameters and plant capacity for ethanol and electricity market prices of 0.30 USD$/l and 56.57 USD$/MWh respectively.

In spite of allowing a higher global efficiency of the plant, the steam parameters of 12 MPa present a lower economic attractiveness than the steam parameters of 8 MPa, which need a lower initial investment.
In the cash flow analyses, another scenario was considered with ethanol and electricity prices of 0.17 USD$/l and 56.57 USD$/MWh. Main results are shown in Figure 10. As shown, the economic feasibility of autonomous distilleries in the range of 180 – 280 tc/h presents high dependence from the ethanol market price. This is not valid for distilleries in the range of 380 up to 580 tc/h with steam parameters of 8 MPa. It’s observed that the increase in the steam parameters for maximising the electricity surplus and choice of the plant capacity are main factors for assuring the economic feasibility of ethanol plants when the market price of ethanol and electricity is variable.

![Figure 10](image_url)

**Fig. 10—Specific Net Present Value for a distillery as a function of steam parameters and plant capacity for ethanol and electricity market prices of 0.17 USD$/l and 56.57 USD$/MWh respectively.**

**Conclusions**

The market price of electricity can compensate possible oscillations in ethanol market prices, so the internal cost allocation gives certain flexibility in reaching economic feasibility during autonomous distillery investment planning and operation.

Actually, the steam parameter that allows obtaining the lowest electricity generation cost is 8 MPa, in spite of steam parameters of 12 MPa resulting in higher plant global efficiency.

The economic feasibility of autonomous distilleries is strongly dependent on the steam parameters adopted for the cogeneration plant, mill capacity and market prices of ethanol and electricity. The increase in the plant capacity enables a higher economic attractiveness.

Thermo-economics, through exergy flows evaluation, is a powerful tool for cost allocation in autonomous distilleries, allowing to obtain final product cost that reflects the process of cost formation in the plant.

Résumé

UN SCENARIO tenant compte des capacités, des paramètres et des prix de commercialisation des équipements pour des systèmes de cogénération a été effectué; des différents coûts de fabrication de source brésilienne ont été examinés et les données y relatives sont présentées par le biais de tableaux et des graphiques. A l'aide du logiciel Gate-Cycle des unités de cogénération ont été modélisées pour des distilleries d'éthanol de capacités différentes. Utilisant les balances énergétiques et les données sur les coûts des équipements, le coût de la production d'électricité a été calculé pour chacun des scénarios évalués. À la lumière des résultats des scénarios évalués, les indicateurs tels que: indice de surplus d'électricité, facteur de l'utilisation d'énergie et l'efficacité énergétique sont présentés. Les recommandations issues des scénarios les plus rentables sont présentées tenant compte des prix actuels de commercialisation de l'électricité d'environ 56.52 $ US/MWh et deux niveaux de prix d'éthanol: 0.30 et USD 0.17 $ / L.

Resumen

SE ELABORÓ un escenario considerando capacidades, parámetros y precios de comercialización para equipos de sistemas de cogeneración, se consideraron diferentes costos de manufactura brasileñas y datos relacionados presentados en tablas y figuras. Empleando el software ‘Gate-Cycle’ se modelaron esquemas de plantas de cogeneración para diferentes capacidades de destilación de etanol. Se calculó el costo de generación de electricidad para cada escenario evaluado empleando datos de balances de energía y costos de equipos. Como resultado de la evaluación de los escenarios se presentan indicadores como el índice de energía sobrante, el factor de utilización de energía y la eficiencia energética. Se ofrecen recomendaciones acerca de los escenarios más rentables, considerando los actuales precios de comercialización de electricidad en el entorno de 56.53 US$/MWh y los precios del mercado de etanol: 0.30 y 0.17 US$/L.
USE OF THE LIFE CYCLE ASSESSMENT (LCA) FOR COMPARISON OF THE ENVIRONMENTAL PERFORMANCE OF FOUR ALTERNATIVES FOR THE TREATMENT AND DISPOSAL OF BIOETHANOL STILLAGE

Abstract

New alternative routes for the treatment and disposal of stillage should be proposed, as fertigation could become unfeasible, due to the increasing transport costs and environmental concerns. The aim of this paper is to show the results of the application of the Life Cycle Assessment methodology for the analysis and comparison of four alternatives for stillage treatment and disposal: conventional ‘in natura’ fertigation, anaerobic digestion, concentration until 40% for fertigation and concentration until 65% for combustion in boilers using fuel oil as supplementary fuel. For the LCA study, a hypothetic Standard Sugar and Alcohol Mill was assumed with a milling capacity of 1.99 million tonnes of sugarcane per crop, producing 154 thousand tonnes of sugar and 81 thousand m³ of ethanol. The mill is located near the city of Sertãozinho and local soil characteristics were also considered. The environmental evaluation results comparing the 4 alternatives of disposal are shown. The Simapro® software and the CML 2 baseline 2000 are used as support tools.

Conventional and concentrated stillage fertigation alternatives have the best environmental performance. In the combustion of stillage, we considered the installation of pollution control devices for SOx and NOx with 95% efficiency. From the point of view of climate change, based on the life cycle greenhouse gases balance, the best alternative was biodigestion.

Introduction

Stillage, the most important by-product of sugarcane bioethanol production, is the aqueous by-product from the distillation of bioethanol. On an average, 8–15 litres of stillage is generated for every litre of alcohol produced.

The pollution load of the distillery effluent depends on different aspects related to the

feedstock and process (Parnaudeau et al., 2008). Stillage might be handled several ways: discharge to an adjacent waterway or land area, return to agricultural fields (fertigation), anaerobic digestion and methane production, incineration, evaporation to an animal feed or use as an aquaculture feed (Willington and Marten, 1982; Wilkie et al., 2000; Pant and Adholeya, 2007; Mohana et al., 2009).

There has been a substantial development of life cycle methodologies to assess the energetic and environmental performance of product systems from cradle-to-grave, namely LCA (Malça and Freire, 2006).

The ISO, a worldwide federation of national standards bodies, has standardised this framework within the ISO 14040 series on LCA (ISO, 1997; 1998; 1999 and 2000).

Preliminary attempts of LCA application for the evaluation and comparison among alternatives of stillage treatment were accomplished by Rocha et al. (2007) and Rocha et al. (2008).

The objective of this work is to accomplish a comparative environmental analysis between the different scenarios corresponding to different stillage treatment and disposal alternatives.

**LCA methodology for this study**

**Definition of the goal and scope**

The function of the systems of products analysed in this work relative to different alternatives for stillage treatment:

- FCDCC: conventional fertigation with *in natura* stillage distribution through concrete channels and dispersal on farms through diesel-fuelled motor-pumps.
- ABDCC: stillage anaerobic biodigestion, with the biogas used for electric power generation and the subsequent disposition of the resulting effluent on farms.
- SCDTT: stillage concentration by evaporation up to 40% of solids, distribution on farms through trucks.
- SCCBA: stillage concentration by evaporation up to 65% of solids, to allow incineration in a boiler, together with an auxiliary fuel for steam and electric power generation. The ashes can be used for supplementary fertilisation.

**Definition of the FU and SB**

The FU is 1 m³ of stillage treated/disposal. In the agricultural system, the sum of the fertigated area with application of ashes and/or the area fertilised with mineral fertilisers will be the same for the four scenarios, but the magnitude changes (Table 1).

The operations of soil preparation, herbicide application, pesticide and limestone, harvest and transport won't be considered because they are the same for all scenarios.

The capital infrastructure contributes on average less than 5% of the global impact in all the impact categories (Rocha, 2009). So the build-up stage of the systems of stillage will not be considered in this study.

A SSAM in the municipal district of Sertãozinho, State of São Paulo, Brazil, was established, hypothetically (Figure 1). The total period of operation will be 20 years, with 210 days of crop a year (4440 useful hours of operation). The milling capacity is of 1.99 Mt of sugarcane per crop, producing 0.154 Mt of sugar and 81,000 m³ of ethanol.

The predominant soil in the region is of the type Rhodic Hapludox and Typic Hapludox, with an average composition of 33.8% silt and 52.9% of clay (Alves, 2002).

Table 2 shows the main parameters adopted in process simulation. It is considered that 12.0 litres of stillage per litre of ethanol will be produced with the composition shown in Table 3 (Elia Neto and Nakahodo, 1995).

The main agricultural parameters considered for energy and emission analyses are presented in Table 4. The diesel consumption in the equipment used during conventional fertilisation, fertigation with ‘in natura’ and concentrated stillage and fertilisation with ashes was calculated starting from indicators presented by Macedo et al., 2004. It is considered that the cycle of the sugarcane consists of the plant cane and four ratoon crops with an average productivity of 87 tc/ha.

In this work, it is assumed that the stillage is applied in the plant and ratoon cane with nitrogen (48 kg/ha) and phosphorus (125 kg/ha) complementation in the plant cane (Penatti, 2008, Pers. Comm.). The emissions originating from the mineral fertilisation were calculated by the indicators shown in Table 5.

**Description of evaluated scenarios**

**Scenario I: FCDC – Conventional fertirrigation**

The stillage application rate during fertirrigation is 183 m³/ha, calculated according to CETESB (2005). The scenario I scheme is shown in Figure 2.

The mass and energy balances were calculated using the software GateCycle® (Figure 3). The steam parameters considered were 6.5 MPa and 480°C.
Fig. 2—Scheme of the FCDCC scenario.
Information about environmental impacts to atmosphere from stillage application to soil is practically nonexistent; only CO₂ emissions were considered according to Almeida (1983).

**Scenario II: ABDCC – Stillage biodigestion**

The bio-digestion plant is composed of four internal circulation anaerobic reactors.

The generated biogas will be used in internal combustion engines for electricity generation, the resulting effluent of the bio-digestion process will be applied on farms through waterproof concrete channels and the dispersal will be accomplished by diesel motor-pumps (Figure 4).

The rate of application of the bio-digested stillage in the agricultural soil is 266 m³/ha.

It is considered that the biogas has the following composition: 60% CH₄, 39% CO₂ and 1% H₂S. The PCI and PCS of the biogas are 18.20 MJ/kg and 20.19 MJ/kg respectively, the specific mass is 1.10 kg/m³ and the mass flow 0.593 kg/s.

The total electric power consumed by the bio-digestion system is 539.0 kW and, for FU, the consumption will be 2.46 kWh.

The sizing of the power generation system was accomplished using the software Thermoflex®, and consisted of 2 motor-generators Jenbacher®, each one with a nominal power of 2.56 MW and global efficiency of 40.0% and 1 group motor-generator Wartsila® with a nominal power of 1.35 MW and efficiency of 31.0%; in that way, the groups will generate 16.82 kWh/m³ of stillage.
Scenario III: SCDTT – Stillage concentration and fertirrigation

In this scenario, the stillage is concentrated by evaporation up to 40.0% solids. The design of the plant was accomplished using the software Aspen Plus® (Moura, 2008, Pers. Comm.).

In the scheme, 5 evaporation effects were considered also a condenser and a CIP system.

Figure 5 displays the outline of the cogeneration plant for this case. The efficiency of the cycle was 19.0%, therefore 173.29 kWh/m³ of stillage are generated. In the whole plant, 2430 kW are consumed; therefore, to the FU, it corresponds to 11.11 kWh.

Surplus electricity is 142.14 kWh. The allocation of the atmospheric emissions will be based on the share of generated/consumed electricity in the following way: 11.6% for the process, 6.4% for the stillage concentration plant and 82.0% for surplus electricity.

The rate of application of concentrated stillage will be 9.25 m³/ha. The fertirrigated and non-fertirrigated areas for the FU will be 0.0081 e and 0.0111 hectares, respectively (Figure 6).

Scenario IV: SCCBA – Stillage concentration and incineration

The stillage is concentrated up to 65% to enable the combustion of the stillage in boilers. The design of the plant was accomplished using the software Aspen Plus® (Moura, 2008, Pers. Commun.). The ashes that result from the combustion can be used in partial substitution of the mineral fertilisers. The concentration plant will have a scheme equivalent to the one in the previous scenario; however, it should have an additional evaporation effect, having in total 6 effects (Figure 7).
Fig. 5—Cogeneration plant modeling results for SCDTT scenario.

Fig. 6—Stillage concentration plant modeling results for SCDTT scenario.
Fig. 7—Scheme of the SCCBA scenario.
Results

Inventory of the consolidated life cycle

The methodology and indicators used in the LCI in this work are described in detail in Rocha (2009). Three evaluation categories were used for the evaluation of the environmental loads in LCI: energy evaluation (output/input energy relationship), GHG emissions balance in relation to the surplus electricity exported for the public grid, and characterisation/normalisation of the environmental impacts in agreement with a specific Eco-Indicator (CML 2 baseline 2000 version 2.03).

Electricity exported as a function of the emission of CO₂ equivalent

For the four appraised alternatives, the value of the electricity exported to the net was determined, and the emissions of GHG released during the system operation (emissions of the mineral fertiliser, cogeneration, use of diesel oil, decomposition of the stillage, etc.), based on the characterisation model developed by IPCC (2006).

The characterisation factors are expressed using the global warming for a horizon of 100 years (GWP100), in kg of CO₂ equivalent/kg of emitted substance.

The substances considered in this study were CO₂ (1.0 kg CO₂ eq./kg), CH₄ (23.0 kg CO₂ eq./kg), CO (1.53 kg CO₂ eq./kg) and N₂O (296 kg CO₂ eq./kg). The results are shown in Figure 8.

Fig. 8—Rate of emission of CO₂ in function of the electricity exported for the public net.

The smallest emissions of GHG per kWh of generated electricity correspond to the scenario ABDCC (1.92 kg CO₂ eq./kWh), followed by FCDCC (2.13 kg CO₂ eq./kWh), SCCBA (2.16 kg CO₂ eq./kWh) and SCDTT (2.28 kg CO₂ eq./kWh).

Evaluation of the energy flows (Output/Input relationship) of the scenarios of disposition of the stillage

In the specific case of this study, the ER relation will indicate which scenario contributes to the largest global energy recovery from stillage before the final disposition in the soil.

The amount of necessary ethanol to assist the functional unit (83.3 litres) and the electricity exported to the net were considered as exits of the system. The outlet will be formed by the sum of the input amounts multiplied by the respective energy coefficient (Figures 9–12 and Table 6).
Fig. 9—Energy inputs and outputs considered for the evaluated scenarios for FCDCC.

Fig. 10—Energy inputs and outputs considered for the evaluated scenarios for ABDCC.

Fig. 11—Energy inputs and outputs considered for the evaluated scenarios for SCDTT.

<td>15.6</td>
</tr>
<tr>
<td>SCCBA</td>
<td>544.16</td>
<td>2564.36</td>
<td>4.7</td>
</tr>
</tbody>
</table>

The alternative with the best energy performance was FCDCC (20.9), followed by ABDCC (19.1) and SCDTT (15.6). The SCCBA alternative presented an energy balance of 4.7 which is lower than that reported in the literature for the whole production cycle of ethanol (Macedo et al., 2004). That is due to the use of fuel oil (9.66 kg fuel oil/m³ stillage) as auxiliary fuel for stillage combustion.

Characterisation and normalisation of the environmental impacts

In this stage, the potential effects caused by the environmental loads emitted in the product system are described in terms of consumption of natural resources, or in impacts caused to the ecosystem and human health, depending on the type of model used (midpoint or endpoint indicator).

The LCIA of the four treatment alternatives and disposition of the analysed stillage were accomplished through the use of the method CML 2 baseline 2000, with the help of the computational tool Simapro 7.0®.

Figure 13 displays a summary of the values of these categories for the disposition alternatives and treatment of the analysed stillage in percentile. Figure 14 presents a percentile comparison of the contribution of each evaluated scenario in each impact category.

In relation to the characterisation of the impacts (Figure 13), the SCDTT scenario obtained the best environmental behaviour in 5 categories, FCDCC scenario was better in 2 categories, ABDCC scenario was better in 1 category and SCCBA was better in 1 category (Table 7).
In relation to the normalisation of the impacts (Figure 14), the CML 2 baseline 2000 considers the emissions of the equivalent substances for the year of 1990. The normalisation factors are: ADP (6.32*10^{-12} kg Sb eq./year), GWP (2.27*10^{-14} kg CO2 eq./year), HTP (1.67*10^{-14} kg 1,4-DB eq./year), FEP (4.83*10^{-15} kg 1,4-DB eq./year), MEP (1.32*10^{-15} kg 1,4-DB eq./year), TEP (3.79*10^{-12} kg 1,4-DB eq./year), POP (9.59*10^{-12} kg C2H4 eq./year), ACP (3.09*10^{-12} kg SO2 eq./year) and ETP (7.53*10^{-12} kg eq./year). Therefore, in the global sum of all the categories, dimensionless the option of SCDTT obtained the best environmental performance (−1.14*10^{-11}), followed by FCDCC (−1.01*10^{-11}), ABDCC (−9.47*10^{-12}) and SCCBA (−7.58*10^{-12}).

Conclusions

The recovery of the energy value of the stillage could be accomplished before its final disposition. In this scenario, the anaerobic bio-digestion was shown to be quite favourable in three indicators: use of the soil, emission of GHG as a function of the generated kWh, and also in the use of abiotic resources. The energy recovery through combustion was shown to be environmentally
unfavourable due to the intensive use of auxiliary fuel (fuel oil), which turned it into an unfavourable scenario from the energy point of view.

The application of LCA for evaluation of the environmental impacts caused by the stillage does not allow a complete analysis, because associated uncertainties exist about the lixiviation and volatilisation of the stillage applied to the soil. Besides, ions in the stillage, mainly potassium, phosphorus (phosphate) and the nitrogen compounds can be lixiviated for the water table. The great obstacle in relation to the quantification of these impacts is the nonexistence of reliable information on what really happens with the stillage when it is applied to the soil.

Résumé

DES NOUVEAUX itinéraires alternatifs pour le traitement et l'élimination de la vinasse doivent être proposés, car la fertigation pourrait devenir non acceptable, en raison de l'augmentation des frais de transport et des préoccupations environnementales. Le but de cette communication est de démontrer les résultats de l'application de la méthodologie d'évaluation du cycle de vie (ECV) pour l'analyse et la comparaison de quatre approches de traitement et d'élimination de la vinasse: fertigation conventionnelle ‘in natura’, digestion anaérobie, concentration jusqu'à 40% pour la fertigation et concentration jusqu'à 65% pour la combustion dans les chaudières utilisant du fioul comme carburant. Pour l'étude ECV, un complexe industriel standard hypothétique de sucre et d'éthanol avec une capacité d’usinage de 1.99 millions de tonnes de canne à sucre par campagne, produisant 154 000 tonnes de sucre et de 81 000 m³ d'éthanol, a été considéré. Le complexe est situé à proximité de la ville de Sertãozinho et les caractéristiques du sol ont été prises en compte également. Les résultats de l'évaluation environnementale en comparant les quatre approches pour l'élimination de la vinasse sont détaillés. Le logiciel Simapro® et le CML2 baseline 2000 ont été utilisés comme outils de support. L'élimination de la vinasse par fertigation par mode conventionnelle et par concentration se sont avérées les meilleures approches sur le plan environnemental. Dans la combustion de la vinasse, nous avons pris en considération l'installation de dispositifs antipollution pour SOx et NOx à une efficacité de 95%. Du point de vue du changement climatique, basé sur l’équilibre du cycle de vie des gaz à effet de serre, la meilleure alternative était la biodigestion.
EMPLEO DE LA EVALUACIÓN DEL CICLO DE VIDA (LCA) PARA LA COMPARACIÓN DEL COMPORTAMIENTO AMBIENTAL DE CUATRO ALTERNATIVAS PARA EL TRATAMIENTO Y DISPOSICIÓN DE LAS VINAZAS RESIDUALES DEL ETANOL

PALABRAS CLAVES: Vinazas, Disposición Final, Análisis del Ciclo de Vida.

Resumen

Es conveniente proponer nuevas rutas para el tratamiento y disposición de las vinazas residuales de la producción de etanol en cuanto la fertirrigación puede resultar inviable debido a los incrementos de los costos de transporte y preocupaciones ambientales. El objetivo de este trabajo es mostrar los resultados de la aplicación de la metodología de Evaluación del Ciclo de Vida (LCA, en inglés) para el análisis y la comparación de cuatro (4) alternativas para el tratamiento y la disposición de las vinazas residuales: convencional con fertirrigación ‘al natural’, digestión anaeróbica, concentración hasta el 40% (de sólidos) para fertirrigación y concentración a 60% para combustión en calderas empleando fuel oil como combustible complementario. Para el estudio del LCA, se asumió un hipotético Central Productor de Azúcar y Alcohol (SSAM), con una capacidad de molienda de 1.99 millones de toneladas de caña por zafra, produciendo 154 mil toneladas de azúcar y 81 mil m³ de etanol. El central está localizado cerca de la ciudad de Sertaozinho y se consideraron las condiciones de los suelos locales. Se presentan los resultados de la evaluación ambiental al comparar las cuatro alternativas de disposición. Se emplearon como herramientas de soporte digital el software SIMAPRO® y la baseline CML 2, 2000. Las alternativas de fertirrigación convencional y la de concentración tuvieron en general el mejor desempeño ambiental. En la combustión de las vinazas consideramos la instalación de componentes de control de la contaminación, con 95% de eficiencia para SOx y NOx. Desde el punto de vista del Cambio Climático, basado en el balance del Ciclo de Vida de Gases de Efecto Invernadero, la mejor alternativa resultó la biodigestión.
EFFECT OF CALCIUM IONS ON ETHANOL PRODUCTION FROM MOLASSES BY SACCHAROMYCES CEREVISIAE

KEYWORDS: Molasses, Ethanol, Calcium, Saccharomyces cerevisiae, Invertase.

Abstract

ONE OF THE most widely used feedstocks for potable or biofuel ethanol fermentation is blackstrap molasses, a by-product of cane sugar production. Inconsistent quality of molasses frequently found in industrial production, however, makes ethanol production much less efficient and cost-ineffective. Besides fermentable sugars (sucrose, glucose and fructose) present in molasses, calcium is also found in the range of 10–20% of the total carbonated ash (15% by weight). In the sugar process, calcium is usually applied as lime, CaO, during defecation, which sometimes results in over-liming if juice quality is poor. In this study, the role of calcium residues (0–0.72% w/v of Ca²⁺ in the form of calcium chloride) on fermentation efficiency of yeast was evaluated using model solutions of sucrose, glucose and fructose (20% w/v). The results suggest a detrimental effect of calcium ions on yeast performance which was concentration dependent. A slight decrease in fermentation rates and ethanol yields was evident when calcium was present at 0.18% w/v Ca²⁺ in all sugar solutions. This effect was more pronounced when calcium ion concentration increased. At 0.72% w/v of Ca²⁺, the rates of fermentation and ethanol yields of all sugars were considerably decreased (the ethanol yields decreased by 14–25% relative to the control sample, i.e. no calcium ion added). At a very high concentration of Ca²⁺ (2.16% w/v), yeast fermentation of sucrose was almost absolutely inhibited. This might be, in part, due to the inhibition effect of invertase enzyme for conversion of sucrose to invert sugars, a limiting step in ethanol fermentation of sucrose by yeast. The pretreatment of molasses by acid and heat prior to fermentation was then introduced to remove calcium which improved the fermentation efficiency.

Introduction

The most widely used feedstock for potable or biofuel ethanol fermentation by yeast, Saccharomyces cerevisiae, is sugarcane in forms of syrup and blackstrap molasses, a by-product from cane sugar production. Molasses is rich in many nutrients that are essential for microbial fermentation. It consists mainly of sugars including sucrose, glucose and fructose (approximately 30–40, 4–9 and 5–12 g/100g molasses, respectively) (Chen and Chou, 1993).

Sucrose, the most available fermentable sugar in molasses, is first inverted by yeast-secreted invertase sugars which are subsequently converted, under anaerobic conditions, by yeast to ethanol and carbon dioxide.
Besides these fermentable sugars, there are other components, viz. protein, minerals (potassium, calcium, sodium, magnesium, copper, iron, manganese, zinc, chloride and sulfur) and vitamins (biotin, folic acid, riboflavin, thiamine and niacin) some of which are essential for yeast growth and metabolism.

Among various minerals present in molasses, calcium is found as the second after potassium, in the range of 0.3–0.9 and 1.5–6.0% by weight of molasses with 75% dry substance for calcium and potassium, respectively (Higginbotham and McCarthy, 1998). In the sugar process, calcium is typically applied as lime, CaO, during defecation, which sometimes results in over-liming if juice quality is poor. Calcium can be discharged into the final molasses which presumably affects the ethanol production efficacy in various process stages, including yeast fermentation and ethanol distillation.

In this study, the role of calcium residues (0–0.72% w/v of Ca$^{2+}$ in the form of calcium chloride) on fermentation efficiency of yeast was evaluated using model solutions of sucrose, glucose and fructose (20% w/v).

**Materials and methods**

**Materials**

Molasses was obtained from MitrPhol sugar factory, Thailand. An invertase enzyme ($\beta$-fructofuranosidase) was supplied by Novozymes Co. Ltd. (Bagsvaerd, Denmark). Yeasts, *Saccharomyces cerevisiae*, were a commercial dry active product (BioFerm-XR, North American Bioproducts Corporation - NABC, USA).

**Effect of calcium on yeast fermentation of sucrose at high calcium concentrations (0–2.16% w/v of Ca$^{2+}$)**

The sucrose solution (20% w/v) containing different calcium concentrations (0–2.16% w/v of Ca$^{2+}$ in the form of CaCl$_2$.2H$_2$O) was prepared with the addition of some nutrients (10 g/L of yeast extract; 1 g/L of KH$_2$PO$_4$; 1g/L of (NH$_4$)$_2$SO$_4$ and 0.5 g/L of MgSO$_4$.7H$_2$O) at pH 4.5. Yeasts, *Saccharomyces cerevisiae* (BioFerm-XR) were added (0.6 g/L) and the fermentation was achieved at 32°C for 48 h in a 5L-fermentor with controlled temperature and pH. The samples were collected at different time intervals and analysed for sugar and ethanol contents by High Performance Liquid Chromatography methods using a Sugar-Pak TMI column (6.5 x 300 mm; Waters Corporation, MS, USA) at 80°C with a Refractive Index detector (Water 410 Differential Refractometer, Waters Corporation, MS, USA) and the eluent of 0.05 g/L Calcium Titriplex® dihydrate at the flow rate of 0.5 mL/min, according to ICUMSA Method GS7-23 (ICUMSA, 1994). The fermentation efficiencies were reported as a percentage of experimental to theoretical yields of ethanol.

**Effect of calcium on yeast fermentation of sucrose, glucose and fructose at low calcium concentrations (0–0.72% w/v of Ca$^{2+}$)**

The sugar solutions, i.e. sucrose, glucose and fructose (20% w/v) containing different calcium concentrations (0, 0.18, 0.36 and 0.72% w/v of Ca$^{2+}$ using 0, 0.5, 1.0 and 2.0% w/v of CaCl$_2$.2H$_2$O, respectively) were prepared with the addition of some nutrients (10 g/L of yeast extract; 1 g/L of KH$_2$PO$_4$; 1 g/L of (NH$_4$)$_2$SO$_4$ and 0.5 g/L of MgSO$_4$.7H$_2$O) at pH 4.5. Yeasts, *Saccharomyces cerevisiae* (BioFerm-XR) were added (0.6 g/L) and the fermentation was achieved at 32°C for 48 h in a 1 L-flask without controlled temperature and pH.

The samples were collected at different time intervals and analysed for sugar and ethanol contents by High Performance Liquid Chromatography methods using a Sugar-Pak TMI column (6.5 x 300 mm; Waters Corporation, MS, USA) at 80°C with a Refractive Index detector (Water 410 Differential Refractometer, Waters Corporation, MS, USA) and the eluent of 0.05 g/L Calcium Titriplex® dihydrate at the flow rate of 0.5 mL/min, according to ICUMSA Method GS7-23 (ICUMSA, 1994). The fermentation efficiencies were reported as a percentage of experimental to theoretical yields of ethanol.
Effect of calcium concentration on hydrolytic activity of invertase enzymes

The sucrose solutions (10% w/v) containing different calcium concentrations, i.e. 0, 0.18, 0.36, 0.72, 1.44, 2.16 and 2.88% w/v (in a form of CaCl$_2$.2H$_2$O) were thoroughly mixed with invertase enzymes (the enzyme concentration was 5.84 mg/mL) at pH 4.5.

The mixtures were incubated at 32 and 55°C for 1 h. Subsequently, the enzyme activities were terminated by boiling for 15 min and the aliquots were used to quantify the amount of reducing sugars by Somogyi-Nelson method (Somogyi, 1952).

Fermentation of molasses with acid pretreatment

The qualities of molasses were analysed including total soluble solids by a refractometer, sulfated ash (GS1/3/4/7/8-11 method) and conductivity ash (GS1/3/4/7/8-13 method) according to ICUMSA method (ICUMSA, 1994) and pH by a pH meter.

The amount of fermentable sugars was quantified using a High Performance Liquid Chromatography (ICUMSA Method GS7-23; ICUMSA, 1994) equipped with a Sugar-Pak TMI column (6.5 × 300 mL, Water Corporation, MS, USA) at 80°C and operated with 0.05 g/L calcium titriplex® dehydrate (Ca-EDTA) at the flow rate of 0.5 mL/min. The calcium content was estimated by Inductively Coupled Plasma technique (AOAC, 2000).

Molasses was pretreated with sulfuric acid prior to yeast fermentation. Sulfuric acid (1N H$_2$SO$_4$) was added to molasses until the pH of sample reached 3.0. The mixture was then heated to 95°C for 0.5 h and then left overnight at room temperature.

The precipitates were then removed by filtration. The pretreated molasses was subsequently fermented by adjusting the total soluble solid content of molasses to 25°Brix at pH 4.5. Some essential nutrients including 10 g/L of yeast extract; 1 g/L of KH$_2$PO$_4$; 1 g/L of (NH$_4$)$_2$SO$_4$ and 0.5 g/L of MgSO$_4$.7H$_2$O were added to ensure a proper growth of yeast during ethanol fermentation.

The fermentation was achieved by *Saccharomyces cerevisiae*, without and with 0.36% calcium (or 1% w/v of calcium chloride, CaCl$_2$.2H$_2$O), at 32°C for 48 h.

The samples were collected at different time intervals and analysed for sugar and ethanol contents by chromatographic methods as described previously.

Results and discussion

Sucrose, a major sugar component found in cane molasses, is a fermentable sugar that can be converted to ethanol by yeast fermentation. During fermentation, yeasts convert sucrose to invert sugars by invertase enzymes secreted by yeasts themselves.

In this study, ethanol was produced from sucrose solutions containing different calcium concentrations (0–2.16 % Ca$^{2+}$). Figure 1 demonstrates the effect of calcium ions on the ethanol production of sucrose by yeasts.

Calcium induced a reduction in ethanol production. The adverse effect was more pronounced when the calcium concentrations increased; the ethanol yield could be reduced up to 86% (the ethanol yields and fermentation efficiencies were decreased from 0.508 to 0.070 g/g sugar as invert and from 99.38 to 13.71% for samples with 0 and 2.16% Ca$^{2+}$, respectively (Table 1).

A reduction of ethanol production during sucrose fermentation induced by calcium was likely caused by an inhibition effect of invertase by calcium.

In fact, the conversion of sucrose to invert sugars is reported as the limiting step for ethanol production by yeast fermentation of sucrose.

Takeshige and Ouchi (1995) reported the effect of some metal ions on ethanol productivity by yeasts, which were strain-dependent.

The yeast strain with low ethanol productivity exhibited a lower invertase activity when it utilised molasses containing metal ions, in particular copper, potassium and calcium, indicating an inhibition effect on invertase activity.

\]

To further investigate that, sucrose solutions were converted to invert sugars by external invertase in the presence of calcium. Regardless of the incubation temperatures at 55°C, an optimum temperature of this enzyme or 32°C, an optimum temperature for *Saccharomyces cerevisiae* yeast, the invertase enzymes were inhibited by calcium as the amount of reducing sugars was lower (Figure 2).

At 55°C, the effect of calcium was less as compared to that at 32°C. At a low calcium concentration (0.18% w/v), the activity reduction of invertase enzymes was 1.84 and 17.29% at 55 and 32°C, respectively, as compared to the control treatment, i.e. no calcium addition.
The effects of calcium, at low concentrations (0–0.72% w/v Ca$^{2+}$), on ethanol productivity were further investigated by fermenting sucrose, glucose and fructose with *Saccharomyces cerevisiae* yeasts at 32°C without controlled conditions to simulate the actual industrial process.

Without calcium ions, the fermentation efficiencies of all sugars were highest, yet the fermentation efficiency of sucrose was lower than the previous trial which was achieved under controlled conditions in a fermentor.

Nevertheless, the results demonstrated the reduction of ethanol productivity during fermentation of sucrose, glucose and fructose by *Saccharomyces cerevisiae* yeasts when calcium ions were added (Table 2).

The degrees of fermentation efficiency reduction were different. It was likely that fermentation of glucose was least affected by calcium.

At the same level of calcium, fermenting sucrose seemed to be the most affected by calcium (% yield reductions were 25.16, 13.72 and 20.18% for sucrose, glucose and fructose fermentation in the presence of 0.72% w/v Ca$^{2+}$, respectively.)

The composition of molasses is presented in Table 3. Calcium can affect the production efficiency of ethanol from molasses as it acts as an inhibitor of invertase enzymes, which are very crucial for breaking sucrose to glucose and fructose.

This causes a slow reaction rate during the limiting step of molasses fermentation. In addition to the inhibition effect, the metal ion can be toxic to the yeasts and influence the ionic strength and pH of the medium.

Some techniques are introduced to minimise this problem such as the addition of external invertase which is not cost-effective and the formation of insoluble complexes of metal ions with some chemicals, e.g. ferrocyanide and EDTA (Oderinde et al., 1986). The pretreatment of molasses with sulfuric acid is also applied in order to remove calcium ions.

In this work, blackstrap molasses containing 0.66% w/v Ca$^{2+}$ was used for ethanol production with the acid pretreatment. As expected, a slight improvement on ethanol production from pretreated molasses was observed (Figure 3).
Conclusion

In the cane sugar process, molasses can be adulterated with calcium ions, leading to its inferior quality and for being used as the feedstock for ethanol production by yeast fermentation.

Calcium ions can act as an invertase inhibitor which inhibits the inversion of sucrose to invert sugars. Furthermore, the fermentation of invert sugars can be adversely affected by calcium.

It is, therefore, critical for ethanol factories to analyse the quality of molasses prior to use. An efficient technique for eliminating calcium should be further developed for industrial uses.

Résumé

UN DES PRODUITS de base le plus largement utilisé pour la fermentation de l’alcool de bouche ou de biocarburant est la mélasse ‘blackstrap’, un sous-produit de la production de sucre à partir de la canne à sucre. La qualité irrégulière de la mélasse, fréquemment issue de la production industrielle, fait cependant que la production d'éthanol soit moins efficace en quantité de produit obtenu et en coût. En outre des sucres fermentescibles réducteurs (saccharose, glucose et fructose) présents dans la mélasse, le calcium se trouve également dans la plage de 10 à 20% des cendres carbonatées totales (15% en poids). Lors de la fabrication de sucre, le calcium est généralement appliqué sous forme de chaux, CaO, au cours de la défécation, ce qui entraîne parfois un chaulage en excès si la qualité de jus est mauvaise. Dans cette étude, le rôle des résidus de calcium (0–0.72% m/v de Ca2+ sous la forme de chlorure de calcium) sur l'efficacité de la fermentation par levure a été évalué à l'aide des solutions modèles de saccharose, de glucose et de fructose (20% p/v). Les résultats suggèrent un effet néfaste des ions de calcium sur les performances des levures qui étaient en relation avec la concentration. Une légère baisse de taux de fermentation et des rendements de l'éthanol étaient évidents lorsque le calcium était présent à 0.18% m/v Ca2+ dans toutes les solutions de sucre. Cet effet a été plus prononcé lorsque la concentration en ions de calcium a augmenté. À 0.72% m/v de Ca2+, les taux de fermentation et les rendements d'éthanol de tous les sucres ont été considérablement réduits (les rendements en éthanol ont diminué de 14 à 25% par rapport à l'échantillon de contrôle, c'est-à-dire aucun ion de calcium ajouté). À une très forte concentration de Ca2+ (2.16% m/v), la fermentation de saccharose par la levure a été presque totalement inhibée. Cela peut être, en partie, en raison de l'effet d'inhibition des enzymes invertases pour la conversion de saccharose en sucres invertis, une étape limitative de la fermentation de saccharose en éthanol par la levure. Le prétraitement des mélasses par acide et la chaleur avant la fermentation a été ensuite introduit pour éliminer le calcium, ce qui a amélioré l'efficacité de fermentation.
EFECTO DE LOS IONES CALCIO EN LA PRODUCCIÓN DE ETANOL A PARTIR DE MELAZAS POR SACCHAROMYCES CEREVISIAE

APARAS CLAVE: melazas, Etanol, Calcio, Saccharomyces cerevisiae, Invertasa.

Resumen

UNA DE LAS materias primas más ampliamente utilizadas para la fermentación del etanol potable y combustible son las mieles finales de caña (miele C), un subproducto de la producción de azúcar de caña. La inconsistente calidad de las mieles en la producción industrial, hacen, sin embargo, la producción de etanol mucho menos eficiente y efectiva económicamente. Además de los azúcares fermentables (sacarosa, glucosa, fructosa) presente en las melazas, también el calcio se encuentra en un rango de 10–20% de la ceniza total carbonada (15% en peso). En el proceso azucarero el calcio se aplica usualmente como lechada, CaO, durante la clarificación, lo que resulta en una sobre alcalización si la calidad del jugo es pobre. En este estudio se evalúa el papel de residuos de calcio (0–0.72% w/v de Ca²⁺ en forma de cloruro de calcio). Los resultados sugieren un efecto depresor de los iones calcio sobre el comportamiento de la levadura que era dependiente de la concentración. Resultó evidente un ligero crecimiento en la velocidad de fermentación y en el rendimiento de etanol cuando el calcio estaba presente a 0.18%w/v Ca²⁺ en todas las soluciones de azúcar. Este efecto fue más pronunciado cuando la concentración de iones calcio se elevaba. A valores de 0,72% w/v Ca²⁺, las velocidades de fermentación y los rendimientos de etanol en base a todos los azúcares caían considerablemente (el rendimiento de etanol decía 14–25% en relación con las muestras de control que no tenían calcio). A muy altas concentraciones de Ca²⁺ (2.16% w/v), la fermentación de azúcares por las levaduras fue casi absolutamente inhibida. Esto puede deberse, en parte, al efecto inhibidor de la enzima invertasa en la conversión de sacarosa en azúcares invertidos, un paso limitante en la fermentación alcohólica de los azúcares por levaduras. El pretratamiento de las melazas con ácido y calor, previa a la fermentación, se aplicó para remover el calcio, lo que mejoró la eficiencia de fermentación.
THERMAL UTILISATION OF VINASSE AS ALTERNATIVE FUEL

By

KEYWORDS: Vinasse, Molasses, Steam Production, Swirlburner.

Abstract

SAACKE has designed a special burner for utilising biogenic fuels that occur as by-products, for example during the production of bioethanol. When the fermented mash from soy or sugarcane molasses is distilled to separate bioethanol, soy molasses and vinasse are produced. From the point of view of combustion, molasses and vinasse are very similar (40–50% water, 40–50% organics, about 10% ash). These are liquid by-products with an extremely low calorific value that could not be used to generate energy in the past. Today, the SSB-LCL swirl burner makes it possible to use these materials in concentrated form, with around 20 percent support fuel added to them, to generate heat, which is in turn fed back into the production process. As a result, 80 percent of the fuels previously required to produce bioethanol can be saved. When soy molasses and vinasse are burnt, only ash remains as a high-quality, odourless fertiliser that can be returned to the soil. This is an enormous benefit for the environment because nowadays the residue from soy and sugar production in Asia and Latin America is generally dumped on the area under cultivation. The first step in this direction has already been taken in Brazil: in Araucaria, in the State of Paraná, where molasses and vinasse have been burnt using SAACKE burners since 2007.

Introduction

Several academic works deal with efforts to achieve ‘zero effluent’ in alcohol distilleries as well as significant energy savings (Perera, 2008, Avram-Waganoff et al., 2009, Schopf and Erbino, 2006). These papers put forward irrefutable arguments demonstrating the feasibility and desirability of this goal.

One of the requirements for achieving these goals is utilisation of vinasse as a fuel, which will be explained in detail in the following.

Functional principle of the SSB-LCL burner

Low calorific fuels such as soy molasses or vinasse have calorific values that are too low to be burnt with conventional burners. However, it is possible to burn such fuels in a SSB-LCL (SAACKE Swirl Burner for Low Calorific Liquids) firing system and to feed the resulting exhaust gases to a boiler or a combustor. The system consists of a SAACKE swirl burner with a special burner throat.

The SSB is a well-proven gun-type burner for industrial and power station plants. This burner was developed for the combustion of natural gas and fuel oil and operates according to the ‘mixing at the burner mouth’ principle. This burner results in particularly low CO and NOx emissions. It is meanwhile also used in a lot of applications for low calorific gases with even below 3 MJ/m³ LHV.

The swirl-type burner primarily consists of the following structural components (Figure 1):

- Tangential wind box.
- Central fuel gun for vinasse.
• Second fuel gun for support fuel (liquid or gaseous).
• Combustion air control damper with control drive.
• Core air damper with control drive.
• Combustion air monitoring system consisting of a pressure monitor with test valve and pressure gauge with isolating valve.
• Flame scanner and gas-electric igniter.

The firing plant is started up with a high calorific fuel using the swirl burner and heated up to the temperature in the throat required for complete combustion of the gases. The typical temperature is about 650°C which is reached in about 30 minutes.

The low calorific fuel is then supplied to the burner via a dedicated atomising system. The fuel quantity required to start up the combustor is reduced for subsequent low calorific combustion so that a pilot flame is continually maintained assuring safe combustion of the low calorific fuel.

The required quantity of support fuel depends on the burning characteristics of the low calorific fuel used.

The required combustion air is tangentially supplied via the burner inlet elbow. In this inlet it is fed into the annulus between inner and outer body and accelerated in the conical part from which the swirled air then enters the furnace. The air annulus is adjusted such that an overcritical swirl is generated in the furnace. The core air is supplied to the burner separately and flows through the annulus between the fuel gun and the concentric core air tube. The combustion air and the core air control damper are adjusted by a control drive depending on the load requirements. The control drives are activated by the compound control system.

By optimum positioning of main and core air a wide control range, optimum combustion and low emission values are safely achieved at all burner loads.

The strong swirling of the combustion air causes a very intense mixing of fuel and air, which together with the hot brickwork lining provides for safe ignition of the mixture and total burn-out with a homogeneous temperature profile. Liquid as well as gaseous fuels can be used as start-up and pilot fuel. Ash fusion is avoided by controlling the flame temperature, either by means of the excess air ratio or percentage of support fuel. Therefore, all ash components are in the flue gas as dry powder.

Vinasse is a final by-product of fermentation to alcohol. After removal of the alcohol by distillation the remaining material is vinasse. For combustion it should be concentrated up to 40–50% of water.

Soy molasses is a final by-product of the soy protein industry. For combustion it should be concentrated.

Case study

Two SSB-LCL burners, each rated at 26 MW, were installed on a boiler at Araucaria in Brazil (Schopf, 2009). At about the same time, a 35 MW burner was installed on another boiler. The case study examines the boiler containing the two 26 MW burners (see Tables 2 and 3).

One of the main fuels is vinasse with either natural gas or fuel oil as support fuel. The specification for the boiler design required that maximum percentage of the support fuel must not exceed 20%. It is planned to upgrade the boiler to 42 Bar (g) and 70 t/h in the future. The burners are designed for this purpose.

Obstacles surmounted in the projects

**High ash content in soy molasses/vinasse fuels**

It was mainly a problem of the boiler design. The solution was achieved by means of an optimised flue gas system design, strategic soot blower system equipment installation and the scrubber system. Considering the high amount of ash in the fuels, we can say the results have been satisfactory. The continuous operation time of the boiler is about 3 months without shutdown. Most of the ash is removed behind the boiler by a Venturi scrubber.

**High water content in soy molasses/vinasse fuels**

It was a major point to be considered from the point of view of the boiler design because the water vapour generated in exhaust gases due to the water content of the fuel is extremely high (up to 40% by volume).

In addition, it is a major obstacle for the combustion system. Flame stability was only possible by using the special SSB-LCL combustion system. The high swirl and special LCL burner throat ensure flame stability.

**Very low heat calorific value of soy molasses/vinasse fuels**

It was a challenge especially for the combustion system. Flame stability was only possible by using the special SSB-LCL combustion system. The high swirl and the combustion chamber ensure flame stability.

**Conditioning system for proper atomisation of soy molasses/vinasse fuels**

This point requires special attention due to the corrosibility of soy molasses, the crystallisation (sugar caramel) that occurs in contact with heated surfaces and the difficulty in achieving good atomisation. The piping material and pumps used are specially designed. The heating system with a viscosity control loop involves direct steam injection. The optimum atomisation was achieved by testing several nozzle types and testing different viscosity conditions as well several molasses concentrations (see Figure 2).

![Vinasse viscosities in dependence on temperature](image)

Fig. 2—Influence of dry matter levels and preheating temperature on the viscosity of vinasse.

**Results**

The experience gained provided good feedback and knowledge for the combustion system manufacturer and the boiler manufacturer. The technology is a proven one.

The main points are that at 5% oxygen in the fuel gas (typical operation point) the CO emissions are significantly below 50 ppm and the NOx value is below 300 ppm (Table 3). Another important point is that no slagging occurs in the burner throat or the boiler, which is achieved by the burner management system (BMS) supplied by SAACKE. This is done by controlling the flame temperature in a small range between 850–950°C with the help of either excess air ratio or percentage of support fuel. By this the continuous operation time of the boiler is more than 3 months.
Last but not least: the plant in Araucaria (Figures 3, 4, 5) will pay for itself within far less than two years because 80% of the natural gas previously used is saved! The results surpassed the initial expectations.

Conclusion

When soy molasses and vinasse are burnt, only ash remains as a high-quality, odourless fertiliser that can be returned to the soil. This is an enormous benefit for the environment because nowadays the residue from soy and sugar production in Asia and Latin America is generally dumped on the area under cultivation.

This paper has shown that firing plants for soy molasses/vinasse offer an economical and ecological answer to the increasing and highly diversified industrial demand for alternative fuels. Various technological innovations and improvements now make it possible to utilise the potential heat energy available in by-products and waste from the sugarcane and bioethanol industries by firing them as alternative fuels instead of merely disposing of them. This means that, depending on the application, they can be used to replace, completely or partially, expensive standard fuels such as natural gas. In addition, CO₂ emissions from non-renewable fuel are considerably reduced as well.

MOTS-CLES: Vinasse, Mélasse, Production De Vapeur, Brûleur à Faible Turbulence.

Résumé

SAACKE a conçu un brûleur spécial pour les carburants biogènes qui sont générés comme des sous-produits, par exemple lors de la production de bioéthanol. Lorsque le soja et la mélasse de canne à sucre sont distillés après fermentation, pour la production de bioéthanol, mélasse et vinasse sont produites. Du point de vue de la combustion, mélasse et vinasse sont très similaires (40–50% d'eau, 40–50% les produits biologiques, environ 10% de cendres). Ce sont des sous-produits liquides avec une valeur calorifique extrêmement faible qui ne pouvaient être utilisés dans le passé pour produire de l'énergie. De nos jours avec le brûleur à faible turbulence, il est possible d'utiliser ces matériaux en forme concentrée en mélange avec 20% de carburant pour générer de la chaleur qui est à son tour réinjectée dans le procédé de production. Ainsi, 80 pour cent des carburants précédemment nécessaires à la production de bioéthanol peuvent être économisés. Lorsque la mélasse et la vinasse sont utilisées comme combustible il en résulte seulement des cendres qui constituent un engrais inodore, de haute qualité qui peut être incorporé au sol. Il s'agit d'un avantage immense pour l'environnement car de nos jours le résidu de la production de soja et de la canne à sucre en Asie et en Amérique latine, est généralement disposé sur les superficies cultivées. Le premier pas dans cette direction a déjà été fait en Araucaria dans l'état du Paraná au Brésil où la mélasse et la vinasse ont été utilisées à l'aide de brûleurs SAACKE depuis 2007.
EMPLEO TÉRMICO DE LAS VINAZAS COMO COMBUSTIBLE ALTERNATIVO

PALABRAS CLAVE: Vinazas, Melazas, Producción de Vapour, Quemador de Torbellino.

Resumen

SAACKE ha diseñado un quemador especial para el empleo de combustibles biogénicos que constituyen sub-productos, por ejemplo durante la producción de bioetanol. Cuando el mosto fermentado de soya o de caña de azúcar se destila para separar bioetanol se producen melazas y vinazas. Desde el punto de vista de la combustión las melazas y las vinazas son muy similares (40-50% de agua, 40–50% de orgánicos, cerca de 10% cenizas). Éstos son subproductos líquidos con un extremadamente bajo valor calórico que no podían ser empleados en el pasado para generar energía. Hoy el quemador de torbellino SSB-LCL hace posible emplear estos materiales concentrados, con adición de alrededor de 20% de combustible soporte, para generar calor, el que es retornado al proceso productivo. Como resultado, el 80% del combustible anteriormente requerido para producir bioetanol puede ahorrarse. Cuando las melazas y las vinazas se queman solo quedan cenizas como un fertilizante de alta calidad e inodoro que puede retornarse al suelo. Este es un enorme beneficio al ambiente, porque actualmente los residuos de la producción de soya y azúcar en Asia y Latinoamérica generalmente se arrojan en las áreas de cultivo. Los primeros pasos en esta dirección se han dado en Brasil, en Araucaria, en el estado de Paraná, donde las melazas y vinazas se queman empleando los quemadores SAACKE desde el 2007.
SUSTAINABILITY OF THE PRODUCTION OF ETHANOL FROM SUGARCANE: THE BRAZILIAN EXPERIENCE

KEYWORDS: Biofuels, Sustainability, Certification, Sugarcane, Greenhouse Gases.

Abstract

The increase in production of liquid biofuels from different feedstocks is causing concern for potential importers and users, as an alternative to reduce greenhouse gas (GHG) emissions. The sustainability of the whole production chain of each biofuel is under review. Some countries, especially in the European Union (EU), are jumping ahead in the process of preparing certification procedures to assure the sustainability of the different alternatives under consideration; this is the beginning of the process to show that all biofuels are not equal. Ethanol from sugarcane has demonstrated, so far, superiority over other biofuels (ethanol from grains or sugar beet, and biodiesel from soybeans or rapeseed), but the demonstration process must be clear and based on measurable parameters. Surplus power generation is an important point to improve the energy and Green House Gas (GHG) balances, increasing the value of ethanol in the GHG abatement process when it displaces the use of gasoline as a transport fuel. Brazil as a major producer and exporter of ethanol from sugarcane is working hard to demonstrate the sustainability of its ethanol, using reliable information, well established procedures and participating in the worldwide effort to produce certification standards. Net energy ratios above eight and GHG abatement efficiency better than 80% for the Brazilian production and use chain have been demonstrated. This paper presents a comprehensive assessment of this Brazilian work toward the demonstration of sugarcane ethanol sustainability, offering some insights and lessons for other countries starting in this process.

Introduction

The fast increase in the production of liquid biofuels from different feedstocks is becoming a cause of concern to the major users, especially with respect to the most important expected benefits, such as Greenhouse Gas (GHG) emission reduction in transport, and the sustainability of the whole production chain of each biofuel alternative.

As a consequence, several countries in the European Union and the USA are starting to develop certification procedures to make sure that the biofuel options under consideration are sustainable and really contribute significantly to the reduction of GHG emissions in the transport sector. This represents a considerable effort in preparing paperwork to demonstrate the carbon footprint and the other important characteristics of the specific biofuel with respect to its sustainability and contribution to global warming mitigation.

Figure 1 shows the growth of biofuels production from 2000 to 2005 (IEA, 2007), and it is a clear indication that choices have to be made at this stage to avoid embarking in a biofuel alternative without future–it is the realisation that biofuels are not equal; not only the biofuel itself, but also the feedstock used in its production. The main driving forces behind the production and use of biofuels are:
Energy security: the volatility of oil prices since 2002 and the political instability in some major oil producing countries are threats for the economies of countries that depend on oil imports.

GHG emission reduction: the transport sector is responsible for 14% of the global GHG emissions and, therefore, the substitution of renewable fuels for fossil fuels has an enormous potential for mitigation.

Rural jobs: the potential of biofuels production to increase the demand for agricultural products has attracted the interest of many countries, especially developing ones, to use this option to strengthen their rural economies and to create jobs in agriculture.

For the countries interested in producing biofuels for export, there are some additional points that need to be evaluated: the potential of biofuel use and which countries are an important target; regulations and certification activities underway in these countries; scenarios for future use of biofuels.

Considering the case of ethanol, the present use of gasoline is an indication of the potential for use of this renewable fuel. Table 1 presents the main gasoline consumers in the world.

Methodology

In this section, the main points are reviewed for selecting biofuel options and compared with the main characteristics of the Brazilian ethanol with respect to sustainability issues. Although the main focus of this work is on ethanol, in many instances biofuels will be treated in a similar way, because they all compete with ethanol in the liquid transport fuel market.

Certification initiatives

As explained above, the USA and EU countries are the ones with the highest potential for producing, using and importing biofuels, and for this reason will be the ones focused in this section.

USA

The RFS mandates the use of renewable transport fuels in an increasing proportion, reaching a total of 136 billion litres (36 billion US gallons) per year in 2022 and divides the biofuels in four different categories: renewable fuel, advanced biofuel, biomass-based diesel and cellulosic biofuel; the 136 billion litres are allocated to each category as 15, 4, 1 and 16 billion US gallons, respectively. The US Environmental Protection Agency can change these quantities in the future. The eligibility requirements for each category include the mandatory GHG reduction thresholds of 20%, 50%, 50% and 60% for renewable fuel, advanced biofuel, biomass-based diesel and cellulosic biofuel, respectively. First generation biofuels such as sugarcane ethanol can be in the advanced biofuel category if it satisfies the GHG reduction threshold. The California GHG target is 10% over the 1990 emissions level in the transport sector. In all cases, the GHG reduction is in comparison with gasoline.

EU

The Directive 2009/28/EC of the European Parliament and of the Council of 23 April 2009 on the Promotion of the Use of Energy from Renewable Sources (Official Journal of the European Union, L140/16, 5.6.2009) establishes mandatory targets of 20% share of renewable energy sources in energy consumption and a minimum of 10% for biofuels in transport to be achievable for each Member State. Extensive procedures to calculate GHG reductions are described and the Sustainability Criteria for Biofuels and Bioliquids are indicated in Article 17 of the Directive. The threshold limits for GHG reductions are set at 35% for plants coming into production from 2010 and will be increased to 50% for plants starting up in 2017 and 60% in 2018 (the existing plants will have to satisfy the limit of 50% minimum reduction).

There are other important certification initiatives in progress such as the Renewable Transport Fuel Obligation (RTFO) in the UK and the Cramer Report in Holland (Cramer et al., 2007), Roundtable of Sustainable Biofuel (RSB) in Switzerland, and Global Bioenergy Partnership (GBEP) coordinated by the UK.

The Better Sugarcane Initiative (BSI) mission is to ensure that current and new sugarcane production is produced sustainably (www.bettersugarcane.org) and is preparing the BSI Standard that is presently going through a public consultation process. Of all initiatives on biofuels sustainability, the BSI is the most specialised in sugarcane and depends on Technical Working Groups with reputable members of the international sugarcane sector to assist in the development of its work.

Key issues

From the analysis of the main biofuels certification initiatives, the key issues for sustainability can be selected for a more detailed assessment:

- Energy balance: it is normally represented by the Net Energy Ratio–NER (renewable energy output of biofuel and co-products divided by the fossil energy input in the
whole production chain). The NER gives a good indication of the capacity of the biofuel to reduce the dependency on fossil energy and can be extended to indicate the oil use in the process.

- Greenhouse Gas mitigation potential: this is presently the main characteristic of the biofuel to contribute to the global warming mitigation; it is an indication on how efficient and competitive it is in this process, for the abatement cost can be easily calculated. The procedures and standards to perform the so called GHG lifecycle analysis (LCA) are yet to be universally defined and accepted; a search in the technical literature shows a wide variation for different biofuels and even for the same biofuel and feedstock (Larson, 2006), mainly due to system boundaries definition, co-products credits calculation, soil emissions and land use change emissions.

- Demand for natural resources: it has to do, mainly, with the land and water demand, and is the key point in the, more emotional than technical, discussions about the impacts of biofuels on the food and feed availability and prices. Therefore, the productivity of the feedstock/biofuel pair in terms of litres/ha, or better GJ/ha, is very important as well as the ability to use rain-fed crops. A careful Agro-ecological Zoning of the main feedstocks is an important tool to demonstrate the ability to produce the biofuels without jeopardising the food and feed production.

- Production cost: there is no doubt that the economic leg of the Sustainability triad is the strongest one and, for this reason, the production cost of the biofuel, preferably measured in terms of US$/litre of gasoline or diesel equivalent, is the best indication if it will be able to compete with fossil fuels and other renewable energy alternatives to reduce GHG emissions, without subsidies in the long term; the parameter here will be US$/tonne CO2 equivalent.

- Impacts on biodiversity: a good Agro-ecological Zoning for the feedstocks will solve most of the problems and doubts. Just by avoiding planting in sensitive areas can be an important step to satisfy the requirements in this area.

- Social impacts: this issue is difficult to quantify. Procedures need to be developed to assess the impacts of the biofuel production on jobs, wealth of the local communities, labour issues, land ownership and others.

- Local environmental impacts: this is easier to monitor and quantify than the social impacts, but nevertheless it brings some challenging issues such as water contamination, soil quality and loss, waste management and air emissions.

There are other topics normally included in the certification procedures being proposed, but the above are the ones normally present in all initiatives.

The Brazilian experience

Having a long tradition in and being the second largest producer and user of ethanol in the world has brought to Brazil some valuable experiences that can be used by other countries to avoid repeating some of our mistakes and to indicate the shortest route to success. Of course this does imply that the Brazilian model can be used as is by any country. Each country has its own culture, experiences, laws and regulations and talents that need to be taken into account.

In sequence, the several indexes and conditions in the Brazilian ethanol production chain will be described and, where possible, quantified.

Energy balance

The energy balance in the ethanol production in Brazil has been analysed since the 1980s bringing some insights to the evolution and critical points for improvements (Macedo and Nogueira, 1985; Macedo, 1992). The methodology was consolidated by Macedo et al. (2004) and updated by
Macedo et al. (2008) with projections for 2020. In all these references, three levels of energy were considered: (a) Level 1: energy consumed directly in the feedstock production and processing such as fuels and electricity; (b) Level 2: energy required for the production of chemicals and materials (fertilisers, herbicides, seeds, chemicals, lubricants, etc.); (c) Level 3: energy embodied in the equipment and buildings and consumed in their maintenance.

A summary of the results is presented in Table 2.

Table 2—Energy consumption in ethanol production (MJ/t cane).

Source: Macedo et al. (2008)

The differences between 2002 and 2005 are mainly due to an update of the facilities configuration, diesel consumption and embodied energy coefficients. Between 2005 and 2020, the projected differences are due to sugarcane burning phase out, gains in sugarcane yield and sugar content, and technological improvements.

The input/output energy balance is shown in Table 3, based on the average conditions in the Center-South region (90% of sugarcane production in Brazil)

The details of this energy balance can be found in the reference (Macedo et al., 2008). The data presented in Table 3 show an excellent energy balance, and the methodology presented in the references can be used by any country to do its own energy balance and compare with the Brazilian one in detail.

**GHG lifecycle analysis (LCA)**

The GHG lifecycle analysis (LCA) derives mainly from the energy balance but there are non-energy related emissions that must be taken into account such as CO₂, methane and NO₂ emissions from cane burning, fertiliser, lime and residue decomposition, and soil carbon stock modification due to land use change. Table 4 presents a GHG LCA for the Brazilian conditions with projection for 2020 for anhydrous ethanol; the emissions due to direct and indirect land use change (LUC and ILUC) are not included due to the dependence on the local conditions (soil, climate, previous use of the land, specific agricultural practices, etc.) and the cause/effect relationship in the case of indirect land use change emissions.

Source: Macedo et al. (2008)
Note: 1 Displacing gasoline by the use of E25

It is interesting to look into the details of the analysis summarised in Table 4 in Macedo et al. (2008). It can be seen that, like in the energy balance, the agricultural area is the major source of GHG emissions and sugarcane yield plays a major role in the balance.

**Demand for natural resources**

In Brazil, sugarcane cultivation is mainly rain fed, although there is a trend to increase the use of irrigation in some dry areas such as the Northeast states and some areas in the new sugarcane frontier in the Center states savannah. The Agro-ecological Zoning of sugarcane will inhibit the expansion in these areas and the development and use of drought-tolerant varieties will help those already installed in these regions.

In most cases, only the salvatin irrigation is used (less than 200 mm/year, and is intended only to keep the sugarcane from dying during an unusually dry spell), but full irrigation alternatives are being evaluated in a few cases.

The water intake for use in the mill is being continuously reduced in Brazil, especially in São Paulo, where the value of 1 m³/t of cane was set as a limit for new mills being installed in the state; the average value for the Center/South region has been reduced from 5 m³/tc to 1.8 m³/tc in the past few years, motivated by the legislation that will introduce payments for water consumption and effluent discharge.

The water use main regulatory item is the Federal Law 9433 of 1997 that establishes the National Resource Policy and the National Water Resources Management System. This Federal law is complemented by several state level laws and regulations that create additional requirements and constraints.
Sugarcane is one of the most productive crops for biofuel production; under the present Brazilian average conditions, some 150 GJ/ha/y of renewable fuel (6500 litres of ethanol/ha/y). This figure can be significantly improved by the increase in sugarcane yields, better agricultural practices (such as precision agriculture, no tillage, maximum use of residues in the fields), optimum use of the sugarcane biomass (power generation and/or advanced technologies for biomass to liquids, BTL, for additional biofuel production).

In Brazil, the expansion of sugarcane cultivation is taking place mostly in pasture lands. There is a growing interest in developing and using technologies to intensify the cattle husbandry activities in terms of reducing land demand through increasing the number of cows per hectare. The integration of cattle and sugar/ethanol mills is also being investigated, with respect to the possibility of the mills to produce cattle feed from bagasse (hydrolysed), molasses and dried yeast.

This intensification process is proceeding in some areas, like the state of São Paulo, and creating a tremendous potential for new areas for sugarcane, without impacts on food/feed production or deforestation, since presently the pasture area is around 200 million hectares; just 10% of that would be sufficient for the sugarcane expansion foreseen for a few decades.

Even bearing in mind that water is an important and critical resource, the use of irrigation should not be ruled out to reduce the land demand and the fossil fuel consumption in the ethanol production chain. It is expected that the Agroecological Zoning, that has been recently approved, will regulate and orient the sugarcane expansion and decrease the impacts on and pressures for land demand.

Today, sugarcane occupies 8 Mha and, bearing in mind that only 55% of that is for ethanol production, the 4.4 Mha devoted to bioethanol represents only 0.5% of the total country area or 7% of the total cultivated land.

Production cost

The economics of biofuels is certainly the most important item in the long-term sustainability of each alternative without subsidies. It is important also to point out that subsidies tend to distort the market balance between production for food/feed and fuel of the agricultural feedstock.

In the case of Brazilian ethanol, a parity price to make it unimportant to produce either sugar or ethanol was a key point at the beginning of the National Ethanol Program back in 1975. The ethanol subsidies were highly reduced in the mid 1980s, and were totally phased out at the end of the 1990s.

The sugar/ethanol parity price was terminated in 1995. In this way, there has never been a sugar shortage, neither for the internal market nor for export, since sugar has always been a better market product than ethanol. Ethanol had its learning curve effect that resulted in a significant production cost reduction (van den Wall Bake, 2006) as shown in Figure 2.

It is expected that further cost reductions are still achievable in this learning curve, due mainly to gains in scale, improved management, precision agriculture, no or minimum tillage, commercial use of transgenic sugarcane and the efficient use of the biomass residues to generate surplus power and/or for second generation biofuels production.

Impacts on biodiversity

Since it is difficult to precisely define and quantify the impacts on biodiversity, the reference on this matter found in the initiatives to produce certification procedures remain vague, stating generally that some attention should be paid to this item.

The most frequent mention is that biofuel feedstocks shall not be grown on areas of high biodiversity value and protected areas. Agro-ecological Zoning could take care of the biodiversity preservation issue by ruling out the use of high biodiversity and sensitive areas. Just by avoiding deforestation, a lot of the ground is covered toward this goal.
In Brazil, there are laws protecting the biodiversity rich areas but the enforcement of these laws is still very loose. Since most of the expansion of sugarcane plantations is taking place on pasture and soybeans areas, the negative impacts on biodiversity are being minimised.

**Social impacts**

The observation of the human rights issues, commitment with the International Labor Organisation (ILO) and local workers organisation agreements are the key topics in the social impacts. Other important items are wages, working conditions, child and slave labour, land rights and competition with food production and jobs (in quantity and quality).

The Brazilian workers of the sugarcane sector are reasonably protected by the existing laws and regulations and, although the enforcement of the legislation is not adequate in some regions, we can say that there are no major problems in the sector compared with other sectors of agriculture (Macedo, 2005).

Government authorities, NGO’s members and even the Catholic Church look after the social issues in the country. If all existing laws were enforced, there would be no problem in this area in Brazil. Just to exemplify one aspect, the mean income of the sugarcane sector is compared with other representative sectors of the country’s economy and the numbers are shown in Table 5 (Macedo, 2005).

**Table 5**: Mean income in all jobs for people occupied or engaged in sugarcane sector and other industries in Brazil (2003).

*Fig. 2—Sugarcane and ethanol learning curves—the Brazilian case*

These data show that the agriculture part of the production chain presents an unfavourable condition when compared with its factory part and other industrial sectors. With the increase of mechanisation in the agricultural operations (harvesting and planting), the situation tends to improve with the change of many low pay/hard work jobs by a smaller quantity of better paid and more stable jobs.

Local environmental impacts

Cane burning phase out in the states of São Paulo and Minas Gerais (approximately 2/3 of the total Brazilian cane) will be nearly accomplished by 2014 and totally finished by 2017, according to the Environmental Protocols signed by representative of the state government, cane growers, mill owners and workers representatives. Other important items such as improved working conditions, workers’ qualification (cane cutters are being trained to perform more qualified functions in the mechanisation system), environmental conditions improvement, etc. Other states will probably follow suit and make similar agreements, resulting in a considerable reduction of negative environmental impacts, especially those derived from cane burning. Green cane harvesting will also decrease soil erosion, agrochemicals carryover to surface water and leaching to ground water and will create the adequate conditions to develop no tillage systems that will reduce even further the negative impacts on soil, air and water.

Final comments

The brief description of the differences in biofuels with respect to long-term sustainability issues and a quick look at the Brazilian experiences will hopefully help the potential biofuels producers to make a more technical decision about the best option for the local conditions.

The first points to be analysed have to do with the level of contribution to the GHG emission reductions (in terms of % of the equivalent fossil fuel emissions), the production costs (an indicator of the economic viability, or US$/t CO₂ eq. and US$/litre of gasoline/diesel equivalent) and the natural resources demands for the full dimension of the specific biofuel program. If the biofuel passes this first battery of tests, it can then go to the next steps of evaluation that are: social issues, impacts on biodiversity and environment. A clear view of the necessary public policies and the investments required to bring the program to a self-sustained level is a must to have a stable biofuel program on line.

Résumé

L'AUGMENTATION de production de biocarburants liquides à partir de différents substrats est une source de préoccupation pour les importateurs éventuels et les utilisateurs dans le cadre des solutions alternatives pour la reduction des émissions de gaz à effet de serre (GES). La durabilité de l'ensemble de la chaîne de production de chaque biocarburant est sous étude. Certains pays, en particulier ceux de Union Européenne (UE), vont de l'avant dans la préparation des procédures de certification afin d'assurer la durabilité des différentes alternatives proposées; c'est le début du processus pour démontrer que tous les biocarburants ne sont pas égaux. L'éthanol produit à partir de la canne à sucre a démontré à ce jour sa supériorité sur les autres biocarburants (éthanol de betterave à sucre ou de céréales) et le biodiesel de soja ou de colza, mais la démonstration du procédé doit être évidente et basée sur des paramètres quantifiables. La production d'énergie excédentaire est un point important pour améliorer l'équilibre entre la production d'énergie de celle de GES, de ce fait augmentant la valeur de l'éthanol dans le processus de réduction des GES lorsqu'il déplace l'utilisation de l'essence comme un combustible de transport. Le Brésil comme un producteur et exportateur majeur d'éthanol à partir de la canne à sucre s'efforce à démontrer la durabilité de l'éthanol, à l'aide d'une information fiable, des procédures bien établis et à travers la participation à l'effort à travers le monde entier pour produire des normes de certification. Des rapports d’énergie supérieurs à huit et des reductions GES supérieures à 80% ont été démontrés à travers la chaîne de production au Brésil. Cette communication présente une évaluation complète des travaux exécutés au Brésil pour démontrer la durabilité de la production d'éthanol à partir de la canne à sucre, propose certaines idées et des enseignements utiles pour les autres pays qui s'apprent à se lancer dans ce processus.
SOSTENIBILIDAD DE LA PRODUCCIÓN DE ETANOL DE LA CAÑA DE AZÚCAR: LA EXPERIENCIA BRASILEÑA.

PALABRAS CLAVE: Biocombustibles, Sostenibilidad, Certificación, Caña de Azúcar, Gases de Efecto Invernadero.

Resumen

EL AUMENTO de la producción de biocombustibles líquidos a partir de diferentes fuentes está generando preocupación en potenciales importadores y usuarios, como una alternativa para reducir la emisión de gases de efecto invernadero (GHG). La sostenibilidad de la cadena total de producción de cada biocombustible está bajo escrutinio. Algunos países, especialmente en la Unión Europea, están saltando adelante en el proceso de preparación de procedimientos de certificación para asegurar la sostenibilidad de las diferentes alternativas bajo consideración, este es el inicio del proceso para demostrar que no todos los biocombustibles son iguales. El etanol de la caña de azúcar ha demostrado, hasta ahora, superioridad sobre otros biocombustibles (etanol de granos, de azúcar de remolacha y bio diesel de soya ó colza), pero el proceso de demostración debe ser claro y basado en parámetros medibles. La generación de energía sobrante es un punto importante para mejorar el balance de energía y de gases de efecto invernadero (GHG), aumentando el valor del etanol en el proceso de abatir los GHG cuando desplaza el uso de la gasolina como combustible automotor. Brasil, como mayor productor y exportador de etanol a partir de la caña de azúcar, está trabajando fuerte para demostrar la sostenibilidad de su etanol, empleando información confiable, procedimientos bien establecidos y participando en el esfuerzo mundial para elaborar estándares certificables. Se han demostrado relaciones de energía neta por encima de ocho y eficiencias de abatimiento de los GHG mejores del 80% para la producción y la cadena de usos brasileña. El artículo presenta una explicación comprensible de este trabajo brasileño dirigido a la demostración de la sostenibilidad del etanol de la caña de azúcar, ofreciendo apreciaciones y lecciones para otros países que inician este proceso.
ALCOHOLIC FERMENTATION WITH TEMPERATURE CONTROLLED BY ECOLOGICAL ABSORPTION CHILLER—EcoChill

KEYWORDS: Alcoholic Fermentation, Temperature, Ethanol, Absorption Chiller.

Abstract

THE FERMENTATION process in ethanol production is where less efficiency and more losses can be found. One of the operational parameters that maximises ethanol production is the control of the fermentation temperature to maintain it at the optimum point. Usually the cooling systems are comprised of evaporative coolers where the lowest temperature that can be reached is a function of the wet bulb temperature. Thus, in tropical countries like Brazil, the temperature in fermentation normally reaches values above 32°C and can reach 36°C in hot periods. This condition has a negative effect in the cellular metabolism reducing ethanol productivity and damaging the viability of cells. To determine the engineering parameters to optimise the ethanol fermentation process in industrial scale designs, Dedini S/A built and installed a semi-industrial demonstration plant in a sugar and ethanol mill of the Cosan Group. The main parameter of the experiments was the control of the fermentation temperature, which ranged from 28°–32°C, as a function of the ethanol content increase and the influence of feedstock in the fermentation yield. The results obtained show that there was a significant increase of alcohol concentration in fermented mash, which reached about 16°GL at 29°C. Thus, increasing ethanol concentration leads to a decrease in steam demand for distillation and a big reduction in volume of vinasse generated. The low temperature of mash leads to a low level of contaminants, assuring good quality and greater fermentation yield. The lithium-bromide absorption chiller operated effectively, indicating that it is a proven product for application in ethanol production.

Introduction

Several references in literature (Dias et al., 2007; Jones et al., 1981; Prescott and Dunn, 1987; Yamakawa, 2008) report a high concentration of ethanol in the fermentation broth from most diverse sucrose feeds (sugarcane, wheat, corn and rice). Operating ethanol fermentation in high concentrations fundamentally increases industrial productivity, reduces steam and utilities consumption, and minimises losses with contaminants and, especially, reduces the volume of vinasse generated. Vinasse requires significant resources for final disposal.

Fermentation is a unit operation in ethanol production in which there is less efficiency and, consequently, greater loss. One of the parameters directly involved is the temperature. The biochemical reaction of converting sugar into ethanol is an exothermic reaction; usually, the Brazilian ethanol plants use water from a closed circuit evaporative cooling system to control the temperature of fermentation by indirect exchange. The evaporative cooling naturally undergoes a change depending on the wet bulb temperature and, in tropical countries like Brazil, the lowest temperature of cooling water is 29°C (Prescott and Dunn, 1987).
In different environmental and nutritional conditions, the yeasts can adopt distinct metabolic routes for the production of different compounds. In anaerobic conditions, glucose can be converted into ethanol, acetic acid, lactic acid and carbon gas. One of the factors associated with the yeast’s preferred reaction is temperature, and there are many references in literature defining that the most favourable temperature for converting sugar into ethanol is below 32°C:

- Rivera et al. (2006): considered temperature as the variable to evaluate the optimum expected parameters of ethanol fermentation; based on experimental data, maximum ethanol production is achieved at 28°C–31°C.
- Prescott and Dunn (1987): found that the optimum temperature for cell growth and ethanol production is 30°C, but higher temperatures (35°C ~38°C) are acceptable. However, at these temperatures, cell growth rate, ethanol production and death rate can be affected negatively.
- Jones et al. (1981): reported that the S. cerevisiae yeast can bear up to 33°C in industrial conditions for ethanol production; minimum growth range is 10°C and the maximum is 40°C, and the optimum temperature is between 28°C and 35°C.
- Dias et al. (2007): reported that high temperatures in fermentation affect the yeasts metabolism and reduces the ethanol concentration in the final broth, which increases steam consumption in distillation. Fermentation at 28°C allows operation with higher concentration sugars in the must, and this reduces the steam consumed in distillation and vinasse generation (5.76 L/ L EtOH).

Therefore, there is a great indication that the fermentation conducted at a controlled temperature below 32°C will result in an increased industrial yield and also will provide the very high gravity fermentation. However, all these studies and conditions are for small scale experiments. To effectively evaluate the optimised temperature of the ethanol fermentation in industrial conditions and scale, in 2008 DEDINI built and operated a 20 000-L ethanol/day demonstration plant with temperature control at 28°C and 32°C. An absorption chiller made by THERMAX was used for this purpose. The results indicate that temperature in the range of 28°C to 30°C is the most appropriate to obtain high alcohol content.

**Process description**

A detailed description of the cooling system process by the steam absorption chiller cooling system and the process of alcoholic fermentation is presented.

**Absorption chiller cooling system**

The goal of the cooling system by absorption chiller is to chill water in the range of 16 to 20°C for controlling the temperature of fermentation in the range of 28 to 32°C. Figure 1 represents the diagram of the refrigeration cycle steam absorption by the solution of lithium bromide. This system uses the principle of vacuum and the capacity of the solution of lithium bromide to absorb steam. The absorption cycle involves three circuits: the cooling water is pumped to the evaporator (1), the lithium bromide used as absorbent flows over the tubes of the evaporator through the heat exchanger for the generator, the cooling water flows in series initially through the tubes of the absorber (1) and partly through the tubes of the condenser (3).

The water to be chilled enters the tubular bottle evaporator (1) where it is chilled indirectly by water spray. The steam is absorbed by a concentrated solution of lithium bromide at low pressure in the absorber (1). Lithium bromide having absorbed the steam is then pumped to the generator (2) to reconstitute the diluted solution. In generator (2) the solution is heated indirectly by hot water at low pressure for concentrating the salt solution before it enters the absorber. The flow of solution coming from the generator (2) goes to the absorber (1) by the difference in gravity and pressure. The water from the generator (2) by boiling is then condensed with cooling water, becomes liquid in the condenser section (3) and condensed back to the evaporator (1).
The application of the absorption chiller in the ethanol process is the reuse of non-thermal sources such as vinasse, flegmass or low steam pressure, replacing the current of hot water in the absorption circuit as shown in Figure 1.

In the case of the demonstration plant, the heat source is the vinasse after the process of regenerative heating of the wine in the distillation column. The temperature range of the waste is 80 to 85°C and the range flow is 100 to 150 m³/h.

**Alcoholic fermentation process**

The process assumed in this work was fed batch fermentation prepared with juice, syrup and molasses from cane sugar and with cell recycle *Saccharomyces cerevisiae*.

In Figure 2, the process flowchart of the demonstration plant Dedini installed at Usina Bom Retiro is presented.
The process begins with the sterilisation of the fermentor (FE-101) and peripherals such as tabulations, heat exchangers and pumps. At the same time, the yeast is reactivated by an acid treatment maintained under aeration and agitation for a period of 30 minutes in a pre-fermentor (PF-101). Then the yeast is transferred to the clean fermentor. The feed was started with set process parameters for temperature and percentage of sugar in the must. The feed is prepared and controlled by addition of juice, molasses, syrup and water in a static mixer (MT-101).

The must flow is controlled such that the biochemical reaction of converting sugars into ethanol does not result in inhibition by substrate, thus slowing the reaction. In this work the flow feed was 6 to 12 m³/h.

The temperature control is enabled when feeding of the sugar solution starts. The temperature transmitter (TT-01) is located in the fermentor and it provides the temperature of the controller (TIC-01) which compares with the value set-point and thus modulates the percentage of opening control valve (TCV-01).

Upon completion of the batch, the wine is discharged to the centrifugal separator (CT-101) and the clarified phase (wine) is sent to the distillation process and the heavy phase (cream yeast) is sent to the pre-fermentor (PF-101) to be treated and reactivated. Then, after the sterilisation process, the yeast returns to the fermentor (FE-101) for a new batch.

**Materials and methods**

In 2008/09 milling season, Dedini S/A Indústrias de Bases built and operated a demonstration plant, with nominal capacity to process 20000 litres of ethanol/day (Figure 3), equipped with a 100-m³ stainless steel fermentor, one 300 TR Thermax absorption chiller and one 315 m³/h evaporative cooling tower. The plant is located at COSAN, Usina Bom Retiro, in Capivari city, state of São Paulo.

The way to get very high gravity fermentation is to increase the amount of sugar in the must by the addition of molasses or syrup. In the 2008 milling season, we used 2 and 3 molasses to raise the alcohol content of the final wine. In the 2009 milling season, we used syrup. The molasses resulting from boiling, comprised of two massecuites, presents higher purity when compared with the molasses from boiling of three massecuites, which is usually called final molasses. Table 1 shows the comparison of the quality of the raw material of juice.
Table 1—Comparison of the raw material quality.

<table>
<thead>
<tr>
<th></th>
<th>Brix %</th>
<th>Pol %</th>
<th>Purity %</th>
<th>TRS %</th>
</tr>
</thead>
<tbody>
<tr>
<td>B Molasses (2 massecuites)</td>
<td>80.40</td>
<td>52.15</td>
<td>64.86</td>
<td>62.50</td>
</tr>
<tr>
<td>C Molasses (3 massecuites)</td>
<td>79.80</td>
<td>46.68</td>
<td>58.80</td>
<td>59.56</td>
</tr>
<tr>
<td>Syrup</td>
<td>55.00</td>
<td>47.85</td>
<td>87.00</td>
<td>50.00</td>
</tr>
</tbody>
</table>

Thus, the must made from molasses will have a lower quality when compared to wine made from syrup. Henceforth, the terms B and C molasses are called only molasses.

**Results and discussions**

We present the main results obtained since the start of operation of the demonstration plant until the middle of 2009. The results were divided into two groups according to the raw material used to prepare the must: molasses and syrup.

**Must from molasses**

Figure 4 shows the result of the fed batch prepared with molasses and controlled temperature of 28°C. The average percentage of ethanol is 9.59°GL and the average standard deviation is 1.1%.

![Fig. 4—Percentage of ethanol in batches conducted with molasses at 28°C.](image)

Figure 5 shows the result of the fed batch prepared with molasses and controlled temperature of 30°C. The average percentage of ethanol is 11.98°GL and the average standard deviation is 1.2%.

![Fig. 5—Percentage of ethanol in batches conducted with molasses at 30°C.](image)
Figure 6 shows the result of the fed batch prepared with molasses and controlled temperature of 32°C. The average percentage of ethanol is 11.37°GL and the average standard deviation is 1.2%.

The results of fermentation temperatures controlled at 28, 30 and 32°C show that it is feasible to obtain alcohol levels above 9°GL. Furthermore, there is a tendency of an optimum temperature at 30°C.

The fermentation yield is reported in Table 2. The mean score was 85% and the results reinforce that a temperature of 30°C is promising.

**Table 2—Fermentation yield by sub-products method.**

<table>
<thead>
<tr>
<th>Temperature</th>
<th>Fermentation yields (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>28</td>
<td>84.02</td>
</tr>
<tr>
<td>30</td>
<td>86.79</td>
</tr>
<tr>
<td>32</td>
<td>85.05</td>
</tr>
</tbody>
</table>

These results indicate it is feasible to reduce the generation of vinasse with the fermentation of concentrated must and obtain alcohol levels above 8°GL. For example, for 9°GL the generation of the vinasse is 9 L / L ethanol and for 13°GL generation of vinasse is 6 L / L ethanol, i.e., there is a reduction of 33%.

**Must from syrup**

Since the best result was previously controlled temperature at 30°C, the tests were conducted with syrup at this temperature in order to produce wines with alcohol levels above 14°GL. Figure 7 shows the result of the fed batch prepared with syrup at 28% of total reducing sugar concentration in average and temperature controlled at 30°C. The average percentage of ethanol is 13.82°GL and the average standard deviation is 0.7%.
Figure 8 shows the result of the fed batch prepared with syrup at 35% of total reducing sugar concentration in average and temperature controlled at 30°C. The average percentage of ethanol is 15.45°GL and the average standard deviation is 1.2%.

Fermentation with high quality must enables the production of average alcohol content up to 15°GL, unlike wine from molasses. So, it can be inferred that the salts present in molasses limit the very high fermentation.

The parameter temperature should be evaluated under these conditions because it is not possible to infer the ideal temperature from these results.

**Conclusions**

According to the results obtained, we can conclude that:

- The operation of the pilot plant in the 2008/09 season was succeeded well, and the results obtained at low temperatures are very promising for very high gravity fermentation;
The increased wine in alcohol is directly related to the quality of raw materials;

The lithium-bromide absorption chiller worked effectively, and one can conclude
that it is a proven product for ethanol production applications;

The results of fermentation with molasses indicate that there is an optimum
temperature at 30°C.

MOTS-CLÉS: Fermentation Alcoolique,
Température, Ethanol, Réfrigirateur d’Absorption.

Résumé

C’EST DANS le procédé de fermentation dans la production d'éthanol que se trouve le moins
d'efficience et les peres les plus élevées. Un des paramètres d’opération pour maximiser la
production d'éthanol est le contrôle de la température de fermentation qui doit être maintenue au
niveau optimal. Généralement, les systèmes de refroidissement sont constitués des refroidisseurs
par évaporation par lesquels la température la moins élevée qui peut être atteinte, est une fonction
de la température de bulbe humide. Ainsi, dans les pays tropicaux comme le Brésil, la température
de fermentation atteint normalement des valeurs supérieures à 32°C et peut même atteindre 36°C
dans les périodes chaudes. Cette condition a un effet négatif sur le métabolisme cellulaire en
réduisant la productivité d’éthanol et tout en nuisant à la viabilité des cellules. Pour déterminer les
paramètres d’ingénierie nécessaires à l’optimisation du procédé de fermentation pour la production
d’éthanol dans la conception des ensembles industriels, Dedini S/A a construit et installé une unité
de démonstration semi-industrielle dans une usine à sucre associée à une unité d'éthanol du groupe
Cosan. Le paramètre principal des expérimentations était le contrôle de la température de fermentation, qui variait de 28º–32ºC, en fonction de l'augmentation du contenu d'éthanol et l'influence des matières premières pour le rendement de fermentation. Les résultats obtenus démontrent qu'il y avait une augmentation significative de la concentration d'alcool dans le moût fermenté qui atteint 16° GL à 29ºC. Ainsi l’augmentation de la concentration en éthanol entraîne une réduction de la demande en vapeur requise pour la distillation et une réduction énorme en volume de vinasse générée. La température basse du moût fermenté mène à un niveau faible de contaminants, assurant ainsi une bonne qualité et un rendement supérieur en fermentation. Le réfrigérateur d'absorption à base de bromure de lithium fonctionne efficacement, donnant ainsi la preuve qu'il s'agit d'un produit éprouvé pour être utilisé dans la production d'éthanol.

Palabras clave: Fermentación Alcohólica, Temperatura, Etanol, Enfriador de Absorción.

Resumen

El proceso de fermentación en la producción de etanol es donde puede encontrarse menos eficiencia y mayores pérdidas. Uno de los parámetros operacionales que maximiza la producción de etanol es el control de la temperatura de fermentación para mantenerla en el valor óptimo. Usualmente los sistemas de enfriamiento están constituidos por enfriadores evaporativos, en los que la temperatura más baja que puede alcanzarse es función de la temperatura de bulbo húmedo. Así en países tropicales como Brasil, la temperatura en la fermentación alcanza normalmente valores superiores a 32º C y puede elevarse hasta 36º C en períodos calurosos. Esta situación tiene un efecto negativo sobre el metabolismo celular reduciendo la productividad de etanol y dañando la viabilidad celular. Para determinar los parámetros ingenieriles para optimizar el proceso de fermentación de etanol en los diseños a escala industrial Dedini S/A construyó e instaló una planta demostrativa semi-industrial en una fábrica de azúcar-etanol del grupo COSAN. El parámetro principal de los experimentos fue el control de la temperatura de fermentación, que osciló entre 28 C y 32ºc, como una función del incremento del contenido de etanol y la influencia de la alimentación sobre el rendimiento de fermentación. Los resultados obtenidos muestran que se alcanzo un significativo incremento en el contenido de alcohol en el vino fermentado, que se elevó a cerca de 16º GL a 29º C. Resultando que el aumento de la concentración de etanol condujo a una disminución en la demanda de vapor para la destilación y una gran reducción en el volumen de vinaza generado, La baja temperatura del vino fermentado indujo una disminución de contaminantes, asegurando buena calidad y mayor rendimiento de fermentación. El enfriador de absorción de Bromuro de Litio operó con efectividad, indicando que es un producto probado para ser empleado en la producción de etanol.
HIGH PRESSURE MULTI FUEL FIRED
BOILERS FOR CO-GENERATION

aksubramanian@ijt.co.in sanjayawasthi@ijt.co.in

KEYWORDS: High Pressure Bagasse Boilers,
Efficient Thermodynamic Cycles, Important Mechanical Features.

Abstract
AN EVER widening gap between power generation and its growing demand, as well as
the problems concerning the steady decline of non renewable energy resources, has
been a major cause of worry, not just for India but for many countries around the world.
Depletion of fossil fuels, environmental concerns and the opportunities presented for
carbon trading between developed and developing countries under the Kyoto Protocol
have added to the importance of Green Power. The cane sugar factories, which have
been generating power only for captive use by burning bagasse during the crushing
season, have taken this as an opportunity to strengthen their revenue stream by
producing power on a year round basis and trading in carbon credits. This has been
achieved by adopting more efficient power cycles using high pressure and high
temperature boilers along with high pressure feed water heaters and extraction cum
condensing steam turbines. This paper reviews the advantages of using high pressure
co-generation boilers in the sugar industries with higher power output, improved cycle
heat rate and lower bagasse consumption. The multi-fuel firing capacity in the boilers
enables the power plant to operate on alternative fuels during the off-season when the
bagasse is fully consumed. The high pressure co-generation boilers thus ensure year
round operation with high availability. The paper also discusses the unique features of
high pressure boilers for ensuring high uptime, enhanced life, ease of operation and
maintenance, high efficiency, low power consumption and environment friendliness.
Salient performance data of one of the operating high pressure boilers is also
highlighted in Table 4.

Introduction
Traditionally, sugar mills have been using low pressure boilers (32 kg/cm²a, 45 kg/cm²a) for
generating power and steam for process. In order to make the plant cycles more efficient, the trend
in the sugar industries worldwide is gradually moving towards higher pressure and temperature
cycles along with multi-fuel firing capability in the boilers in order to maximise generation of
power from the available bagasse. This results in increased power generation during the crushing
season with savings in bagasse, hence keeping the power plant operational beyond the crushing
season. The plant operates on alternative fuel during the rest of the period, when bagasse is fully
consumed.

The advantages of using high pressure boilers for co-generation can be seen in Table 1.
With high pressure and temperature cycles, the benefits are as follows:
1. Higher power generation per tonne of bagasse.

It is also clear from this table that keeping the pressure constant and increasing the steam
temperature is not advantageous due to higher fuel consumption and drop in steam/fuel ratio.

Development of high pressure co-generation boilers

High pressure and high temperature cycles are important for increasing the operating efficiency and power output from co-generation plants. The choice of pressure and temperature levels for the steam cycle depends on several factors including fuel and ash properties, quality of feed water and water treatment systems available, cost of boiler and steam turbine systems and the level of confidence of plant operators.

Thermodynamically, the energy recovery from the Rankine cycle depends more on steam temperature than pressure. The cycle efficiency will increase with higher steam temperature. However, because of the nature of the working medium, pressure also plays a major role in ensuring optimum extraction of useful energy from the working medium as the enthalpy changes with pressure. Hence, an increase in steam temperature should be accompanied by a matching increase in steam pressure. The temperature selection is decided by the metallurgy of boiler pressure parts, piping, turbine components and the creep-fatigue behaviour of materials at higher temperature. For temperatures up to 400ºC, carbon steel material (SA 210 Gr A1/SA 210 GrC) is used for the heating surfaces. Alloy steel material (SA 213 T11, SA 213 T22) is used for temperature up to 520ºC. For higher temperature (540/545ºC), special alloy steel material (SA 213 T91) is used for the heating surfaces.

Having gained wide experience with operation of 66 kg/cm²(a), 485ºC cycle, the Indian sugar industry graduated to the next higher cycle using 87 kg/cm²(a), 515ºC cycle. Several co-generation boilers using this pressure cycle are successfully operating in India. The current trend is for still higher pressure operation at 105/110 kg/cm²(a) and 540ºC. Three units using this pressure cycle have been in operation for the past two years. Many more units using 110 kg/cm²(a) pressure are currently under execution.

The concept of regenerative feed water heating was introduced in the co-generation cycles to improve cycle efficiency. High pressure feed water heaters using bleed steam from the turbine have become a standard feature in all co-generation plants. The 66/87 kg/cm²(a) cycle uses one high pressure feed water heater to increase the feed water temperature to around 170ºC before entering the economiser. The 105/110 kg/cm²(a) cycle uses two stages of high pressure heaters to raise the feed water temperature to around 220ºC before entering the economiser. Regenerative feed water heating reduces the heat input to the boiler, thus optimising fuel consumption and increasing steam/fuel ratio.
The significant advantages of using a high pressure boiler in co-generation are:

- Saving in bagasse, hence extended period of operation.
- Higher power generation per tonne of bagasse.
- Lower fuel and steam consumption for the same power output, hence reduced boiler size.
- Improved heat rate, hence better cycle efficiency of the plant.

While efforts are being made to increase power generation by adopting higher pressure cycles, energy conservation efforts are also being introduced for optimising auxiliary power consumption and increasing the exportable surplus power to the grid.

Variable frequency drives are being extensively used to bring down the auxiliary power consumption. Boilers are designed with multi-fuel firing capability so as to ensure year round operation of the plant.

One of the major considerations for high pressure operation is the quality of feed water, boiler water and steam. Total solids and silica are required to be maintained at low levels in drum water at high pressures to maintain desired steam quality. Silica, in particular, is carried over in the form of vapour at high pressures and, hence, the silica content in feed water needs to be maintained at a very low level. Feed water is used for attemperation in the superheater system and any contamination in the feed water will enter the superheater circuit. This necessitates high purity for make-up water. Hence demineralisation and volatile treatments become necessary and the boiler water quality control becomes critical to minimise steam impurities to prevent deposits in tubes and turbine blades. Demineralisation can produce the acceptable make-up water quality with specific electrical conductivity less than 0.5 µs/cm with hardness completely removed and silica less than 0.02 ppm. Demineralisation of boiler feed water prevents failures due to deposits, ductile gouging, hydrogen embrittlement and corrosion.

The recommended feed water and boiler water quality is shown in Table 2 and Table 3 respectively. Salient performance data of one of the operating high pressure boilers is also highlighted in Table 4.

Features of high pressure boilers

For developing a boiler for cogeneration and suitable for generating power on a sustainable basis the following points are important:

1. Need for multi fuel firing.
2. Ability to give trouble free service throughout the year.

Of the several technologies available, the Travelling Grate boiler can burn bagasse as well as a variety of biomass fuels and agro wastes including rice husk, wood chips, and cotton stalk, besides fossil fuels like coal, lignite, oil and gas during the off season. Examples are shown in Figures 1, 2 and 3.

Fig. 1—Travelling grate boiler with boiler bank. Source: ISGEC John Thompson.
Fig. 2—Single drum design travelling grate boiler with evaporator pass.

Fig. 3—Single drum design travelling grate boiler with evaporator bank.
For robust and reliable operation on a year round basis, the high pressure co-generation Travelling Grate boiler needs to have the following essential features.

- High uptime
- High efficiency
- Low power consumption
- Environment friendly
- Low O & M cost

The specific design and construction features that IJT has incorporated in their Travelling Grate boilers are:

**High boiler uptime**

1. Stoker of rugged construction using heat resistant grate bars of Spheroidal Graphite iron metallurgy and chains made of hardened and tempered steel, cross beams and skid bars made of heavy sections and heat resistant material.
2. Pressure part tubes of seamless construction
4. Optimum flue gas velocities across heating surfaces to minimise erosion.
5. Furnace made of water cooled membrane wall construction to ensure gas tightness and minimum use of refractory to avoid maintenance.
6. Use of SA 213 T91 material for final elements of secondary superheater for high creep, fatigue and corrosion resistance.
7. Convective superheaters with wide pitching to avoid fouling due to alkali content in ash.
8. Double casing arrangement for economiser to protect bends from erosion.
9. Use of corten steel tubes in cold end section of tubular airheater to avoid corrosion.
10. Use of ferrules for airheater inlet tubes to avoid erosion.
11. Use of pre-dust collector at economiser outlet to reduce particulate loading on ESP; this avoids larger unburnt carbon carry over to ESP and hence eliminates fire hazards.
12. Stoker shaft provided with self lubricated graphite bearings ensures high reliability, minimum maintenance.
13. Refractory band provided at lower furnace zone above the grate to sustain combustion even with high moisture in bagasse.
14. Single drum design for high pressure (> 100 kg/cm²a) boilers. High ligament efficiency of drum (85–90%), lower drum thickness, no tube expansion and better circulation due to non-heated downcomers.
15. Tall furnace, generous volumetric loading ensures adequate residence time for fuel, hence reduces unburnt carbon loss.
16. On-line vibration monitoring system provided for critical rotating equipment ensures predictive maintenance and avoids failures.
17. On-line steam and water analyser system ensures strict control of water chemistry.
18. Automated operation with Distributed Control System with supervisory controls and data acquisition for accurate control with less manpower.

**High efficiency**

a) Generous sizing of furnace (conservative grate area and furnace volumetric loading) for efficient combustion of fuel.
b) Good secondary air distribution using high pressure air jets to ensure better turbulence and mixing due to staggered arrangement for efficient combustion of fuel.

c) Heat recovery through economiser and airheater for lower back and temperature.

d) Optimum excess air levels to reduce dry flue gas loss.

e) Refiring of grit and cinder for lower unburnt carbon loss.

f) Use of high pressure feed water heaters for fuel economy.

g) Use of variable frequency drive for feeders to regulate fuel feed.

**Low power consumption**

a) Use of low flue gas velocity across heating surfaces to reduce draft loss in gas path.

b) Use of variable frequency drives for fans and boiler feed pumps.

**Environment friendly**

a) Use of Electrostatic Precipitators to limit particulate emission to 30–50 mg/Nm³. Electrostatic Precipitators also have low flue draft loss (25–30 mm WC).

b) Use of closed dense phase system for fly ash disposal.

c) Use of efficient silencers to meet occupational Health and Safety Administration (OSHA) norms.

**Low O & M cost**

a) Automated operation, hence less manpower.

b) On line monitoring of condensate and boiler feed water quality using Steam and Water Analyser System (SWAS) prevents scaling and corrosion in boiler tubes, hence avoiding tube failures and ensuring high boiler availability.

c) Seamless steel tubes for boiler pressure parts, eliminates tube leakages, ensures high boiler availability with minimum maintenance.

d) Alloy steel tubes for superheaters, corten steel material for cold end of airheater provides resistance to corrosion, fatigue and ensures high boiler availability.

e) Replaceable wear liners for ID fan blades ensures resistance to erosion.

f) Use of soot blowers at strategic location for efficient on-load cleaning of heating surfaces hence avoiding fouling and bridging of ash particles in the heating surfaces.

g) Use of air bypass arrangement for the air preheater to avoid cold end corrosion during boiler start up, part load operation and also during low ambient air temperature conditions to ensure high boiler availability.

**Specific design and construction features of high pressure boilers**

- Rotary single drum feeder/Three drum feeder/Chain feeder for bagasse with pneumatic spreaders.
- Drag chain feeder for coal with mechanical/pneumatic spreaders.
- Three stage feed water heating (deaerator and two stages of HP heaters).
- Spray-cum-Tray type deaerator to achieve low dissolved oxygen (< 0.007 ppm) in boiler feed water.
- Convective superheater arrangement (shielded by nose) with interstage attemperator).
- Use of drum coil heaters for minimising cold end corrosion in economiser due to sulfur in fuel.
- Use of steam coil air preheater for minimising cold end corrosion in air heater during very low ambient air temperature.
- Conservatively designed steam drum to enable boiler operation with rapid load swings and fast response to load changes.
• Efficient drum internals consisting of cyclone separators, demisters to ensure high steam purity at all loads.
• Self lubricated graphite bearings (Morganite bearings) provided for stoker shaft. The morganite carbon bearing is chemically inert, dimensionally stable, non hygroscopic and highly resistant to wear.
• Drum internals of bolted construction for easy replacement/removal
• Temperature elements are provided on the Travelling Grate skid bar, cross beam and riddling hoppers with temperature indication in the control room.
• Minimum use of refractory in the boiler, thereby eliminating cumbersome maintenance.

Conclusion

With the rapid industrial growth over the last few decades, the demand for electrical energy has been growing at a tremendous pace. The application of the clean development mechanism (CDM) of the Kyoto protocol which gives monetary value to CO₂ emission reduction has become an important financial driver for biomass based co-generation.

Due to concerns related to cost and to bring about a reduction in emission of air pollutants and greenhouse gases, owners of industrial and commercial facilities are actively looking for ways to produce energy more efficiently. The incentive of trading carbon credits has become a motivation for considering the co-generation route. India has no doubt emerged as one of the leaders in co-generation.

The sugar industry in India has made phenomenal progress in co-generation particularly since bagasse, a waste product from sugar mills, is available at almost no cost as fuel. However, as bagasse is a seasonal fuel, there is a need to find other biomass fuels for year round generation of power. This has led to the development of multi-fuel fired boilers using high pressure and high temperature cycles which are crucial for increasing operating efficiency and power output from co-generation plants.

The additional power generation is a source of revenue for the sugar plant with opportunities to generate more income through trading of carbon credits.

CHAUDIERES A HAUTE PRESSION ET A MULTIPLE COMBUSTIBLES POUR LA COGÉNÉRATION

Par

A.K. SUBRAMANIAN et SANJAY AWASTHI

aksubramanian@ijt.co.in sanjayawasthi@ijt.co.in

MOTS-CLÉS: Chaudières Bagasses De Cannes à Sucre à Haute Pression, Cycles Themodynamic Efficace, Importantes Caractéristiques Mécaniques.

Résumé

UN FOSSÉ toujours grandissant entre la production d'électricité et de sa demande croissante, ainsi que les problèmes relatifs à la diminution constante des ressources énergétiques non renouvelables, a été une des causes d'inquiétude majeure, non seulement pour l'Inde, mais aussi pour de nombreux pays à travers le monde. L’épuisement des combustibles fossiles, les préoccupations environnementales et les opportunités présentées pour les échanges de carbone entre pays développés et ce en voie de développement dans le cadre du protocole de Kyoto ont donné davantage d’importance à l'énergie verte. Les usines de canne à sucre, qui ont été génératrices de
puissance uniquement pour leur usage interne par combustion de bagasse de canne pendant la saison de broyage, ont saisi cette opportunité pour augmenter leurs revenus en produisant de l’énergie toute l'année et à travers la négociation des crédits de carbone. Cet objectif a été atteint par l'adoption des cycles d'alimentation plus efficaces à l'aide de chaudières à haute pression et à haute température associées à des systèmes d’alimentation d’eau à forte pression et des turbines à vapeur d’extraction cum condensation. Cette communication présente les avantages de l'utilisation de chaudières de cogénération de haute pression dans les industries sucrières avec une augmentation de puissance générée, une amélioration du taux de transfert de chaleur et une diminution dans la consommation de bagasse de canne. La capacité des chaudières à utiliser différents types de combustibles pendant la période d’inter-récolte quand la bagasse n’est plus disponible, permet à la centrale électrique de fonctionner pendant toute l’année. Les chaudières de cogénération à haute pression assurent ainsi le fonctionnement pendant toute l'année avec un haut degré de disponibilité. La communication comprend également des fonctionnalités uniques des chaudières à haute pression pour assurer une meilleure disponibilité, une durée de vie accrue, une facilité d’opération et d'entretien, une meilleure efficacité, une faible consommation et le respect de l'environnement. Les données saillantes de la performance d’une chaudière à haute pression en phase d’opération sont également mises en évidence au tableau 4.

CALDERAS DE ALTA PRESIÓN MULTICOMBUSTIBLES PARA LA COGENERACIÓN

Por

A.K. SUBRAMANIAN y SANJAY AWASTHI

aksubramanian@ijt.co.in y sanjayawasthi@ijt.co.in

ISGEC John Thompson, India

PALABRAS CLAVE: Calderas de Bagazo de Alta Presión, Ciclos Termodinámicos Eficientes, Factores Mecánicos Importantes.

Resumen

UNA BRECHA permanentemente creciente entre la generación de energía y la ampliación de su demanda, así como el problema relativo al sostenido decrecimiento de las fuentes de energía no-renovables, ha resultado causa de la mayor preocupación no solo para la India sino también para muchos países del mundo. Depresión de los combustibles fósiles, alarma ambiental y las oportunidades que presentó el comercio de carbono entre los países desarrollados y en desarrollo bajo el Protocolo de Kyoto, han contribuido a añadir importancia a la Energía Verde. Las fábricas de azúcar de caña que han generado energía solamente para un uso cautivo por las fábricas de azúcar de caña que han generado energía solamente para un uso cautivo durante el periodo de producción azucarera, han tomado esto como una oportunidad para fortalecer corrientes de ingresos por la vía de producir energía todo el año y negociando en créditos de carbono. Esto se ha alcanzado adoptando ciclos energéticos más eficientes, empleando calderas de alta presión y temperatura, junto a calentadores de alta presión de alimentación y turbinas de extracción-condensación. Este artículo revisa las ventajas de emplear calderas de alta presión para cogeneración en la industria azucarera con mayores producciones de energía, ciclos con relaciones de calor mejorados y menores consumos de bagazo. La capacidad de las calderas de quemar varios combustibles permiten a las plantas de energía operar en el periodo de no producción azucarera con combustibles alternativos una vez consumido todo el bagazo. Las calderas de alta presión para cogeneración aseguran, así, una operación todo el año con alta disponibilidad. El artículo discute también, la propiedad única de las calderas de alta presión para asegurar elevada operacionalidad, larga vida útil, facilidad de operación y mantenimiento, alta eficiencia, bajo consumo energético y ser eco-amigables. En la tabla 4, se destacan las cifras de desempeño de una caldera de alta presión en operación.
REPORT: ISSCT COPRODUCTS WORKSHOP 2009

By

KEYWORDS: Cogeneration, Boilers, Bagasse and Trash Handling,
Cellulosic Ethanol, Vinasse, Biocomposting, Biofermentation, Molasses.

Abstract

The ISSCT Coproducts Workshop 2009 was held in Coimbatore, India from 15-19 March 2009 and attracted 41 participants from 8 countries. There were two main themes: Monday was termed the ‘Energy day’ and dealt with liquid and solid energy production from coproducts, as well as cogeneration of electrical power from bagasse and cane trash. Very good audience participation and lively debate was prevalent. On Tuesday, 2 sugar mills were visited (Sakhti Sugars and Bannari Aman), which had high pressure boilers. Sakhti Sugars also has equipment for vinasse concentration and incineration, while Bannari Aman has a plant for biocomposting of vinasse mixed with filter cake. Wednesday was the ‘Derivatives day’ where issues such as Biofermentation of sugar into high-value chemicals, pulp and paper production from bagasse and addition of molasses to animal feed were debated in a smaller circle. On Thursday we visited an impressive printing and industrial paper production plant (SPB) and an adjacent sugar factory (Ponni Sugars) that provides bagasse for the paper plant as well as a very efficient common treatment of waste water. The Workshop was hosted and graciously sponsored by Ponni Sugars (Erode) Ltd. as well as by SPB – Seshaysee Paper and Boards Ltd. Erode. All papers were well presented and generated discussion and interaction among the participants. The main conclusions of the Workshop were: In view of the necessity to reduce greenhouse gas emissions, the importance of cogeneration from bagasse and other biomass as well as the production of bioethanol from molasses and cane juice will continue to increase; High pressure boilers and efficient power generation cycles (110 bar, 540°C) are well established and investment costs are coming down; Practical alternatives to deal with the large volumes of vinasse arising during the production of bioethanol are available, but optimisation of the technologies and investment volumes is still required; To adequately cover promising subjects, the division into 2 sections (Energy and Derivatives) should be kept for future workshops. The actual emphasis on either one of these could vary according to the amount of contributions received. To encourage better participation for participants with limited time, there should be 2 days of consecutive presentation sessions followed by 2 days of plant visits for the next workshop. Many papers were considered suitable for submitting to the ISSCT Congress in Mexico in March 2010.
Introduction

The ISSCT Coproducts Workshop 2009 was held at the Residency Hotel, Coimbatore, Tamil Nadu (South India) from 16–19 March 2009 and was hosted by Ponni Sugars (Erode) Ltd. and SPB- Seshasayee Paper and Boards Ltd, who were in charge of the local organisation of the venue and site visits. The Sugar Technologists’ Association of India (STAI) helped generate interest amongst its members in attending the workshop.

The overall theme of the workshop was ‘After the Oil has gone: Utilisation of Sugar Cane Coproducts’. Two main theme blocks were chosen: Energy and Derivatives. The first two days of the workshop were dedicated to Energy related themes and plant visits, whereas the third and fourth days were dedicated to Derivatives and related plant visits.

The workshop was attended by 41 participants from 8 countries (30 from India and 11 from Australia, Germany, Mauritius, Reunion, Sweden, Thailand, Uganda and the United Kingdom). Some Coproducts Section Members and sugar technologists from Brazil and other Latin American countries, who had initially expressed interest, were prevented from participating due to the economic crisis.

Financial support as well as great personal input was provided by the top management of Ponni Sugars Ltd and SPB, without which this workshop would not have been possible. Hospitality at the three sugar mills visited (Sakhti Sugars, Bannari Aman and Ponni Sugars) and especially at the paper plant (SPB) was very warm and generous.

Technical sessions

Session A – Overview speeches

After the oil has gone: potential for coproducts of the cane sugar industry (P. Avram, IPRO Industrieprojekt GmbH, Braunschweig, Germany)

There is a wide range of coproducts available from sugarcane, respectively ‘downstream’ products derived from bagasse and molasses. Most of these, however, have not reached particular economic significance or are ‘niche products’ that have only a limited market. The two currently most economically significant coproducts are bagasse as a fuel and molasses for ethanol production.

Worldwide cogeneration potentials for bagasse-based cogeneration are about 100 kWh per tonne of cane export power from sugar mills. This figure is already being attained in the more efficient sugar factories in Brazil, Guatemala, Reunion, Mauritius, India, etc, where the price being paid for electrical power from sugar mills is economically attractive. If the major cane producing countries could fully realise this potential, the sugar mills could cover an average of 7.5% of their total national electricity demand.

The results of an earlier case study for a 20 000 t/d fully electrified sugar mill employing 65 bar steam boilers, condensing-extraction turbines and additionally dried bagasse show that 112 kWh/t can be sold to the grid. With higher pressure boilers (110 bar, 540°C) available today, this figure can be raised additionally by about 13% due to the higher thermodynamic cycle efficiency.

In recent years, fuel ethanol produced mostly from either sugarcane or corn (maize) has reached levels of over 40 ML annually and continues to rise. The worldwide cost situation of various biofuels shows that cane-based bioethanol in Brazil has an average production cost of €0.24 per litre, ethanol from corn in the US €0.42 per litre and gasoline costs wholesale an average of €0.54 per litre. The cost advantage of cane-based ethanol lies in its higher yield per ha (6000 L/ha vs. 3000 L/ha from corn) and easier conversion via direct fermentation of molasses from cane juice. Also the fossil energy balance of ethanol from sugarcane is approx 8:1, compared to only 1.5:1 for corn and 0.80:1 for gasoline from crude oil.
In the future, ethanol from cellulose crops appears to have great potential regarding an
even better fossil energy balance than ethanol from sugarcane. Also synthetic gasoline from
gasification of agricultural wastes / biomass has shown good potential but, in both cases,
production costs are still far from being competitive. The greenhouse gas emissions of these
alternatives appear to be somewhat better when considering all sources of greenhouse gases
 emitted during cultivation, transport and production / conversion.

An overview was also given of a very energy efficient beet-juice and syrup-based
ethanol plant designed by IPRO that went on stream in 2008 in Germany. By employing a
double-effect distillation scheme, the process steam demand has been reduced to 1.7 kg/L
anhydrous ethanol. Further, the residual vinasse is concentrated in a six-effect evaporation
plant to 60° Brix and sold as a fodder additive. The applied technologies can be easily
transferred to cane-juice or molasses-based distilleries.

Overview of the Indian Coproducts situation (R. Chandramouli, Ponni Sugars Ltd.,
Erode, India)

The sugar industry is the second largest agro-based industry (after Textiles) in India.
There are about 500 sugar mills operating, out of which 41% are in private hands and 59% are
cooperatives or belong to the public sector. Each mill employs directly 300–500 persons and
indirectly another 200–300 persons. Total annual cane production in the last 3 years has
exceeded 300 Mt. About 70% of this amount is processed in the sugar factories, while the
balance is employed for jaggery and handsari (artisan sugar) and for seed planting.

Total sugar production has reached 28.2 Mt in 2006–07 and 25.5 Mt in 2007–08. Per
capita consumption of sugar in India is 19–20 kg/annum with a current population of
1130 million. The area under sugarcane varies between 3.5 and 4.5 Mha, depending strongly
on the price paid to farmers and competition from other cash crops as well as on drought or
pest attacks.

The most important coproduct is bagasse, with an annual production of 60 to 75 Mt.
Its main use is for power and energy production in the sugar factories. Currently there is
installed electrical generation capacity of 1280 MW, from which 847 MW are exported to the
grid. Potentially up to 10 500 MW of power could be produced, out of which 6270 MW could
be additionally exported once all mills have high pressure boilers and fully electrified factory
drives. Sugarcane trash has also been recognised in India as a valuable source of additional
fuel, because of its much higher calorific value than bagasse. Several schemes of trash
utilisation in the boilers are being tested with good results.

A smaller user for excess bagasse is the pulp and paper industry. The overall demand
for paper in India is currently 6.6 Mt per annum and rising rapidly. Currently about 32% of
the raw material employed for pulp and paper making is agricultural wastes, out of which a
good part is bagasse. It is estimated that potentially 6–10 Mt of bagasse could be used by the
paper industry. The particle board industry is another smaller user for excess bagasse,
accounting for about 375 000 t per annum.

Final molasses production has varied between 8.5 and 13 Mt during the past 3 years.
Over 70% of this amount is diverted to alcohol distilleries. The balance is employed in oil
mills, cattle feed, poultry units and chemical derivatives. The total installed distillation
capacity in India is currently 2900 ML per annum, out of which 1300 ML are adjunct to sugar
mills. Of the total annual demand of 2069 ML, about 29% is ethanol for fuel blending, 37%
for potable uses and 34% for industrial uses. There is a severe shortage of ethanol for fuel
blending.

Filter cake with an annual production of 6.5 Mt is next in order of importance. Over
60% is employed for biocomposting (increasingly together with vinasse from alcohol
distillation) and the balance is sold to farmers as manure. Lastly, M. Chandramouli referred to the lift irrigation scheme devised at Ponni Sugars for jointly treating the waste water emanating from the adjacent SPB paper mill and employing it for irrigating the cane fields. Also, the treated waste water from the sugarcane process is recirculated, thus reducing the fresh water consumption for the process to zero.

**Greenhouse gas abatement policy initiatives (Dr Bryan Lavarack, Mackay Sugar Ltd., Queensland, Australia)**

Policies developed at an international scale to mitigate the effects of climate change were briefly reviewed. The Kyoto Protocol sets binding targets for 37 industrialised countries and the European community for reducing greenhouse gas emissions. A total of 186 parties of the Convention on Climate Change have ratified the Protocol to date. The targets amount to an average of 5% against 1990 levels over the 5-year period 2008–2012. The majority of the industrialised countries, i.e. the European Union and the UK, have established targets for 2020 of 20–32% reduction below 1990 levels. The new US Administration is proposing to achieve a per capita reduction of 25% below 1990 levels by 2020.

The allowed emissions are divided into ‘assigned amount units’. As per the Kyoto Protocol, a trading mechanism allows countries that have emission units to spare—emissions permitted to them but not used—to sell this excess capacity to countries that are over their targets. Emitter of greenhouse gases (industrial production units) need to acquire a permit for all greenhouse gases they emit. The number of permits issued by the Government in each year will be limited. Firms will compete to purchase the number of permits they require. The ones that value them most highly will pay more for them, either at auction or at a secondary trading market. For a number of firms it will be cheaper to reduce emissions than to buy permits. Therefore, the marketplace will help to reduce CO2-emissions on a global scale.

Most sugarcane producing countries are not liable to achieve this target for the short term since these countries are regarded as developing. The Government of Australia accepted the requirements for the Kyoto Protocol in December 2007 and has committed the country to achieving these targets. Under current accounting rules, carbon dioxide emissions from the combustion of biofuels and biomass are zero-rated, because these emissions are equivalent to carbon sequestering through growth of these feedstocks. Therefore a major opportunity is developing for sugarcane coproducts as biofuels and biomass.

**Session B – Liquid energy**

**Late technology in vinasse evaporation (C Stoffers, Alfa Laval, Sweden)**

This presentation reported on the lessons learned from concentrating vinasse up to 60% solids with plate heat transfer equipment. The properties of the vinasse, in particular propensity to scaling, raw material quality and treatment and viscosity all influence the design. Rising film plate evaporators are suitable for concentrating up to 40% solids. Forced circulation through plate heat exchangers with flashing in a separate vessel is required to achieve higher concentrations. A three effect system with thermal vapour recompression is suggested to achieve solids levels up to 60%. Some of the vapour from the first effect is recycled through thermal vapour recompression (TVR). An installation capable of concentrating up to 52% solids for a distillery in Colombia was reported during the presentation. The presentation noted that support fuel is required for boilers that are fired with the concentrated vinasse.

**Evaporation system for molasses-based distillery effluent: a successful leap towards zero discharge (S. Chaudhari, Praj Industries, India)**

This presentation described several options for processing the effluent from distilleries with close examination of the option for evaporation and incineration. The main concerns for
Evaporators concentrating spent wash (vinasse) are scaling, plugging, foaming and require CIP (clean-in-place). The design for CIP should focus on the cost of chemicals, shut-down frequency for cleaning and methods for disposal of spent cleaning chemicals. The concentration of solids in the spent wash is directly proportional to the viscosity which in turn is proportional to (i) higher capital costs requirement for additional heat transfer area and (ii) increased operating costs from higher power consumption in pumps because of higher pressure drops. The higher the requirement for solids in the concentrated spent wash (exiting the evaporators), the higher are the capital and operating costs.

Conventional falling film, forced falling film, forced circulation and fluidised bed types of evaporators are suggested as solutions for the evaporation of spent wash. A system has been designed for Bannari Amman in India. The evaporator station is designed to produce 58–60% solids for a distillery rated at 60 kL/d. The incineration boiler can provide all the requirements of high pressure steam for power generation and of exhaust steam for process heating in the distillery and evaporators. Other evaporator installations were briefly reported.

**Zero liquid discharge through spent wash incineration (R. Rajesh, Thermax Boilers, India)**

The policy of zero liquid discharge being implemented in India at present requires that ethanol plants adopt new technologies for effluent discharge. The production of bio-compost from filter mud and spent wash is not viable for new stand-alone distilleries and another solution is required. This presentation described the requirements for a boiler incinerating concentrated vinasse (spent wash) for Bannari Amman in India. Brief details of three similar boilers presently under construction are also given.

For the boiler at Bannari Amman, the firing rate of concentrated spent wash is 8.8 t/h and steam generation capacity is 23.4 t/h of which about 16.6 t/h is required for process heating. About 1.6 MW of power is generated. The incineration boiler can provide the entire needs for power and steam for the stand-alone distillery. The boiler is a fluidised bed design which requires concentrated vinasse at 55–60% solids and 10–15% support fuel. Coal is the support fuel in the application described. The boiler assembly is a gas tight design. Total combustion is ensured through adequate residence time in the combustion chamber.

The high alkali content in ash from incinerating concentrated spent wash fouls the heat transfer surfaces. This is minimised through multi-pass design and provision of mechanical rappers for soot removal. The presence of chlorides leads to high temperature corrosion of the superheater. The boiler is reported to have operated successfully for more than 45 days without cleaning.

**Vinasse as a fuel – practical results (Dr N. Schopf, Saacke, Germany)**

This presentation focussed on the application of burners to incinerate vinasse and similar materials. Two case studies are presented for factories incinerating vinasse-like material at Araucaria and Cambé, both in the Parana state of Brazil. Both boilers are 42 bar boilers with 40 t/h and 60 t/h steam capacities. The main design issues for the burners for these boilers are high ash content, low calorific value (resulting from high water content) and conditioning system required for atomisation of the fuel.

The design for the boiler requires a support fuel to bring the boiler up to temperature and to ensure the flame is stable in the burner. The requirements for the support fuel are low once the boiler is at temperature. Typical support fuels required are natural gas, heavy fuel oils and animal fats.

Detailed descriptions of the burners required for the boilers were given in the presentation. The typical characteristics of the feed materials and the combustion products were presented and comparisons between vinasse and the vinasse-like material were given.
Technology to reduce, re-use and recycle spent wash from ethanol production
(A. Vadanagekar, KBK Renuka, India)

This presentation described proprietary designs for ethanol plants in India, Thailand and Africa.

Reduction of low volumes of concentrated spent wash is achieved by recycling a certain proportion of spent wash to fermentation. A typical production value of 3 volumes of concentrated effluent per volume of ethanol (or 3:1) is claimed for the 160 kL/d ethanol plant at Athani, Karnataka State. The typical value for the industry in India is about 8:1. 12% alcohol concentration is being achieved in the fermenters. Excess spent wash is concentrated to 30% solids content and sent to biocomposting.

Developments in cellulosic ethanol – Australian perspective (B P Lavarack)

The main technologies to produce ethanol from bagasse and other cellulosic materials were reviewed in this presentation. The review only included information on major technological developments that have been published in the open literature. The two main pathways for the production of ethanol from bagasse were described; namely biochemical and thermochemical technologies. In the biochemical pathway, the DHR, Iogen, Lignol, Arkenol, Verenium and permutations of the technologies were discussed. The thermochemical pathway of gasification was reviewed and some recent developments in North America were described.

For cellulosic ethanol to be successful, it should be more competitive than existing ethanol production technologies based on starch (e.g. corn) or sugar (e.g. cane molasses) feedstocks. A target minimum selling price of US$1.07/US gal (at 2002 pricing) has been set by the USA Government agency (NREL) for the development of cellulosic ethanol. At time of presentation, it was apparent that cellulosic ethanol is not competitive, but this situation is changing rapidly, as the cost for the necessary enzymes has come down significantly in recent years.

Introduction to Sessions C and D

The Monday afternoon session was dedicated to solid fuels, recognising the direct energy value of sugarcane fibre: primarily bagasse but also trash. Economics dictated that most of the topics were commercial scale but there was some domestic scale as well.

Fundamentally, cane fibre has a bone dry GCV of almost 20 000 kJ/kg [not far from coal at perhaps 26 000], but it is a carbohydrate so has a higher wet gas loss than coal, more akin to gas or oil. The problems are that it is never bone dry – more like 50% moisture – it has an erosive ash content and it has a low bulk density plus difficult mechanical handling properties. It turned out that there were three natural divisions to the proceedings: solid fuels, trash utilisation and export cogeneration.

Solid fuels

Handling and storage of solid fuels) (Dr Bryan Lavarack, Mackay Sugar Ltd., Queensland, Australia)

The large scale storage of bagasse is essential for the more industrial uses of bagasse and it is its physical characteristics which dictate how this can be done: low bulk density; mat forming; high moisture content; subject to decomposition [and hence possible spontaneous combustion]; potential for environmental issues [dust, water run-off, odour]

Storage options range from low technology [and high use of mobile equipment] open piling through open air linear piling with units similar to wood chip pilers to high technology storage sheds which can be either circular [Australia] or linear [Southern Africa]. Several countries have also tried baling in one form or another but without too much success.
The solution adopted depends primarily on local conditions for operations but it will become more important in the future as nations seek to reduce greenhouse gas emissions. Innovative answers will be required which are safe, economic and environmentally friendly.

**Bagasse briquettes and pellets (Dr M.B. Inkson, TSE, UK)**

The low bulk density of bagasse [125 to 150 kg/m³] is a serious drawback to its use, except when it comes to suspension firing. Techniques are required to increase the density for large-scale transport and/or storage or to create a solid fuel for domestic or small-scale industrial use.

The issue is economics: the cost of plant and energy to compress the bagasse and again to decompress it. Low pressure baling to something closer to 1000 kg/m³ is, therefore, probably the answer, a technique which also reduces the oxygen content in the pile and reduces the fire risk of bagasse storage.

Pelletising [to make 8–15 mm extrusions] and briquetting [to make >50 mm extrusions] are techniques for making solid fuel. Typically they rely on the natural components of the biomass – waxes and the like – to bind the pellet or briquette. Unfortunately, bagasse is highly abrasive so the dies in the machines do not last long and are expensive to replace so that the economics at an industrial scale do not add up. There is also the issue of moisture: pre-drying is required and, if that was easy, it would be routine for all boiler fuel.

However, the desire for ‘green fuels’ is distorting economics and bagasse pellets are being made at industrial scale and shipped across oceans so maybe the future holds promise.

**Trash utilisation**

**Cane trash as boiler fuel (N.Prabhakar, Nava Bharat Sugar, India)**

Trash, up to 15–20% of the clean cane mass and with only about 30% moisture has about one quarter of the crop’s total energy content. There is the potential to produce an additional 730 kWh per tonne of trash – which would, if fully utilised, increase the industry’s power export by 87% in India and reduce the country’s annual energy deficit by 28%.

Another reason for investigating trash as a fuel is that, in India, at least, newer cane varieties have lower fibre contents. The average has decreased from 14 to 12.64% in this decade alone.

The higher cost of separate handling for trash and the impact of the high alkali metal content on the boiler led Nava Bharat to try whole-cane processing. The benefits were as expected with no serious impact on boiler operations, although bagasse moisture and ash contents were higher. There was a slight increase in cost of transportation and a reduction in sugar recovery due to pol loss through increased bagasse and juice purity.

**Cane field residues as boiler fuel (K N Nibe, Pandurang Sugar, India and D K Goel, STM, India)**

The very recent results of separate harvesting and burning trash at a mill in Maharashtra were reported.

Typically, 100 t of clean cane is harvested per hectare with green tops going for animal feed, leaving 8–10 t of trash. The trash is baled with commercially available units and delivered to the factory at a cost of US$16 per tonne. The trash has a GCV of almost 16 000 kJ/kg, two thirds more than that of the factory’s bagasse so the price is equivalent to about US$10/t.

The bales are shredded again in specially made, electrically driven units and fed to the boilers at a rate of about 5% of the bagasse feed rate. No adverse impact on the boiler operation has been observed in the first 60 days of the trial.
Export cogeneration

Overview of modern bagasse power stations (Dr M.B. Inkson, TSE, U.K.)

Export cogeneration involves a series of steps, each of which reduces the overall efficiency of the process. The boiler contributes the highest apparent loss but the hidden and sometimes highest loss lies in the overall time efficiency of the factory: those periods when not crushing and therefore not making boiler fuel but still consuming steam.

Over 90% of boiler losses are stack losses so boiler efficiency can be optimised by minimising excess air and the flue gas exit temperature. However, the first focus should be on minimising bagasse moisture in the factory [or by drying – a topic sadly missing from the workshop] as the greatest by far of the stack losses is the wet gas loss.

Although turbine efficiency is important to the work recovered [and hence the station’s export capability], it contributes little to energy loss as the un-recovered energy appears in the exhaust steam. It is worth noting, however, that the efficiency can be optimised by selecting high speed machines and considering twin shaft units if a lot of condensing is involved. Condensing, however, should be considered with care: cogeneration is more efficient than condensing and it is only the ‘free’ fuel that permits competition with a utility.

The HP steam condition is the final point for efficiency discussion: thermodynamics dictate that higher conditions deliver a higher efficiency. However, when economics are considered the return on investment at higher conditions seems to fall.

Experience with bagasse-based cogeneration (G.V. Raman, Avantgarde, India)

There has been a steady increase in HP steam conditions in India with several stations at or about 110 bar/540°C and now one at 125 bar/540°C, although how the two different pressures with one temperature can both be optimal was challenged. There is an 8% improvement in work recovered when going from 67 bar/485°C to 87 bar/515°C and another 7% in going from there to 110 bar/540°C. The capital cost increase from the lowest condition to the highest is 25%.

The most important points during conceptual design are to take the OTE (overall time efficiency) into account and to downsize the station to ensure a good load factor. Other factors presented also reinforced those made in the previous paper and then focused on the steam % cane ratio.

Mills in India are now achieving 36% steam % cane: a value which delivers 10.7% more electricity than 50% steam on cane on a gross basis. The point was also made that re-injecting medium pressure bleed from the turbine into the boiler, whilst counter-intuitive, is a valuable way of improving cycle efficiency.

On the turbine side, the issue of silica solubility in steam was highlighted which leads naturally to the need for considerable attention to be paid to boiler feedwater and boiler water qualities. Membrane technologies have mainly been adopted for water treatment in India and membrane costs have come down considerably.

Operating costs are more favourable than ion exchange technologies too, although they do start to converge at low raw water dissolved solids levels.

The final point addressed was the question of the station’s parasitic power. In the early 1990s, the parasitic power of a typical station was about 12% of gross. Ten years later it had dropped to about 8%, just by using VFDs instead of dampers and valves to control flows and pressures.

High pressure multi-fuel boilers (A.K. Subramanian, ISGEC John Thpmon, India)

This paper examined the features of a typical modern Indian boiler firing bagasse, other fibrous fuel and Indian coal. The HP conditions were 105 bar/540°C.
It is a single drum unit rather than bi-drum but otherwise much like similar boilers operating at lower conditions. It did, however, receive much hotter feedwater because of the two-stage BFW heating in the thermodynamic cycle. That is possible because of the higher saturation temperature at which the boiler operates.

The single drum can be much thinner walled as there are few penetrations and it also allows for non-heated downcomer tubes so circulation is improved. The separate steam generation bank eliminates tube expansion and the associated issues. The particular design adopted the so called flag concept with the tubes at the top of the heat recovery tower.

Higher HP conditions do require careful attention to be paid to materials of construction, as was evident in this boiler.

**Advanced bagasse boilers (E. Browne, Cethar Vessels, India)**

The paper also examined the features of a typical modern Indian boiler firing bagasse, this time generating at 107 bar/545°C. The unit, however, was a conventional bi-drum design.

This particular company is currently building the boiler for the highest HP conditions in India: 135 bar/545°C

**Power generation efficiency of Greenfield Sugar Plants (D K Goel, STM, India)**

This important paper compared the results from six Indian export cogeneration factories as being typical of 36 surveyed in total. Brief cycle characteristics were:

- A: 45 bar/430°C back pressure power cycle without HP heater.
- B: 45 bar/430°C extraction condensing power cycle without HP heater.
- C: 67 bar/500°C back pressure power cycle without HP heater.
- D: 87 bar/515°C back pressure power cycle without HP heater.
- E: 87 bar/515°C extraction condensing power cycle without HP heater.
- F: 87 bar/515°C extraction condensing power cycle with HP heater.

The survey confirmed that higher HP conditions and using the boiler as part of the cogeneration are both beneficial. The station efficiency of the six examples was presented as the net electrical export MW per MW available in the fuel bagasse expressed as percent:

<table>
<thead>
<tr>
<th>Station efficiency</th>
<th>A</th>
<th>B</th>
<th>C</th>
<th>D</th>
<th>E</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>9.00%</td>
<td>12.94%</td>
<td>12.30%</td>
<td>13.68%</td>
<td>14.58%</td>
<td>15.34%</td>
</tr>
</tbody>
</table>

Extrapolating the data, an efficiency of 16% was predicted for a 110 bar/540°C cycle and, if bagasse drying is adopted, an efficiency of about 17% might be expected.

**Overview of high efficiency turbines (Dr M.B. Inkson, TSE, U.K.)**

Little has changed fundamentally with steam turbines since Parsons hit upon the need to have many small let-down stages rather than a single large stage over a century ago. Higher-speed machines are more efficient than low-speed ones, but speed is limited by the need to keep the tip speed below the speed of sound. Every single shaft multi-wheel turbine is therefore a compromise and efficiency suffers. As we move to more stages – and particularly extraction condensing machines – the problem gets worse.

The other issue is that a condensing section requires typically at least 10% of the steam flow to pass through the back-end in order to keep it cool.

One solution is to install more than one turbine, using a back-pressure machine during crop and a condensing machine during off crop operation: an expensive approach. A better solution is to have twin shaft machines [on the basis that triple or more shafts are uneconomic] with each shaft at an optimum speed. It might then be possible to decouple the condensing section during crop.
Overview on bagasse gasification (Dr B.P. Lavarack, Mackay Sugar Ltd. and Dr P.A. Hobson, Queensland University of Technology, Queensland, Australia)

Ultimately, though, the way to improve the efficiency of electricity production from bagasse is to adopt bagasse gasification coupled to a combined cycle station: a gas turbine followed by an HRSG (heat recovery steam generator) and steam turbine. A doubling of the gross electrical production can be expected.

There are many types of gasifiers with much work on-going. A search in 2007 identified 13 ‘credible’ technology suppliers using a range of technologies but none of them is yet able to offer anything over 5 MW-electrical and nothing has been achieved yet in the cane sugar industry. Of the work that has taken place in our industry, nothing has yet reached commercialisation and work seems to have more or less stopped for now.

Beyond gasification with combined cycle lies gasification to produce biofuels and hydrocarbons: essentially the Fischer Tropsch process. This lies still further in the future and it is unclear how it would be integrated into the sugar factory – one point which has at least been resolved with the combined cycle option.

Sessions E and F – Biofermentation of sugar into chemicals

Biofermentation of sugar into high value chemicals and polymers (Prof. D. Jhurry, University of Mauritius, Réduit)

This presentation discussed the option for Mauritius to produce products both from the sugar industry and the sea (the two main local resources available in the country). In particular they focus on (i) polymers for medicines and therapeutics, (ii) value added chemicals and (iii) green analytical procedures for quality control.

The concept of white biotechnology was explained: the application of nature’s toolset (yeasts, mould, enzymes and plants) to synthesise products that are easily degradable, require less energy and produce less waste. An interdisciplinary approach is required.

Examples of the fermentation of sugars into sugar alcohols were discussed. The potential for application as low calorie sweeteners is large.

Biobased polymers (Prof. D. Jhurry, University of Mauritius, Réduit)

Microbiological produced polymers manufactured include polysaccharides (xanthan gum and hyaluronic acid) and polyesters (polyhydroxbutrate (PHB), Natureworks™ and Sorona®). The advantages of these biobased polymers are (i) they use renewable resources and up to 55% less fossil resources, (ii) they contribute to reducing greenhouse gas emissions and (iii) require cheap biological feedstocks. The basics for the production of PHB (biodegradable plastic) were discussed, including fermentation and chemical recovery.

From sugar to lactic acid and polylactic acid (Prof. D. Jhurry, University of Mauritius, Réduit)

The potential for lactic acid as an intermediate chemical for conversion to both esters and polylactic acid was described. Lactic acid esters are used in cosmetics and in the food industry. Polylactic acid (PLA) is a polymer with applications in the packaging industry and in the medical field.

Preliminary results were presented for the production of lactic acid from mixed juice and syrup feedstocks using a Lactobacillus strain. The steps for the recovery and purification of lactic acid were given. CMR (Carbon 13 magnetic resonance spectroscopy) and NMR (nuclear magnetic resonance spectroscopy) results were presented that indicate that the process is technically feasible. The initial laboratory work will transfer to pilot plant scale.

Market opportunities exist in India for lactic acid as well as for other fermentation products including L-lysine, gluconic acid, itaconic acid and glutamic acid (MSG).
Session G – Pulp and Paper production

**Pulp and paper manufacture from sugarcane bagasse (K. Viswanathan, SPB-Seshasayee Paper & Boards Ltd, Erode, India)**

SPB (Seshasayee Paper and Boards Ltd.) and TNPL (Tamil Nadu Newsprint and Papers Ltd) produce over 120 000 and 200 000 tonnes, respectively, per year of newsprint, as well as printing and writing paper from bagasse and wood. SPB was established in 1960 and TNPL in 1992 and both have achieved high productivity and ecologically friendly production methods. While raw materials for paper worldwide consist of 57% wood, 39% waste paper and only 4% agro residues (i.e. bagasse and others), in India the proportions are 37% for wood as a raw material, 32% waste paper and 31% of agro wastes (mostly bagasse).

Agro fibres require only 50% of chemicals when compared to wood. About 5.5 t of bagasse are required for producing 1 t of bagasse chemical pulp. By adding a minimum necessary amount of wood pulp (10–15%), the paper mill produces approx. 1.17 t of printing and writing paper from 1 t of bagasse chemical pulp.

Bagasse as a fibre source for paper making has a number of advantages over other raw materials such as bamboo, soft or hard woods and wheat or rice straw:

- Lower alkyl-benzene extraction requirement (because of lower content of wax and resins)
- Higher pentosan content (good bonding characteristics)
- Lower lignin content and more open structure (easily pulpable with less chemicals)
- One disadvantage in relation to soft and hard woods is the higher 1% NaOH solubility, indicating potential deterioration during storage (this can be handled with adequate precautions)
- ith separated from the bagasse fibre is burnt in steam boilers, thus providing energy
- Lower tearing strength of bagasse pulp is due to short fibre length due to crushing in the sugar mill; this can be compensated by adding wood pulp with longer fibres

The presentation was complemented by a very well organised visit to the SPB plant and to the adjacent Ponni sugar mill.

**Production of bagasse-based particle boards in India (V.S. Raju, Ecoboard Industries Ltd, Pune, India )**

India produces annually about 200 000 m$^3$ of bagasse-based particle board in 17 plants located in Maharashtra, Gujarat and Uttar Pradesh. These particle boards are employed for furnishing office, school and household furniture with good appearance and better mechanical properties than wood-based particle boards, thus saving an equivalent felling of trees. India’s potential requirement of particle boards is assessed at 10 Mm$^3$ to meet increasing construction and housing activity; the same could be produced by establishing about 1000 similarly sized plants and by using pith-free fibre from bagasse produced by the existing 560 sugar mills and other agri-crop residues.

About 250 t of bagasse are required to produce 100 m$^3$ of particle board per day (typical size of the existing plants), respectively 3.5–4 t of sugar mill bagasse with 48% moisture are required to produce 1 t of particle boards.

Presently, however, bagasse is also in great demand for cogeneration purposes. Both uses contribute to the reduction of green-house emissions.
Session H – Animal feed and others

Addition of molasses to cattle feed (S. Ramamurthy, SKM Feeds, India)

Compounded cattle feed is a concentrated feed i.e., high in nutrient content. It does contain a maximum of 11% moisture, minimum of 60% total digestible nutrients (TDN) and not more than 18% crude fibre (CF). The main raw materials for the compounded dairy cattle feed are maize or corn, sorghum, broken rice and ragi. That apart, some deoiled rice bran, wheat bran, maize bran and rice polish are also used as ingredients. Additionally, certain oil cakes such as cottonseed extraction, coconut extraction, soybean extraction and Gingelly oil cake are also used.

Molasses is another major component which is used in cattle feed manufacture. It has the unique advantage of stimulating the rumen activity, improves appetite, increases forage and dry matter intake and enhances digestion. Molasses as a byproduct of sugar manufacture is more attractive so that forage intake can be increased and is economically viable. The other ingredients used are salt, calcite, dicalcium phosphate, mineral supplement, vitamin AD3 supplement, etc.

Sugar cane coproducts in Thailand (Dr P. Weerathaworm, Mitr-Phol Group, Thailand)

The Thai sugar industry produces about 7 Mt of sugar yearly, from a cultivated cane area of about 1 Mha. There are 47 sugar mills with daily processing capacities ranging from 5000 to 40 000 t/d. One of the largest groups is Mitr Phol, which has five modern factories with crushing capacities of 14 000–31 000 t/d in Thailand and five factories in China ranging from 5000 to 15 000 t/d. Through close supervision, Mitr Phol accepts only properly cleaned and loaded green-cut cane. Cane is mostly hand-cut and trash is left on the fields as a protective blanket.

Mitr Phol has invested heavily in byproduct utilisation in recent years. At the Phu Khieo site (‘Mitr Phol Park’), for example, it operates a biomass boiler utilising 85% bagasse and 15% rice husks and corn cobs as fuel and selling 65 MW to the grid. At the Dan Chang site 53 MW are sold.

At Phu Khieo there is also a distillery producing 200 000 L/day and a second distillery at the Kalasin site, both producing fuel-grade ethanol for blending with gasoline. Also at Phu Khieo, there is a particle board plant, already established in 1990 with a capacity of 90 000 m³ per year. It uses more than 200 000 t of bagasse per year.

Finally, through adequate waste-water treatment and usage of excess condensate from the sugar production process, irrigation schemes have been implemented to irrigate cane fields during the dry months. Agricultural extension services and its own sugarcane research station round off a highly successful enterprise.
RAPPORT: ATELIER DE TRAVAIL DE L’ISSCT SUR LES CO-PRODUITS 2009

MOTS-CLÉS: Cogénération, Chaudières, Manutention de la Bagasse et de la Paille, Éthanol Cellulosique, Vinasse, Biofermentation, Mélasse.

Résumé

L’ATELIER de travail de l’ISSCT sur les Co-Produits s'est tenu à Coimbatore, Inde du 15 au 19 mars 2009 et a attiré 41 participants de huit pays. Il y avait deux thèmes principaux : le lundi fut appelé le ‘Jour de l'énergie’ et les communications traitaient de la production d'énergie sous forme liquide et solide émanant des coproduits, ainsi que de la cogénération d'énergie électrique de la bagasse et de la paille. La participation de l’audience fut très active et les discussions animées. Le mardi des visites furent effectuées à deux usines sucrières notamment Sakhti Sugars et Bannari Aman qui sont équipées de chaudières à haute pression. Sakhti Sugars dispose également d'équipements pour concentrer et incinérer la vinasse alors que Bannari Aman a une unité de biofermentation à partir de la vinasse et des égouts des moulins. Le mercredi a été consacré au ‘Produits dérivés’ et les questions telles que la production des produits chimiques à forte valeur ajoutée par biofermentation de sucre, la production de la pulpe et du papier à partir de la bagasse et l’incorporation de la mélasse pour l'alimentation animale, ont été débattues dans un cercle restreint. Le jeudi, une visite a été effectuée à un complexe industriel impressionnant (SPB – Seshasyee Paper and Boards Ltd. Erode) dédié à la production de papier d’impression et industriel en association avec une usine de sucre (Ponni Sugars) qui fournit de la bagasse à l'usine de papier. Une unité de traitement des eaux usées est commune aux deux activités. L'atelier était organisé et gracieusement sponsorisé par Ponni Sugars (Erode) Ltd., ainsi que par SPB. Tous les communications ont été bien présentées et ont généré des vives discussions et une bonne interaction entre les participants. Les principales conclusions de l'atelier étaient : Compte tenu de la nécessité de réduire les émissions de gaz à effet de serre, l'importance de la cogénération à partir de la bagasse et autre biomasse, ainsi que la production de bioéthanol de la mélasse et du jus de canne ne cessera d'augmenter. Des chaudières à haute pression et cycles efficients (110 barres, 540°C) sont bien établies et les coûts d'investissements sont entrain de diminuer. Des solutions pratiques pour gérer de large volume de vinasse émanant de la production de bioéthanol sont disponibles, mais ces technologies ainsi que les investissements requis doivent être optimisées. Pour couvrir adéquatement les sujets prometteurs, la division en deux sections (énergie et dérivés) doit être retenue pour les ateliers futurs. L'emphasis sur l’un ou l'autre de ces thèmes pourrait varier selon le nombre de contributions reçues. Afin d'encourager une meilleure participation des technologistes avec des emplois de temps chargés, il devrait y avoir deux jours consécutifs de sessions qui seraient suivis de deux jours de visites à des unités industrielles pour le prochain atelier. De nombreuses communications ont été jugées aptes pour être présentées au Congrès de l’ISSCT au Mexique en mars 2010.

PALABRAS CLAVE: Cogeneración, Calderas, Manipulación de
Bagazo y Paja de Caña, Etanol Celulósico,
Vinazas, Biocomposteo, Biofermentación, Mieles.

Resumen

El taller de Coproducios de la ISSCT del 2009 se realizó en Coimbatore, India, del 15-19 de marzo del 2009 y contó con 41 participantes de 8 países. Se identificaron y consideraron dos Temas Principales: El Lunes se denominó ‘Día de la Energía’ y en él se abordó la producción de energía sólida y líquida a partir de los coproducios, así como la cogeneración de energía eléctrica a partir del bagazo y la paja de la caña. Prevalecieron una muy buena participación de la audiencia y vivos debates. El Martes se visitaron dos ingenios azucareros (Sakhti Sugars y Bannan Aman), que tienen calderas de alta presión. Sakhti Sugars posee también equipos para la concentración e incineración de las vinazas, mientras Bannan Aman cuenta con una planta para compostar las vinazas mezcladas con las tortas de los filtros. El miércoles fue el ‘Día de los Derivados’, cuando se debatieron, en grupos más pequeños, aspectos como la biofermentación de azúcar para la obtención de productos químicos de alto valor, la producción de pulpa y papel de bagazo, la adición de mieles finales al alimento animal. El jueves visitamos una impresionante planta productora de papeles de imprenta e industriales (SPB) y un ingenio azucarero adyacente (Ponni Sugars) que provee de bagazo a la planta de papel, así como también un eficiente tratamiento conjunto de aguas residuales. El Taller fue acogido y gratamente patrocinado por Ponni Sugars (Erodes) Ltd., y por SPB-Seshaysee Paper and Board Ltd. Erodes. Todos los trabajos técnicos fueron bien presentados y generaron discusión e interacción entre los participantes. Las principales conclusiones del Taller fueron: En razón de la necesidad de reducir la emisión de gases de efecto invernadero, continuará incrementándose la importancia de la cogeneración con bagazo y otras biomasas, así como la producción de bioetanol a partir de las mieles y jugo de caña; La generación de vapor en calderas de alta presión y ciclos eficientes de generación de potencia (110 bar, 540°C) están bien establecidos y se reducen los costos de inversión; Están disponibles alternativas prácticas para manejar los grandes volúmenes de vinazas residuales de la producción de bioetanol, sin embargo, aún se requiere la optimización de las tecnologías y los volúmenes de las inversiones; Con el fin de cubrir adecuadamente aspectos promisorios, debe mantenerse en futuros Talleres la división en dos (2) Secciones (Energía y Derivados). El énfasis real sobre cualquiera de ellos variará en correspondencia con la cantidad de contribuciones que se reciban; Para promover, en el próximo Taller, una mayor participación de especialistas que disponen de tiempo limitado, deberán realizarse las presentaciones en dos (2) días consecutivos de sesiones, seguidos de dos (2) días de visitas a plantas; Muchos trabajos técnicos discutidos en el Taller se consideran con méritos suficientes para ser presentados en el Congreso de la ISSCT en México en Marzo del 2010.
INTEGRATED PRODUCTION OF ORGANOMINERAL BIOFERTILISER (BIOFOM®) USING BY-PRODUCTS FROM THE SUGAR AND ETHANOL AGRO-INDUSTRY, ASSOCIATED WITH THE COGENERATION OF ENERGY

KEYWORDS: Organomineral Biofertiliser, Vinasse, Ethanol.

Abstract

BRAZILIAN bioethanol and sugar production generates large amounts of vinasse, filter cake and boiler ashes (originated from biomass combustion). On the other hand, the distribution of these by-products in the field is usually inadequate, considering the environmental aspects and the best use of nutrients and organic material present in these by-products. This work presents a study for reprocessing of these by-products into a solid and granular organom ineral biofertiliser developed by Dedini S/A Ind. Base (BIOFOM®), which can be formulated according to the soil and vegetable specific needs. This article shows the process of an integrated BIOFOM, ethanol and electricity from biomass production system for an industrial unit of large capacity. The results of BIOFOM preliminary agronomic greenhouse tests and analysis of process profitability are also shown. These results indicate an excellent internal rate of return (IRR) and attractive payback time as well, resulting from surplus power sales, reduction of chemical fertiliser and fuel consumption, reduction of by-products distribution infrastructure, and decrease (elimination) of the mill’s water withdrawal. Moreover, BIOFOM gave a good agronomic performance in greenhouse use experiments, and it will provide an appropriate reuse of the by-products, in accordance with green technologies. Therefore, the studies show that BIOFOM will lead to the existence of a more profitable and sustainable agro-industry that adopts rational and friendly practices for the environment.

Introduction

According to UNICA (União da Indústria de Cana-de-Açúcar, 2008), 495.7 million tonnes of sugarcane were processed in the Brazilian 2007–2008 milling season, producing 2.5 million m³ of ethanol (anhydrous and hydrated) and 30.9 million tonnes of sugar.

The volume of vinasse generated is about 10 times the volume of ethanol produced, 28 kg to 40 kg/t cane of filter cake, and 6.25 kg/t cane of ash and soot resulting from bagasse burning. These by-products are reused in the cane field, but sometimes the disposal of such materials is not made appropriately, with losses in nutrients, N, P, K and organic matter contained in the by-products.

This paper proposes a profitable production system of a solid and granular organom ineral fertiliser from these by-products for any mill producing ethanol and co-generating electricity. The system permits a significant reduction in the use of chemical fertilisers and diesel oil, thus reducing the greenhouse gas emissions (GGE) and allowing the recovery of water contained in vinasse for reuse in the industry or in the crop (ESALQ, 2007 and 2008; Gurgel, 2009).
Materials and methods

For a technical-economic evaluation of the proposed solution, a case study was carried out for an ethanol producing mill equipped to produce power by cogeneration, with capacity to process 20,000 tonnes of cane per day (Table 1A).

For the purposes of the study, an industrial plant to meet this capacity was dimensioned and price quotations were duly requested. The costs of handling and distribution of the by-products in the cane field (vinasse, filter cake, ash, soot and chemical fertilisers) were calculated, and these costs were compared with those involved in the production and distribution of the organo ineral biofertiliser, called BIOFOM® (Gurgel, 2009; Kiël, 1985; Mantelatto et al., 2007).

To evaluate BIOFOM’s agronomic potential, batches of this fertiliser were produced (see Figure 1) from vinasse, filter cake, ash and soot and complemented with chemical fertilisers, which were granulated and dried (Carmello et al., 2009). The biofertiliser granulation was made in a plate granulator with 35 r/m disc rotation. The experiment (ESALQ, 2009, Carmello et al., 2009) was conducted in the greenhouse of the Department of Soil Sciences of ‘Luís de Queiroz’ College – ESALQ (University of São Paulo, 2009) in Piracicaba, SP.

The experiment was designed for 25 treatments: Control sample, mineral fertiliser 100%, 75% and 50% of 50 kg of N, 100 kg of P₂O₅ and 100 kg of K₂O; BIOFOM from vinasse (resulting from ethanol production), concentrated, 30% and 45% total solids with 100%, 75% and 50% of the N, P and K doses in the treatment with m ineral fertiliser; BIOFOM from vinasse plus sugar, concentrated, 30% and 45% total solids with 100%, 75% and 50% of the N, P and K doses in the treatment with m ineral fertiliser; BIOFOM from vinasse (resulting from sugar production), concentrated, 30% and 45% total solids with 100%, 75% and 50% of the N, P and K doses in the treatment with m ineral fertiliser; concentration of vinasse (30% total solids) from ethanol production with m ineral com plmentation for 100% of 50 kg of N, 100 kg of P₂O₅ and 100 kg of K₂O; concentrated vinasse (30% to tal solids) from ethanol and sugar production with m ineral com plmentation for 100% of 50 kg of N, 100 kg of P₂O₅ and 100 kg of K₂O; concentrated vinasse (30% total solids) from sugar production with m ineral com plmentation for 100% of 50 kg of N, 100 kg of P₂O₅ and 100 kg of K₂O, with four replications each, resulting in 100 plots. All treatments received limestone, including the control sample. Each plot was represented by a 2.5 L capacity pot, wherein 2 kg of earth, 0.625 g of CaCO₃ and 0.625 g of MgO were added.

Two corn seeds were planted in each pot, and the seedlings were then thinned out to one plant per pot on the 5th day of the experiment. The results were evaluated with respect to the foliar area, dry matter of the aerial portions and roots, amount of nutrients in the plant’s aerial portions and roots, and remaining BIOFOM after harvest.

Results

Technical-economic evaluation of the BIOFOM producing unit

Figure 1 shows the organo ineral fertiliser made from cake, ash, soot and concentrated vinasse and complemented with chemical fertiliser, called BIOFOM (Gurgel, 2009; Kiël, 1985; Mantelatto et al., 2007).

Figure 2 presents a chart of the unit operations, feedstock and utilities for BIOFOM production for a basic formulation of the end fertiliser. In this process, filter cake, boiler ashes and soot are mixed and dried. The vinasse generated by the distillation of ethanol is concentrated up to 50% dry substance (DS) in multi-effect vacuum evaporators and is further mixed with a mineral source of N, P and K and sent to be mixed with cake, ashes, and soot previously dried. The mixture is granulated and dried, resulting in a solid organo ineral fertiliser (Figure 1) according to the planned formulation. The energy required for the vinasse concentration is obtained from the integration of energy with distillery, and the dried mixtures result from the combustion in the furnace of bagasse and/or trash (‘straw’) and/or optionally concentrated vinasse.
Fig. 1—BIOFOM.

Fig. 2—BIOFOM flow sheet.
Fertiliser savings with the use of BIOFOM

Table 1 (A) is a summary of the case study of a mill producing ethanol, power and BIOFOM. According to the data presented, a unit processing 3 600 000 tonnes of cane/season (20 000 tonnes of cane/day), equipped with a 67 kgf/cm² boiler that consumes some 430 kg of steam/tonne of processed cane, it is possible to process 1 500 000 L of ethanol/day, cogenerate 65 kWh/tonne of cane, and produce 180 955 tonnes of biofertiliser/season with a formulation (3, 3, 4).

| Mass flow (60% DS) t/season | 115 350 |
| Recovery water t/season | 2 272 314 |
| Volume reduction # | 20.7 |

Filter cake

| Mass flow (40%DS) t/season | 104 818 |
| Ash from boiler | |
| Ash from boiler/furnace t/season | 40 680 |

Chemical fertiliser complementary

| Urea (45% of N) t/season | 6265 |
| SSP (21% P205) t/season | 1322 |
| Potassium cloride (KCI) t/season | 196 |

Biofertiliser—BIOFOM

| Total production (85% DS) t/season | 180 995 |
| Specific production of BIOFOM kg/tc | 50 |
| Specific rate of application on land t/ha/year | 4.3 |

In this case, the power used to concentrate vinasse comes from the vegetal steam generated by juice evaporation and the alcoholic vapours of the distillery.

Table 1 (B) shows the savings obtained with BIOFOM fertiliser. According to these data, 35% of nitrogen, 62% of phosphorus and 98% of potassium can be recycled, which reduces dramatically the amount of fertiliser to be purchased.

In the overall picture, about 67% of the fertiliser to be used in the milling season can be optimally recycled and distributed in the field.

In addition, 2 272 314 m³ of water via recovered condensates by vinasse concentration can be used in the industry or in the field.

Economic evaluation

To evaluate the economic impact of BIOFOM production and use in the ethanol and energy producing complex, a study considering all investments and the fixed and variable costs for the production of this fertiliser in industrial and agricultural operations was carried out.

The study points out that the main advantage of BIOFOM lies in the reduced expenses with acquisition of fertilisers and the reduction in the investment and operational costs regarding agricultural operations. Vinasse distribution is no longer required, eliminating the need for trucks to transport such huge volumes.

In the case studied, it was assumed that vinasse would be concentrated up to 50% DS before mixing with the filter cake and ashes. A BIOFOM plant was designed for such a system, taking into consideration N, P and K complements to meet exactly the total sugarcane plantation needs.

Fertiliser expenses, which in the BIOFOM process refer to the N, P and K complements, reduced 70% when compared to the use of mineral fertilisers. Investments in trucks and distribution systems showed a reduction about 67% for the worst case (ethanol mill very close to the plantation).

Even when taking into account the extra labour required for the BIOFOM plant, the steam, electricity and bagasse consumption by the BIOFOM process, the net result is very positive.

Considering a capital cost of 12% per year and typical equipment costs, it can be shown that the discounted payback time of such a project ranges from 2 to 3.5 years, depending on the distance between the ethanol mill and the sugarcane plantation.
Another study shows that a water-exporting ethanol mill, based only on vinasse concentration but not producing BIOFOM, is not profitable, due to the low incomes and high investment. Since the BIOFOM process is a step further in that process, including the benefit of water exportation (Gurgel, 2009; Mantelatto et al., 2007), and was demonstrated to be profitable, it can be concluded that BIOFOM is a solution that makes water-exporting mills not only environmentally beneficial but also profitable.

Greenhouse results

Table 2 presents a summary of the comparative results (100% of the formula to sugar-cane) of the samples that were treated with BIOFOM (by using vinasse with 45% DS), conventional fertiliser and those that did not receive fertiliser (control sample). Both those pots fertilised with BIOFOM and those fertilised with a formulation prepared with chemical fertiliser only were prepared to meet 45%, 75% and 100% of the amount of N, P and K required for sugarcane culture. The BIOFOM samples were prepared with three different types of vinasse, obtained from fermentation of mixed juice (J), or molasses (M) or mixtures of molasses and mixed juice (MJ).

After harvesting, 50 days after planting, all samples were evaluated with regards to foliar area, dry mass and nutrients present in the aerial portion of the plants and in the root system, residual N, P and K in soil, and the remaining BIOFOM in the granule after harvest.

As the results presented in Table 2 show, all treatments had significantly better performance than the control sample. Also, there were no significant differences between the treatments with BIOFOM using different vinasses (MJ, M and J).

Note: MJ : vinasse from molasses and juice, M: vinasse from molasses, J: vinasse from juice, nd: not detected

The mineral fertiliser produced a bigger mass of dry matter in the aerial portion of the plant, which shows that some of the nutrients present in BIOFOM were not available 50 days after application, which is an advantage in an open system environment where leaching of the mobile nutrients in the soil occurs. In fact, it should be noted that more than 50% of the nutrients in
BIOFOM initially applied remained in the soil after 50 days. It should also be taken into account that, in this experiment, being a closed system, no losses occurred, resulting in a slightly higher efficiency in the treatments where chemical fertiliser was applied.

For sugarcane, whose cycle is 12 to 18 months, there is enough time for the remaining BIOFOM nutrients to be available and, therefore, it can be expected that it responds similarly or even better than the treatments with mineral fertilisers (Carmello et al., 2009). Kiel (1985) reported the benefits of the application of organic matter in soil, which promotes the improvement of the soil physical-chemical properties, the CEC – Cation Exchange Capacity, and porosity, which facilitates the absorption of nutrients and reduces the losses caused by leaching. By using BIOFOM in soil, the same benefits reached with organic matter can be expected, given that at BIOFOM is composed of about 40 to 70% of organic matter, depending on the formulation used.

Conclusions

According to the results obtained, we can conclude that:

- It is evident that BIOFOM is a competitive and sustainable organomineral fertiliser;
- BIOFOM permits an optimum and profitable distribution of sugar, ethanol and energy by-products, which enables recycling of more than 50% of the fertiliser required in sugarcane plantation;
- BIOFOM can be formulated according to the specific needs of the soil, permitting optimum use of chemical fertilisers;
- Additional gains with the use of BIOFOM, because of its high content of organic matter, will be obtained with the improvement of the soil physical-chemical properties, the CEC – Cation Exchange Capacity, and porosity, which facilitates the absorption of nutrients and reduces the losses caused by leaching;
- The economic study showed the feasibility of the project implementation for BIOFOM production: excellent internal rate of return (IRR) and payback time of 2 or 3 years;
- The use of BIOFOM in the crop land allows a significant reduction of the infrastructure required to distribute fertiliser, vinasse, filter cake and ashes;
- With implementation of BIOFOM, it is possible to reduce or even eliminate water withdrawal by the mills by using only the water contained in sugarcane: a portion of the recovered water in vinasse concentration can be reused in the industry or in the field.
- Optimisation of power consumption in the mills in connection with the implementation of a BIOFOM plant will certainly increase the profitability of the sugar and ethanol complex, due to the integrated production of biofertiliser, ethanol, sugar, surplus power generation and water recovery.

MOTS-CLÉS: Bioengrais Organomineral, Vinasse, Éthanol.

Résumé
LA PRODUCTION de bioéthanol et de sucre au Brésil génère de grandes quantités de vinasse, des tourteaux et des cendres des chaudières (provenant de la combustion de la biomasse). D'autre part, la distribution de ces sous-produits dans le champ est généralement pas satisfaisante, quand l’on considère les aspects environnementaux et la possibilité d’un meilleur usage des éléments nutritifs et des matières organiques présents dans ces sous-produits. Cette communication présente une étude de traitement de ces sous-produits afin de produire un bioengrais organom ineral solide et granulaire développé par Dedini S/A Indiana Base (BIOFOM ®), qui peut être formulé conformément aux caractéristiques du sol et aux besoins spécifiques des plantes. Le procédé d’un système de production intégré de BIOFOM, d’éthanol et d’électricité à partir de la biomasse pour une unité industrielle de grande capacité est décrit. Les résultats des tests préliminaires agronomiques effectués en serre avec le BIOFOM et de l’analyse de rentabilité du procédé sont également présentés. Ces résultats indiquent un excellent taux de retour interne sur l’investissement et le temps de recouvrement est aussi attrayant, etant issu de la vente du surplus d’énergie, de la réduction de la consommation de carburant et des engrais chimiques, de la réduction de l'infrastructure de distribution des sous-produits et de la diminution (élimination) du retrait de l’eau de l’usine. En outre, BIOFOM a donné une bonne performance agronomique dans des essais en serre, et il fournira une réutilisation appropriée des sous-produits, en conformité avec les technologies vertes. Par conséquent, les études montrent que BIOFOM conduira à l’existence d’une agro-industrie plus rentable et durable qui adopte des pratiques rationnelles et favorables à l'environnement.

PALABRAS CLAVE: Biofertilizantes Organometálicos, Vinazas, Etanol.

Resumen

LA PRODUCCIÓN de bioetanol y azúcar generan grandes cantidades de vinazas, tortas de los filtros y cenizas de las calderas (originadas de la combustión de la biomasa). Por otra parte, la distribución de estos subproductos en el campo es usualmente inadecuada, considerando los aspectos ambientales y los usos más efectivos de los nutrientes y los productos orgánicos en estos subproductos. Este trabajo presenta un estudio para el reprocessamiento de estos en un organobiofertilizante sólido y granular, desarrollado por DEDINI S/A ind. Base (BIOFOM*), el cual puede formarse en correspondencia con las necesidades de los suelos y los vegetales. Este artículo muestra el proceso de un sistema integrado, BIOFOM*, etanol, energía a partir de biomasa, para una unidad de producción industrial de gran capacidad. Se muestran también los resultados preliminares, de las experiencias agronómicas en invernadero, del BIOFOM*, así como un análisis de los beneficios económicos. Los resultados indican excelentes retornos internos de retorno (IRR) y atractivos tiempos de recuperación de la inversión, resultando de las ventas de energía sobrante, reducción de fertilizantes químicos, y consumo de combustible y en la infraestructura de la distribución de subproductos, junto al decrecimiento (eliminación) de la extracción del agua en el Central. Adicionalmente, BIOFOM* ofrece un buen comportamiento agronómico en los experimentos en invernadero y brindará un reuso apropiado de los subproductos en correspondencia con tecnologías verdes. Por tanto, los estudios muestran que BIOFOM* conducirá a la existencia de una agroindustria más rentable y sostenible, que adopta prácticas racionales y amigables con el entorno.
RHODOTORULA SPP. A POTENTIAL CANDIDATE FOR BIODIESEL PRODUCTION

KEYWORDS: Biodiesel, Microbial Oil, Oleaginous Yeast, Feed Protein, β-Carotene.

Abstract
This paper assesses the production of lipids in Rhodotorula spp. yeast biomass under certain propagation conditions. For lipid accumulation, a double-stage culture was arranged with a full balanced medium for cell propagation and afterwards, under nitrogen deficiency, to initiate the conversion of organic matter into triglycerides. This mode was compared with single-stage culture in terms of cell concentration, lipid productivity, protein content in final biomass, and lipid and biomass yields. Significant differences were found in respect to all parameters tested favouring single-stage culture except for cell concentration that was higher in the double-stage mode. Lipid productivity, the most important parameter, was 0.22 and 0.33 kg/m³/h for double and single-stage cultures respectively, whereas lipid content was 28.60% for double stage and 29.84% for single stage. Protein in final biomass was 29.98 and 30.46% for double and single-stage respectively. This latter is important, since the resulting biomass after lipid extraction can be used as animal feed. Taking into account that yeast production is far more intensive than with vegetal crops, oil-yeast production could be an attractive alternative to oil seeds for biodiesel production.

Introduction
One of the major challenges facing mankind at present is diminishing fossil fuel stocks. The burning of these materials is one of the key factors for global warming due to carbon dioxide and other greenhouse gas emissions. In addition, with the rapid rise in the price of crude oil and projected decrease in oil supplies, there has been increasing interest in biofuels in scientific and entrepreneurial communities (Pahl, 2005; Soriano et al., 2006; Kemp, 2006). To deal with these problems, alternative renewable biofuels are receiving considerable attention (Hill et al., 2006). One of the most prominent renewable energy resources is biodiesel, which is produced from renewable biomass by transesterification of triacylglycerols, yielding monoalkyl esters of long-chain fatty acids with short-chain alcohols: for example, fatty acid methyl esters (FAMEs) and fatty acid ethyl esters (FAEEs).

Biodiesel contributes no net carbon dioxide or sulfur to the atmosphere and emits fewer pollutants than normal diesel (Lang et al., 2001; Vicente et al., 2004). In the production of biodiesel, various renewable lipids have been chosen, including vegetable oils, animal fats and wasting oils (Aggelis et al., 1995).

Palm oil, rapeseed oil, and soybeans have been used to produce biodiesel. However, these require energy and land area for sufficient production. In spite of the favourable impacts that its commercialisation could provide, the economic aspect of biodiesel production has been restricted by the cost of oil raw materials (Antolin et al., 2002). If plant oil was used for biodiesel production, the cost of feedstock accounts for 70–85% of the whole production cost. Therefore, reduction of the high cost of biodiesel is of much interest.
Microorganisms have often been considered for the production of oils and fats as an alternative to agricultural and animal sources. However, a substitute for a fossil fuel should have not only superior environmental benefits or be economically competitive but also must provide a net energy gain over the energy sources used to produce it. Biodiesel production using microbial lipids has attracted increasing attention since it is expected to accomplish these requirements.

Yeasts and fungi (especially moulds) have been considered as favourable oleaginous microorganisms since the 1970s (Hall and Ratledge, 1977). Some yeast strains, such as *Rhodosporidium* sp., *Rhodotorula* sp. and *Lipomyces* sp. can accumulate intracellular lipids as high as 70% of their biomass dry weight.

The most efficient oleaginous yeast, *Criptococcus curvatus*, can accumulate storage lipids up to >60% on a dry weight basis, when it grows under N-limiting conditions, with a percentage of saturated fatty acids of about 44% which is similar to many plant seed oils (Ratledge, 1982). Other authors found similar fatty acid concentration in *Rhodotorula glutinis* grown on sugarcane molasses with N-limitation in the oil accumulation step (Almazan et al., 1981; Alvarez et al., 1992; Diaz et al., 1993; Alvarez and Steinbüchel, 2002). These fatty acids can be extracted, saponified and esterified with low molecular weight alcohols to yield biodiesel. The main limitation of yeast lipids as a feedstock is that they show almost 30% saturated fatty acids with scarce on no nutritional properties. On the other hand, some of these fatty acids have odd carbon numbers which is an additional drawback, as they cannot be metabolised by animals or human beings (Almazan et al., 1981; Alvarez et al., 1992).

The first step in such a production is the efficient accumulation of as much lipid as possible in yeast biomass. It is well known that *Rhodotorula* spp. synthesise yeast when nitrogen or any other important nutrient is scarce in growth medium (Enebo and Iwamoto, 1966; Coccuci et al., 1975).

The propagation step can be arranged in many modes, batch or continuous. The comparison between double-stage or simple-stage continuous culture is the subject of the present paper.

**Materials and methods**

**Microorganism**

*Rhodotorula glutinis* from the ICIDCA collection was propagated in all experiments. Inocula were prepared from agar-malt slants, grown overnight in a medium containing sugarcane molasses at 20 mg/mL of total reducing sugars concentration and nutrient salts (diammonium phosphate and sulfate) to cover cell nutritional requirements in a rotary shaker at 32ºC. A 2.5 L Marubishi MD5 fermentor was used to start batch propagation with the same culture medium at $\mu(=D) = 0.20h^{-1}$.

The exhausted medium with yeast cells was discharged in equal volumes to commence the second stage and was fed with fresh medium without nitrogen containing the same concentration of sugars as the first stage.

For single-stage experiments, the growth medium was the same except that nitrogen was fixed at 70% of nutritional requirements.

Dilution rate ($=\mu$) was set at $0.1h^{-1}$. Other fermentation parameters were temperature 32ºC, pH 4.0 and aeration one volume of air for volume of medium per minute (vvm). All experiments were run for 96 hours.

**Chemical analysis**

Nitrogen was determined according to Kjeldahl (Anon., 1983) in a 1030 Kjeltec Auto System (Tecator AB, Hoganas, Sweden). Reducing sugars were estimated by copper reduction (Greenfield and Geronimus, 1985).

Dry matter was desiccated at 105ºC overnight and lipids by extraction with ethyl ether and desiccation until constant weight in a vacuum oven at 60ºC.
Results

Batch culture

The basic physiology of lipid accumulation in microorganisms has been understood for many years (Enebo and Iwamoto 1966; Hall and Ratledge 1977).

Normally, the organism is cultivated in a medium consisting of an excess of the carbon source and a limited quantity of an inorganic nutrient, usually nitrogen. Other limiting components of the growth medium can also be used to promote lipid accumulation such as P, Mg, etc., but they lead to lower biomass production and hence lower productivity.

When one of the nutrients is depleted, the organism can no longer grow and divide and it starts to synthesise lipids as nutritional stock. Figure 1 shows the behaviour of biomass and lipid concentration under nitrogen limitation.

Continuous culture

Continuous culture has several advantages when compared with batch mode. Productivity increases several times and the whole process is more homogeneous once steady state is achieved.

Lipid accumulation is a typical double-stage process in which cells are propagated under full-requirement conditions and, in a second stage, cells are left to accumulate lipids through nitrogen limitation (Almazan et al., 1981).

A typical fermentation arrangement for double-stage culture can be seen in Figure 2.
Figure 3 shows the pattern of the second stage for lipid accumulation in terms of cell biomass and lipid production. As lower D values favour lipid accumulation, this parameter has to be set up like a batch system to get as much lipid in the final biomass as possible. Under such conditions, lipid productivity ranged from 0.28 to 0.34 mg/mL/h.

The kinetic behaviour of lipid accumulation seems to be as if it were growth associated. This is a consequence of steady state propagation under continuous culture, even at a low dilution rate.

This pattern suggests that it is possible to achieve such a steady state in a unique stage provided that two premises were accomplished: a) nitrogen limitation has to be sufficient to sustain growth, so total absence of this nutrient is not possible, and b) dilution rate must be higher than those values corresponding to maintenance, otherwise growth will not occur.
Given these conditions, single-stage culture was set up at the same temperature and pH as above for double-stage. Total reducing substances were fed at 30 mg/mL and nitrogen with 70% of sufficiency. Finally, D was established at constant value of 0.1h⁻¹.

Single-stage culture was set up according to parameters given in Material and Methods section. Figure 4 shows the behaviour of yeast culture under this arrangement.

Nitrogen limitation up to 30% of cell requirements guarantees similar results as in the double-stage culture in a unique reactor. Lipid productivity, the main interest in this technology, ranges from 0.31 to 0.36 mg/L/h, 6% higher than that obtained in a double-stage arrangement.

**Fig. 4—Pattern of cell and lipid concentration in the lipid-accumulation step in continuous single-stage culture of Rhodotorula glutinis.**

**Discussion**

Biodiesel production from microalgae has been suggested by different research groups. These microalgae have the advantage that they are sunlight-driven cell factories that convert carbon dioxide to potential biofuels (Metting and Pyne, 1996; Spolaore et al., 2006) and can provide several different types of renewable biofuels, including methane produced by anaerobic digestion of the algal biomass (Banerjee et al., 2002; Gavrilescu and Chisti, 2005), and they are high lipid microbes. On the other hand, they need larger acreages for culture and a longer fermentation period than bacteria or yeasts.

Bacteria such as *Arthrobacter* sp. and *Acinetobacter calcoaceticus* can accumulate about 20–40% of lipids per dry biomass but propagate at pH values close to neutrality; thus, the probability of foreign contaminants to compete for nutrients is a real drawback.

Yeasts are able to propagate in an ample range of pH, are significantly larger than bacteria, which means lower g values in industrial separators, and yeast culture is widely known everywhere. In addition, in an area slightly larger than two hectares, a 30 t/day factory can be implemented with an output of about 15 t/ha, a yield not achieved by any known oleaginous seed. Therefore, yeast seems to be the most promising candidate for microbial biodiesel production.

Single-stage culture has several advantages over the double-stage arrangement. In addition to a slight increase in lipids and biomass productivity, we have to take into account the capital
investment savings incurred in connection with the number of reactors needed in both arrangements which make single-stage culture less expensive than double-stage.

Some liquid wastes such as distillery vinasse or black liquors from paper industry could be tested to assess its utilisation in this process, which would add another environmental advantage.

In the course of fatty acid production, there are usually some other by-products useable by industry. In addition to oils, oleaginous microorganisms contain significant quantities of proteins, carbohydrates and other nutrient contents (Sanchez et al. 2003); therefore, how to make use of these by-products and improve their industrial value is another way to reduce the production cost of biodiesel.

For example, the residual biomass from biodiesel production can be used potentially as animal feed (Chisti, 2007), and also to produce methane by anaerobic digestion. The waste glycerol from the biodiesel industry could, therefore, be easily transformed into highly valuable chemicals (Hirschmann et al., 2005). *Rhodotorula* spp. produces ß-carotenes (provitamin A) and important proteins useful for animal feeding.

Résumé
Ce document évalue la production de lipides dans la levure Rhodotorula spp. sous certaines conditions de propagation. Pour l’accumulation des lipides, une culture en deux étapes a été réalisée avec un support équilibré pour la propagation de la cellule et par la suite sous carence azotée pour initier la conversion de la matière organique en triglycérides. Ce mode a été comparé avec une culture en une étape en termes de concentration cellulaire, de productivité des lipides, de teneur en protéines dans la biomasse finale, de rendement en biomasse ainsi qu’en lipides. Des différences significatives ont été trouvées en fonction des paramètres évalués favorisant la culture en une seule étape à l’exception de la concentration de cellule qui a été plus élevée en deux étapes. La productivité en lipides, le paramètre le plus important, était 0.22 et 0.33 kg/m^3/h pour les cultures en
deux étapes et une étape respectivement, considérant que la teneur en lipides était 28.60 % pour la phase double et 29.84% pour la seule étape. Les protéines dans la biomasse finale étaient de 29.98 et 30.46% pour les doubles et simple étape respectivement. Ce dernier point est important, car la biomasse obtenue après l'extraction de lipides peut être utilisée comme aliments pour bétail. Étant donné que la production de levure est beaucoup plus intensive que les cultures végétales, la production de biodiesel à base de levure pourrait être une alternative intéressante aux espèces d’oléagineuses.

**Resumen**

Este artículo describe la producción de lípidos en la biomasa de la levadura *Rhodotorula ssp.* Bajo ciertas condiciones de propagación. Para la acumulación de lípidos se estableció un cultivo en doble etapa, con una primera etapa de propagación celular a partir de medio de cultivo totalmente balanceado, seguido de la segunda etapa bajo condiciones de deficiencia de nitrógeno para inducir la conversión de la materia orgánica en triglicéridos. Este esquema se comparó con el cultivo en simple etapa en términos de concentración celular, productividad de lípidos, contenido de proteína en la biomasa final, así como rendimiento de lípidos y biomasa. Se encontraron diferencias significativas con respecto a todos los parámetros estudiados, favoreciendo el cultivo en simple etapa, excepto en lo referido a concentración de biomasa que fue mayor en el esquema de doble etapa. La productividad de lípidos, el parámetro más importante, resultó de 0.22 y 0.33 kg/m³/hr para doble y simple etapa respectivamente, mientras que el contenido de lípidos fue de 28.60% para la doble etapa y 29.84% para simple etapa. Los contenidos de proteína en la biomasa final fueron de 29.98% y 30.46% para simple y doble etapa respectivamente. Esto último es importante, en cuanto la biomasa resultante después de la extracción de los lípidos puede ser empleada como alimento animal. Tomando en consideración que la producción de levadura es mucho más intensa que los cultivos vegetales, la producción de levaduras ricas en grasas resultaría una alternativa atractiva en comparación con el cultivo de semillas de oleaginosas para la producción de biodiesel.
PRODUCTION DIVERSIFICATION FROM SUGARCANE LIGNOCELLULOSIC BYPRODUCTS

KEYWORDS: Sugarcane Biomass, Diversification, Mushroom, Pulp And Paper, Fermentable Sugar.

Abstract

The actual process of sugar and ethanol production in Mexico only uses the carbohydrates in the sugarcane juice and molasses. The remaining material, trash, bagasse and pith, constitutes the lignocellulosic byproducts (biomass) of this industry. In this work, three production alternatives were investigated: edible mushroom Pleurotus ostreatus, pulp and paper and fermentable sugar productions from sugarcane biomass. The characterisation of byproducts was carried out according to AOAC test. For the case of mushroom production, sugarcane trash and a 50:50 mixture of trash and bagasse showed the highest yields (biological efficiencies) of 106% and 103% respectively. For acid hydrolysis, trash samples generated in the local industry were used. Several tests were performed to obtain the maximum production of fermentable sugars using diluted H₂SO₄ at concentration level of 1.0%, temperatures (80–160°C) and hydrolysis times (0 to 330 minutes). A pseudo first-order kinetic model was developed to explain the hydrolysis from sugarcane trash using sulfuric acid. In the last alternative, bagasse pulping and ECF Bleaching (elementary chlorine free) were analysed in detail using TAPPI standards to establish the optimum pulping conditions for this lignocellulosic material.

Introduction

Sugarcane (Saccharum officinarum) is a grass that is harvested for its sucrose content. Sugarcane residue is composed of green cane leaves, tops and what is known as cane residue or trash. After the extraction of sugar from the sugarcane in the mill, the plant material that remains is termed bagasse (Castellan, 1999).

Composition of sugarcane biomass

The chemical characterisation was done according to the TAPPI (2000) and AOAC (1995) methods (Tables 1 and 2).

Production of bagasse pulp

Soda Pulping was performed according to a batch cooking (semi-pilot scale) on depithed bagasse samples (87% fibre and 13% pith) from a sugar mill at Cordoba Veracruz. Four liquor compositions were used as a charge in aqueous caustic soda (NaOH) (19, 17, 15 and 13% as Na₂O on weight percent on a dry basis bagasse and liquid/solid relation 1:7) cooking time (165°C) for 30 min to obtain the lowest kappa number (The Kappa number is determination of relative bleachability or degree of delignification of pulp) (Table 3).

The term used to describe solid content of pulp during pulp processing. For pulp and paper making, this is the most important process parameter. All equipments are designed to handle pulp at and up to certain consistency. Pulp consistency is roughly divided into three ranges: low Consistency: <5%, Medium Consistency: 5 – 15%, High Consistency: >15%.

**Pleurotus ostreatus cultivation in sugarcane biomass**

*Pleurotus ostreatus* has been cultivated on different substrates: sawdust, corncobs, waste paper, straw, bagasse and others byproducts (Mandeel *et al.*, 2005; Contreras *et al.*, 2004).

The substrates, waste wheat straw (control treatment) (*T*₁), sugarcane trash (RAC) (*T*₂), depithed bagasse (BD) (*T*₃), sugar mill bagasse (BI) (*T*₄) and a 50:50 RAC and sugar mill bagasse (*T*₅) were evaluated using a randomised experimental design with five different treatments.

Each substrate was ground, soaked and pasteurised at 85°C by hot water, cooled and packaged in 40 x 60 cm polyethylene bags and inoculated by hand with the spawn (*Pleurotus ostreatus*) in a 5% w/w proportion of fresh substrate weight per test.

The average temperature was 25°C and relative humidity was > 60%. The production was determined according to the biological efficiency (BE). (BE is defined as the weight of fresh mushrooms harvested divided by dry weight substrate at spawning expressed as a percent for each experiment).

**Yield of edible mushroom.**

The highest biological efficiencies were attained by the RAC (*T*₃) substrate and the trash/bagasse mixture (*T*₅). The lowest BE was for sugar mill bagasse (*T*₄). (Table 6).

Fermentable sugar from sugarcane trash

Hydrolysis of sugarcane trash was carried out using dilute sulfuric acid solutions (0.5, 1.0 and 1.5%, w/w) in a batch reactor. Operating conditions of the reactor were hydrolysis time (60 to 120 min), temperature (100 to 160°C) and mass ratio of solid to liquid 1:10 on a dry basis.

The determination of the Fermentable Sugars or Recovered acid hydrolysates (%) was evaluated by the Saeman Method (Canizales and Aguilar, 2004) through a 3^3 factorial design with two replications with respect to the interactions of acid concentration (AC), temperature (TEMP) and time (T). Variance analysis was performed with THE SAS SISTEMS® (Table 8).

The results were statistically significant for interaction AC*TEMP ($R^2 = 0.938491$), and indicated the possibility to obtain a considerable amount of fermentable sugars from sugarcane trash.

Kinetic models

The hydrolysis reactions in dilute-acid medium are very complex (Zheng, 2007, Canizales and Aguilar, 2004; Bustos *et al.*., 2003; Pessoa *et al.*., 1997); based on the Saeman model and the two-fraction model, kinetic parameters for predicting these compounds in the hydrolysates were: $k_1= 0.00702631$ and $k_2=0.0003951$; and the hydrolysis model was $Y = -10.830114 +22.3378444(X_1)+0.07505037(X_2) − 7.1239111 (X_1^2)$ ($Y$: AFT mol/L, $X_1$: sulfuric acid %, $X_2$...
Temperature °C). The optimal conditions selected were 160°C, 1.5% H₂SO₄, and 38.52 min (2311.2 seg) (Table 9).

The results emphasize the remarkable potential of sugarcane biomass for applications for the extractive, chemical, food and biochemical industry with sustainable technologies for sugarcane farmers, sugar mills or by products industries. The diversification is a complement to sugar production, improving the exploitation of sugarcane and contributing in this way to the sustainability of the Mexican sugar economy.

Résumé

LE PROCESSUS RÉEL de la production de sucre et d'éthanol au Mexique utilise uniquement les carbohydrates dans le jus de la canne et de la mélasses. Les autres matières, paille, bagasse de canne à sucre de par leur caractère, constituent les sous-produits lignocellulosiques (biomasse) de cette industrie. Trois axes de production ont été étudiées: production du champignon comestible Pleurotus ostreatus, pâtes et papiers et sucres fermentescibles à partir de la biomasse de la canne. La caractérisation des sous-produits a été effectuée conformément au protocol AOAC. Dans le cas de la production de champignons, la paille de canne et un mélange 50/50 de paille et de bagasse ont démontré des rendements plus élevés (efficacité biologique) de 106% et 103% respectivement. Pour l'hydrolyse acide, des échantillons de paille générés dans l'industrie locale ont été utilisés. Plusieurs tests ont été réalisés pour obtenir la production maximale de sucres fermentescibles à l'aide de l'acide sulfurique dilué à une concentration de 1.0%, des températures de 80 à 160°C et la durée de l'hydrolyse (0 à 330 minutes). Un modèle de cinétique de premier ordre a été développé pour expliquer l'hydrolyse de la paille de canne à l'aide d'acide sulfurique. Dans la dernière alternative, la bagasse et l'ECF blanchi (sans chlore) ont été analysés en détail à l'aide des normes TAPPI pour établir le mélange optimal pour produire de la pulpe à partir de ce matériau lignocellulosique.
DIVERSIFICACIÓN PRODUCTIVA A PARTIR DE LOS SUBPRODUCTOS LIGNOCELULÓSICOS DE LA CAÑA DE AZÚCAR.

PALABRAS CLAVE: Biomasa de la Caña de Azúcar,
Diversificación, Hongos Comestibles, Pulpa y Papel.

Resumen

El proceso de producción de azúcar y alcohol en México actualmente emplea solamente los carbohidratos de los jugos de la caña y las melazas. Los restantes materiales, paja de caña, bagazo y meollo, constituyen los subproductos lignocelulósicos (biomasa) de la industria. En este trabajo se investigaron tres alternativas de producción: hongos comestibles, pulpa y papel y la producción de azúcares fermentables a partir de la biomasa de la caña de azúcar. La caracterización de los subproductos se realizó de acuerdo a las pruebas AOAC. Para el caso de producción de hongos comestibles, la paja de la caña y una mezcla 50:50 de paja y bagazo presentaron los mayores rendimientos (eficiencias biológicas) de 106% a 103% respectivamente. Para la hidrólisis ácida se emplearon muestras de paja de caña generadas en la industria local. Se realizaron varias pruebas para obtener la máxima producción de azúcares fermentables, empleando ácido sulfúrico diluido a una concentración de 1.0%, temperatura de 80-160°C y tiempo de hidrólisis entre 0 y 330 minutos. Se desarrolló un modelo cinético de pseudo-primer orden para explicar la hidrólisis de la paja de caña empleando ácido sulfúrico. En la última opción se desarrollaron en detalles pulpeo de bagazo y blanqueado ECF (elementary chlorine phase) utilizando estándares TAPPI para establecer las condiciones óptimas de pulpeo para este material lignocelulósico.
BIODIESEL STARTING FROM NON EDIBLE OILS AND ETHANOL FOR SELF-CONSUMPTION IN THE AGRO INDUSTRIAL PRODUCTION OF SUGAR AND OTHER FOODS

KEYWORDS: Renewable, Energy, Biodiesel, Ethanol, Biofuels.

Abstract

The decrease of fossil fuels in the near future and climate change constitute the main drivers at the present time for the development of biofuels. They are doubly relevant to the sugar industry because it is a consumer of fuels as well as a potential producer. This paper shows the results of an experimental preliminary study with oleaginous plants, which can be cultivated in soils unsuitable for the production of food, with high yields of around 1 t/ha. Experiences of the synthesis of fuel from such oil and ethanol are reported, which turn out to be somewhat complex but allow the production of biodiesel starting from totally renewable sources with important environmental advantages. An example is shown in which it is possible to achieve biodiesel production to substitute for the consumption of all agricultural diesel by using a small percentage of the land belonging to a farm complex for the production of sugar and other foods. Results for the use in cane transport, at mixtures of 5, 10, 20, 50 and 100% (total substitution) of biodiesel are also presented.

Introduction

According to experts, petroleum prices will tend to increase (US. Department of Energy. September 2008; US Senate, 2005; Benjamin, 2007). It could be strategically important for the agro-industrial production sector (for example, sugar production) to introduce new energy alternatives using renewable sources, as in the case of biodiesel that uses raw materials such as oils of vegetable origin that can be obtained every year and of ethanol that also comes from a renewable source.

We have designed a small plant for biodiesel production using the oil of *Jatropha curca* or *Ricinus communis* as the source of fatty acids. They are oleaginous plants producing non-edible oils and are adapted well to soils which are not fit for food production.

Consequently, there is no competition for the use of soils where foods can be produced.

The biodiesel to be produced would allow the substitution of the diesel fuel that is currently used as the main energy source in the production of foods including sugarcane.

The proposal is to install the biodiesel production plant in a strictly agricultural production farm or in an agro-industrial complex with the purpose of substituting in a partial or total way the consumption of diesel fuel either partially or totally.
The process of biodiesel production is already common in the world, mainly using edible oils whose production in commercial plantations is much more extensive, for example, soy or sunflower oils. In almost all the processes, methanol is used that allows a quicker synthesis process and, in many cases, with slightly higher yields. Methanol has a higher price than ethanol, and the latter allows the production of biodiesel starting from completely renewable sources and it has less effect on the environment and, for these reasons, ethanol was selected for use in the process of this plant.

The complexities for the synthesis from ethanol have already been solved in the ICINAZ up to and including the pilot plant scale. Biodiesel could be employed in mixtures substituting 10, 20, 50% of the diesel fuel, even up to B100 (100% biodiesel) provided that it fulfils the quality specifications of the existing standards.

Results of the simulation of a plant for the production of biodiesel with the software Super Pro Designer version 3.04

With the designed plant, a study was conducted to enlarge the capacity until arriving at one acceptable time of recovery. The results of this study of sensitivity appear in Table 1.

Table 1—Analysis of the plant capacity influence upon the time of investment return.

<table>
<thead>
<tr>

<td>4.43</td>
</tr>
<tr>
<td>320</td>
<td>2.70</td>
</tr>
</tbody>
</table>

Increasing production capacity of one alternative to another, it also increased the capacity of the equipment and the tanks, as well as their costs.

The simulation included a non-complex technology, without glycerine purification nor recovery of the solvent used, and this gave a minimum capacity of 320 t per year of biodiesel for the given costs of the raw materials, selling price of the biodiesel (similar to diesel fuel), cost of labour, cost of equipment, etc. The calculated capacity is similar to the planned diesel fuel expenditures of the ‘Honduras’ agricultural enterprise to which this farm belongs. Any variation in the values of some of these variables has an influence on the time of the return of the investment. This can be shown in the sensitivity analysis carried out in the 160.3 t/y plant when the price of alcohol diminishes (Pérez, 2006) (Table 2).

Study of the behaviour of a Yuchai motor with different biodiesel proportions in the diesel mixture (Alfonso, 2008).

Tests were conducted in the engine testing setup of the CETER, for which standard samples of diesel fuel and mixtures of this with biodiesel in different compositions were used. Measurements were conducted for the following parameters – Effective Power (Ne), Torque (Me), Hourly fuel consumption (Gc) and Specific Consumption (gc) – against frequency of revolution (r/min) when the fuel control valve is completely open, that is, when the maximum dosage of fuel is achieved (Table 3). This parameter gives useful information when giving the maximum parameters
of power and torque with their minimum specific consumption and the revolutions at which these are obtained.

**Test results**

With the study of the combustion of the biodiesel in a motor and with the parameters of operation of the diesel, it was possible to reach the following conclusions:

- When the biodiesel content increases above 20%, the characteristics of the motor diminish slightly and a slight increase of the specific consumption of fuel was observed.
- The emissions of NOx diminish markedly as the biodiesel content is increased, which could be due to the decrease in the temperature in the combustion chamber as the content of biodiesel increases.
- The appropriate mixture for use in this Motor of Internal Combustion is B20, that is to say 20% biodiesel, because with this you achieve a compromise between the emissions and the benefits of the motor.

It is important to point out that these results were obtained without physical or operational modification to the motor. Even better behaviour for the biodiesel and the mixtures should be expected by correcting the angle of injection of the motor.

**Preliminary results of the agricultural parameters in the ‘Paraguay’ farm**

The study of the behaviour of *Ricinus communis* in the soils of category N of the ‘Paraguay’ farm began in the year 2007 with two species coming from the farm denominated red and green.

Later on, the Imias species labelled white was incorporated in the year 2008. In the year 2008, the study of the *Jatropha curcas*, variety of Cape Verde, coming from the bank of germplasm of CATEDES also began (Center of the CITMA, located in Guantánamo province)(Table 4).

</tbody>
</table>

The experimental areas had been subjected to an extreme drought for 6 months. However, a suitable yield was obtained particularly in the case of the *Ricinus* red species coming from the same ‘Paraguay’ farm.

Food security requires two fundamental aspects:
- Availability of fuel sources for the production of foods (quantity and prices).
- No use of foods for energy production

This compromising situation can be avoided if such premises are applied as:
- Using oleaginous plants for biodiesel. These are not used for the production of food or other uses such as microalgae fermentation in residual waters.
- The use of oleaginous plants that can be planted in degraded soils not fit for food production (*Jatropha curcas* and *Ricinus communis*) as the present study shows.
- Stimulate the local production of biodiesel with the purpose of substituting it in agricultural machinery, pumping stations, electrical power-plants, etc.

Conclusions

Positive results were obtained in biodiesel production with ethanol, at the pilot plant level. The use of the produced biodiesel and their mixtures with diesel in motors of trucks hauling sugarcane were good in spite of not making any modifications to the motor. -Preliminary and encouraging results exist in the exploitation of experimental areas of so called N soils with *Jatropha* and *Ricinus*.

Recommendations

- To continue the studies in the ‘Paraguay’ farm and in other edapho-climatic areas of the different species of oleaginous plants of non-edible oils.
- To continue studies in the use of biodiesel in the main types of diesel motors used for agricultural purposes.
- To continue studying the synthesis of ethyl esters using as starting materials the raw oils of *Jatropha* and *Ricinus*.

Résumé

LA DIMINUTION de combustibles fossiles dans un avenir proche et les changements climatiques constituent les principales motivations à l'heure actuelle pour le développement des biocarburants. Elles sont doublement pertinentes à l'industrie sucrière car elle est consommatrice d'énergie aussi bien que producteur potentiel. Cette communication présente les résultats d'une étude préliminaire expérimentale avec des plantes oléagineuses produisant des huiles non comestibles telles que le Jatropha curcas et Ricinus communis, qui peuvent être cultivées dans les sols improprens à la production de denrées alimentaires, avec des rendements élevés d'environ 1 t/ha. Des expérimentations de la synthèse de telles huiles et de bioéthanol sont rapportées. Elles se sont avérées quelque peu complexes mais ont permis la production de biodiesel à partir de sources totalement renouvelables avec les avantages environnementaux concrets. A titre d'exemple il est démontré qu'il est possible de produire suffisamment de biodiesel équivalent à la consommation totale de diesel agricole à l'aide d'un faible pourcentage des terres appartenant à une ferme orientée vers la production de sucre et d'autres aliments. Des résultats pour l'utilisation dans le transport de la canne à sucre, à des mélanges de 5, 10, 20, 50 et 100% (substitution totale) de biodiesel sont également présentés.

Resumen

El decrecimiento de los combustibles fósiles en el futuro cercano y el cambio climático constituyen los principales impulsores actuales para el desarrollo de biocombustibles. Éstos son doblemente relevantes a la industria azucarera porque es una consumidora de combustibles, así como una potencial productora. El artículo presenta los resultados de un estudio experimental preliminar con plantas oleaginosas productoras de aceites no comestibles como la Jatropha curca y Ricinos communis, que pueden ser cultivadas, con altos rendimientos de cerca de 1 t/ha, en suelos no aptos para la producción de alimentos. Se reportan experiencias de la síntesis del combustible a partir de estos aceites y etanol, que resultan ser algo complejas, pero permiten la producción de biodiesel a partir de recursos totalmente renovables con importantes ventajas ambientales. Se muestra un ejemplo en el que es posible alcanzar una producción de biodiesel para sustituir la totalidad del consumo agrícola de diesel, con el uso de un pequeño 5 de tierras que pertenecen a un complejo agrícola dedicado a la producción de azúcar y otros alimentos. Se presentan también resultados de su uso en el transporte de caña, en mezclas de 5, 10, 20, 50, y 100% (sustitución total) de biodiesel.

Abstract

PRESENT day gasohol and biodiesel from a mixture with ethanol emerge not only as renewable fuels but also as a support to the sugarcane agro-industrial sector. To synthesise a cubic metre of ethanol, about 12 to 13.5 t of sugarcane are needed. The increasing interest in ethanol production is due to the unavoidable need for energy diversification and the wish of many countries to reduce the emission of greenhouse gases according to the Kyoto protocol. In 2007, 5.57 million cubic metres of ethanol were produced worldwide, 2.0 million m³ in Brazil from sugarcane. In addition, biodiesel production is estimated to increase 10–12% annually from current levels of 985 000 m³. Pure biodiesel is biodegradable and non toxic, and eliminates contamination and toxic emissions as well as aromatic components present in fossil fuels. Brazil is the Latin American leader in R&D and promotion of ethanol use, while Mexico has been far behind in that subject. The mixtures of gasohol E10 and E85 are used in all vehicle types improving their performance. In addition, by MTBE substitution, contamination is reduced. At the beginning, MTBE appeared to be the best additive, but later it was proven to have a carcinogenic effect that could provoke genetic modifications and contribute to formation of ‘photochemical smog’. MTBE is still used in many countries through the import of large amounts of this additive. The promotion of biofuels must be based on the edification of a solid culture about their benefits to human health and the environment. The substitution of MTBE by ethanol and the subsequent addition of ethanol with vegetable oils to obtain biodiesel could increase dramatically the ethanol demand in the market. This paper deals with the actual possibilities and limitations of biofuels production in sugar-producing countries from technological and socio-economical points of view.

Introduction

Much has been discussed in several cane sugar producing countries about the possibilities of developing an ethanol fuel program. However, most of these initiatives have been frustrated due to apparently economical reasons, although today the concept is being re-examined.

Gasohol and biodiesel, blended with ethanol, are emerging as the renewable fuels of the future. This comes from the health point of view and to support the sugarcane agricultural and industrial sectors which have been affected by several well known causes (Lois, 2003).
Today, the importance of the energetic matters all over the world causes us to be in permanent search for those alternatives which can be economical options regarding the availability of oil fuels. World trade in ethanol is shown graphically in Figure 1, and the main uses of ethanol are shown in Figure 2.

The main producers of ethanol are shown in Table 1. A comparison of ethanol production in Brazil, the USA and Europe is presented in Figure 3.

*Table 1—Ethanol production by countries.*
The importance of the gasohol production

Ethanol (C₂H₅OH) mixed with gasoline forms biogasoline or *gasohol* E10 (10% of ethanol in the mix and 90% of gasoline), but the ethanol could be used in higher amounts like *E85* (85% of ethanol). The gasohol improves the octane number of the fuel mix and also of the emissions of the motors.

**What is biodiesel?**

Biodiesel is a cleaner and safer liquid fuel of vegetable origin obtained from renewable sources, such as vegetable oils and animal fats, by means of a process known as transterification; today the EU supplies around 66% of the world biodiesel production with 6500 million litres per year. Brazil has decided to mix 3.0% biodiesel with all the diesel commercialised in the country. The pure biodiesel is biodegradable, non toxic, and mainly free of sulfur and aromatic substances. A mix of 20% biodiesel with petroleum diesel or 25% with ethanol and conversion catalyst totally eliminates air pollution.

**What is methyl-tertiary-butyl ether (MTBE)?**

It’s an oxygenating agent obtained by the reaction of isobutylene and methanol, widely used as an additive in gasoline and a substitute for lead tetraethyl (CH₂CH₃)₄. Initially, it appeared to have good performance, but lately it has been proved to be highly toxic. In México it’s still widely used.

**Steps and challenges for the development of a strategic program of biofuels from sugarcane juices**

i) Public acceptance and support for ethanol as fuel or as *gasohol* and *biodiesel*.

ii) Economic viability in the use of local production facilities for the manufacture of ethanol from locally produced cane juice.

iii) To learn more about the ecological and health benefits from the removal of MTBE and its substitution by ethanol obtained from sugarcane.
iv) Diversification of sugarcane production by the manufacture of higher value-added co-products.

Conclusions

- The removal of MTBE by ethanol for the production of biofuels could dramatically increase ethanol demand.

  In this way, the sugar industry would be able to double its production capacity in a short time and satisfy the demand originated by the replacement of MTBE.

- The net increase in the ethanol production capacity must be as a result of an improvement in agricultural yields in the cane fields, as well as a diversified use of the existing sugar mills. All this will have a solid positive impact over net production and income, and will increase employment possibilities in the country.

Résumé

DE NOS JOURS, l’essence et le biodiesel en mélange avec l’éthanol émergent non seulement comme combustibles renouvelables, mais aussi comme un soutien au secteur agro-industriel de la canne. Pour synthétiser, un mètre cube d’éthanol, il faut environ 12 à 13.5 tonnes de canne. L’intérêt croissant pour la production d’éthanol est dû à la nécessité incontournable de diversification de l’énergie et le souhait de nombreux pays de réduire les émissions de gaz à effet de serre dans le protocole de Kyoto. En 2007, 5.57 millions de mètres cubes d’éthanol ont été produits dans le monde entier comprenant 2.0 millions de m³ au Brésil a partir de la canne. En outre, la production de biodiesel est voulue à augmenter de 10–12% par an part rapport au niveau actuel de 985 000 m³. Le biodiesel pur est biodégradable et non toxique et élimine la pollution et les émissions toxiques, ainsi que des composants aromatiques présents dans les combustibles fossiles. Le Brésil est le leader latino-américain dans la recherche, le développement et la promotion de l'utilisation de l'éthanol, tandis que le Mexique a été loin derrière dans ce domaine. Les mélanges d’essence E10 et E85 sont utilisés dans tous les types de véhicules pour améliorer leurs performances. En outre, par substitution au MTBE, la pollution est réduite. Au début, le MTBE semblait être le meilleur additif,
mais il a été prouvé éventuellement qu’il avait un effet cancérigène susceptible de provoquer des modifications génétiques et de contribuer à la formation de brouillard photochimique. Le MTBE est toujours utilisé dans de nombreux pays comme le prouve par le biais de l’importation de grandes quantités de cet additif. La promotion des biocarburants doit être basée sur l’élaboration d’une campagne intense sur leurs avantages pour la santé humaine et l’environnement. La substitution du MTBE par l’éthanol et le mélange ultérieur de l’éthanol aux huiles végétales pour obtenir le biodiésel pourraient faire augmenter considérablement la demande d’éthanol sur le marché. Cette communication traite des possibilités réelles et les limites de la production de biocarburants dans des pays producteurs de sucre du point de vue technologique et socio-économique.

LOS BIOCOMBUSTIBLES: UNA OPCIÓN LIMPIA Y RENOVABLE A PARTIR DE LA CAÑA DE AZÚCAR

Resumen

En la actualidad el gasohol y el biodiesel con una mezcla con etanol emergen no solo como combustibles renovables, sino también como un soporte para el sector agro-industrial azucarero. Para sintetizar un metro cúbico de etanol se requieren entre 12 y 13.5 t de caña de azúcar. El creciente interés en la producción de etanol se debe a la inevitable necesidad de diversificar las fuentes energéticas y el deseo de muchos países de reducir la emisión de gases de efecto invernadero de acuerdo con el Protocolo de Kyoto. En el 2007 se produjeron en el mundo 5.57 millones de m³ de etanol, 2.0 millones en Brasil, a partir de la caña de azúcar. Por otra parte, la producción de biodiesel se estima crece entre 10 y 12% anualmente a partir del actual nivel de 985 000 m³. El biodiesel puro es biodegradable y no-tóxico, elimina la contaminación y las emisiones toxicas, así como los compuestos aromáticos presentes en los combustibles fósiles. Brasil es el líder latinoamericano en la I&D y la promoción del uso del etanol, México, sin embargo, está muy detrás en este aspecto. Las mezclas de gasohol E10 y E85 se utilizan en todo tipo de vehículos, mejorando su desempeño. Adicionalmente, al sustituir el MTBE se reduce la contaminación. En un inicio el MTBE pareció ser el mejor aditivo, pero posteriormente se comprobó que tenía efectos cancerígenos, que podía provocar modificaciones genéticas y contribuir a la formación de ‘nieblas fotoquímicas’. El MTBE se emplea aún en muchos países, importándose grandes cantidades de este aditivo. La promoción de los biocombustibles debe basarse en la edificación de una sólida cultura de sus beneficios a la salud humana y el entorno. La sustitución del MTBE por etanol y la combinación del etanol con aceites vegetales para obtener biodiesel puede incrementar dramáticamente la demanda de etanol en el mercado. Este artículo trata acerca de las reales posibilidades y limitaciones de la producción de biocombustibles en los países productores de azúcar desde el punto de vista tecnológico y socio-económico.
OPTIMISATION OF FRUCTOOLIGOSACCHARIDES (FOS) PRODUCTION USING BOTH INTRACELLULAR AND EXTRACELLULAR FRUCTOSYLTRANSFERASE (FT-ASE) PRODUCED BY ASPERGILLUS sp. ISOLATED FROM AN INDONESIAN SUGAR FACTORY

By

TRIANTARTI, ARIS TOHARISMAN, YAHYA KURNIAWAN, HENDRO SANTOSO and SIMPING YULIATUN

Abstract

FRUCTOOLIGOSACCHARIDES (FOS) were produced from sucrose with a number of desirable characteristics such as low calories, non-carcinogenic effect, safe for diabetics, and having bifidus-stimulating functionality. Aspergillus sp. isolated from the Wonolongan Sugar Mill area in Indonesia was a potential isolate for FOS production. The aim of our research was to determine the optimum condition for conversion of sucrose to FOS using both intracellular and extracellular FT-ase of Aspergillus sp. Wet cells were used as a source of intracellular FT-ase while extracellular FT-ase consisted of crude FT-ase (broth medium) and semi pure FT-ase. Semi pure FT-ase was FT-ase in broth medium after isolation using ethanol 60% (v/v) and diluted back to the initial volume of broth medium using buffer pH 7. The effect of varying pH from 3–7, varying concentration of extracellular FT-ase, varying concentrations of wet cells and varying incubation times were tested in this experiment. All reactions for FOS production were conducted at 50°C containing sucrose 40% (w/v) as a substrate in the enzymatic reaction. Results showed that the optimum pH for FOS production was 7, both for intracellular and extracellular FT-ase. The optimum condition for FOS production using intracellular FT-ase was 2 g wet cells /100 mL substrate followed by 4 h incubation, and FOS yield reached 39.1% of the initial sucrose concentration. The optimum condition for FOS production using crude extracellular FT-ase was 1.5 times dilution using buffer pH 7 followed by 8 h incubation time and FOS yield reached 29.1%. The optimum condition for FOS production using semi-pure extracellular FT-ase was stock semi-pure FT-ase without any dilution followed by 8 h incubation and FOS yield reached 25.2%. This experiment showed that both intracellular and extracellular FT-ase of Aspergillus sp. could be used for FOS production.

Introduction

Fructooligosaccharides (FOS) is a prebiotic which is composed mainly of 1-kestose (GF2), nystose (GF3) and fructofuranosyl nystose (GF4). Industrial scale for FOS production is done mainly using fungal enzymes. Indonesian Sugar Research Institute (ISRI) has isolated Aspergillus sp. from a sugar mill area in Indonesia for FOS production namely Aspergillus sp. FOS-1(ISRI). Fermentation has been optimised for producing FT-ase in flask fermentation. Fermentation broth as a source of crude FT-ase was used for conversion of sucrose to FOS (Toharisman et al., 2008). The objective of this research project was to determine the optimum conditions for conversion of sucrose to FOS using both intracellular and extracellular FT-ase of Aspergillus sp. FOS-1(ISRI).
Materials and methods

Cultivation conditions

Fermentation using *Aspergillus sp. FOS-1(ISRI)* was conducted in a 15 litre fermentor filled with 10 litres of fermentation medium. The composition of the fermentation medium was the same as the previous experiment (Toharisman *et al.*, 2008). Fermentation was conducted at 30°C for 24 hours. pH was controlled at 7.0 with aeration 1.0vvm and agitation 100 rpm. At the end of fermentation, the broth was separated from the fungal cells by filtration. Wet cells were used as a source of intracellular FT-ase while extracellular FT-ase consisted of crude FT-ase (broth medium) and semi-pure FT-ase. Semi-pure FT-ase was FT-ase in broth medium after isolation using ethanol 60% (v/v) and diluted back to the initial volume of broth medium using buffer pH 7. FOS concentration was determined using HPLC as in the previous experiment (Toharisman *et al.*, 2008).

Effect of pH on the conversion of sucrose to FOS

Effect of pH on the conversion of sucrose to FOS was conducted only for intracellular enzyme, while the optimum condition for conversion using extracellular FT-ase was determined in the previous experiment (Toharisman *et al.*, 2008). Two grams of wet cells were added to the buffer containing 40% sucrose with pH between 3 and 7. Cells in buffer with various pH were incubated at 50°C for 1 hour.

Conversion of sucrose to FOS using intracellular and extracellular FT-ase

All reactions for FOS production were conducted in buffer pH 7 containing sucrose 40% (w/v) as a substrate for 8 hours at 50°C. Crude enzyme and semi-pure enzyme were diluted with buffer pH 7. Ratios of crude enzyme to buffer pH 7 (v/v) were various at 1:2, 2:1, and one treatment without dilution. Cells of *Aspergillus sp.* were added in buffer pH 7 containing 40% sucrose, at various cell concentrations i.e. 2, 4 and 8% (w/v).

Results and discussion

Table 1 shows the effect of various pHs on conversion of sucrose to FOS using wet cells of *Aspergillus sp. FOS-1(ISRI)* as a source of intracellular enzyme. Optimum pH for conversion was pH 7. There was no FOS synthesised on reaction between pH 3–5; on the other hand, invertase enzyme or hydrolytic enzyme was active in that pH range. Fernandez *et al.* (2004) reported a similar result that the hydrolytic activity of *Aspergillus* sp 27H isolated from soil was highest at low pH (pH 4). The optimum pH of intracellular enzyme was the same as the optimum pH of extracellular enzyme (Toharisman *et al.*, 2008).

**Table 1**—Effect of various pH on the carbohydrate composition after enzymatic reaction using wet cells of *Aspergillus sp. FOS-1(ISRI)* with sucrose as a substrate.

Figure 1 shows the effect of various concentrations of wet cells on FOS production after incubation for 8 hours. The results showed that the highest FOS production was 2 g wet cells/100 mL substrate followed by 4 h incubation time, and FOS yield reached 39.1% of the initial sucrose concentration. The higher concentration of wet cells on the conversion reaction resulted in
the faster degradation of FOS during the long incubation time. It indicated that wet cells of *Aspergillus sp. FOS-1 (ISRI)* contained not only FT-ase, which produced FOS from sucrose, but also had a hydrolysing enzyme capable of hydrolysing FOS. However, in this experiment when the enzymatic reaction was conducted at optimum condition, high concentration of FOS was still produced. Others have reported that pellets of *Aspergillus oryzae* CFR 202 could be reused for six recycles. *Aspergillus sp. FOS-1 (ISRI)* was tested only for three recycles with consistent results.

Figure 2 shows the effect of various concentrations of crude enzyme on FOS production. The optimum condition for FOS production using crude extracellular FT-ase was 1.5 times dilution using buffer pH 7 followed by 8 h incubation time, and FOS yield reached 29.1%. The longer incubation time resulted in a higher concentration of FOS produced, except for crude enzyme without any dilution. This profile was different to the conversion using wet cells. It seemed that the activity of the hydrolysing enzyme on the enzymatic reaction using crude enzyme was not as high as its activity on the conversion process using wet cells.

![Fig. 1—Effect of various concentrations of wet cells on FOS production.](image1)

![Fig. 2—Effect of various concentrations of crude enzyme on FOS production.](image2)
Semi-pure FT-ase was prepared by isolation using ethanol 60% (v/v) and diluted back to the initial volume of broth medium using buffer pH 7. Smith and Luenser (1982) also reported the possibility of isolating FT-ase from black yeast *Aureobasidium pullulans* by water-soluble organic solvent. Figure 3 shows the effect of various concentrations of semi-pure FT-ase on FOS production.

The optimum condition for FOS production using semi-pure extracellular FT-ase was stock semi-pure FT-ase without any dilution followed by 8 h incubation and FOS yield reached 25.2%. FOS syrup produced using semi-pure FT-ase was free from residual compounds previously present in the fermentation broth medium.

**Conclusions**

FOS can be produced using both intracellular and extracellular FT-ase enzyme from *Aspergillus sp. FOS-1 (ISRI)*. So far the highest yields of FOS resulting from enzymatic reaction using intracellular FT-ase enzyme, crude extracellular FT-ase and semi-pure extracellular FT-ase were 39.1, 29.1 and 25.2% (w/w of initial sucrose concentration) respectively.

OPTIMISATION DE LA PRODUCTION DE FRUCTOOLIGOSACCHARIDES (FOS) A L’AIDE DE FRUCTOSYLTRANSFERASE (FT-ASE), INTRA ET EXTRA CELLULAIRE PRODUITE PAR Aspergillus spp. ISOLEE DANS UNE SUCRERIE EN INDONESIE

Par

TRIANTARTI, ARIS TOHARISMAN, YAHYA KURNIAWAN, HENDRO SANTOSO et SIMPING YULIATUN

Indonesian Sugar Research Institute
triantarti@gmail.com

MOTS-CLÉS: Fructosyltransferase, Fructooligosaccharide, Extracellulaire, Intracellulaire.

DES FRUCTOOLIGOSACCHARIDES (FOS) ont été produites à partir de saccharose avec un certain nombre de caractéristiques intéressantes telles que peu de calories, effet non cancérogène, sans danger pour diabétiques et ayant une fonctionnalités bifidus stimulante. Un isolat d'Aspergillus trouvé dans l’usine sucrière de Wonolongan en Indonésie s’est avéré avoir un potentiel pour la production de FOS. Le but de notre recherche était de déterminer la condition optimale pour la conversion de saccharose en FOS à l'aide de fructosyltransferase intracellulaire et extracellulaire provenant de cet isolat d'Aspergillus. Des cellules en milieu liquide ont été utilisées comme source de FT-ase intracellulaire tandis la FT-ase extracellulaire provenait d’un milieu de culture brut et aussi de la FT-ase semi purifiée. La FT-ase semi purifiée provenait d’un bouillon de culture après précipitation à l'aide d'éthanol à 60% (v/v) et dilués au volume initial du bouillon de support à l'aide de solution tampon de pH 7. Les effets de varier le pH de 3 à 7, des concentrations variées de FT-ase extracellulaire de différents niveaux provenant de différentes concentrations des cellules en milieu liquide et une gamme de période d'incubation ont été évalués dans cette étude. Toutes les réactions pour la production de FOS ont été menées à 50°C dans un substrat de saccharose à 40% (p/v) pour la réaction enzymatique. Les résultats ont démontré que le pH optimal pour la production de FOS était de 7 pour la FT-ase intracellulaire comme extracellulaire. La condition optimale pour la production de FOS à l'aide de FT-ase intracellulaire était de 2 g de cellules pour 100 ml de substrat en milieu liquide pour une période d'incubation de 4 h ce qui résultat en un rendement de FOS à 39.1% de la concentration initiale en saccharose. La condition optimale pour la production de FOS à l'aide de la FT-ase extracellulaire à l'état brut, était une dilution de 1.5 à l'aide du tampon de pH 7 suivi par une période d'incubation de 8 h ce qui mena à un rendement de FOS atteignant 29.1%. La condition optimale pour la production de FOS à l'aide de la FT-ase extra cellulaire semi-purifiée était l’utilisation de la solution stock sans dilution pour une période d'incubation de 8 h ce qui donna un rendement de FOS de l’ordre de 25.2 %. Cette expérimentation a démontré que la FT-ase intracellulaire et extracellulaire provenant d’une espèce Aspergillus pouvait être utilisée pour la production de FOS.
OPTIMIZACIÓN DE LA PRODUCCIÓN DE FRUCTOOLIGOSACÁRIDOS (FOS), USANDO TANTO FRUCTOSILTRANFERASA (FT-ASA) INTRA Y EXTRA CELULAR, PRODUCIDA POR ASPERGILLUS sp. AISLADOS EN UNA FÁBRICA DE AZÚCAR INDONESIA

PALABRAS CLAVE: Fructosiltransferasa, Fructooligosacárido, Extracelular, Intracellular.

Resumen

LOS FRUCTOOLIGOSACÁRIDOS (FOS) fueron producidos a partir de sacarosa con un conjunto mde características deseables tales como, bajas calorías, sin efectos cancerígenos, seguros para diabéticos y con funcionalidad bifido estimulante. El Aspergillus sp para la producción de FOS fue aislado en áreas del Central Wonolongan en Indonesia. El propósito de nuestra investigación era determinar las condiciones óptimas de conversión de la sacarosa en FOS, usando tanto la FT-asa intra y extracelular del Aspergillus sp. Se utilizó pasta de levadura como fuente de FT-asa intracelular, mientras la FT-asa extracelular consistió en FT-asa cruda (medio de cultivo) y FT-asa semipura. La Ft-asa semipura fue la FT-asa del medio de cultivo después de ser aislada usando etanol al 60% w/v y diluida de nuevo al volumen del medio de cultivo con solución buffer pH 7. En este experimento se probó el efecto de variar el pH de 3–7, variando la concentración de FT-asa extracelular, variado la concentración de la pasta de levadura y el tiempo de incubación. Todas las reacciones para la producción de FOS se realizaron a 50°C, conteniendo sacarosa al 40% (w/v) como sustrato en la reacción enzimática. Los resultados mostraron que el pH óptimo para la producción de FOS era 7, tanto para ft-asa intra como extra celular. La condición óptima para la producción de FOS empleando FT-asa intracelular fue de 2 g de pasta de levadura/ml de sustrato, con 4 horas de incubación y el rendimiento de FOS alcanzó 1% de la concentración inicial de sacarosa. La condición óptima para la producción de FOS empleando FT-asa cruda extracelular fue con dilución 1.5 veces empleando buffer a pH 7, seguida de 8 horas de incubación y el rendimiento de FOS alcanzó 29.1%. La condición óptima para la producción de FOS usando FT-asa extracelular semipura fue conservar la Ft-asa semipura sin dilución, seguida de 8 horas de incubación y el rendimiento de FOS alcanzó 25.25. Este experimento mostró que tanto la FT-asa intra como extracelular del Aspergillus sp podían ser empleadas en al producción de FOS.
DIVERSIFYING SUGAR CANE: CELLULOSE FROM BAGASSE

By

KEYWORDS: Sugarcane, Bagasse, Cellulose, Diversification.

Abstract

CANE SUGAR industries are going through severe economical crises. To increase profitability, they must use every product or by-product of cane. As an example of diversifying potential, ethanol and cellulose, both obtained from bagasse, are compared. In Mexico, bio-ethanol is worth around US$0.45 per litre, and about 200 litres can be obtained per tonne of dry bagasse. Non-treated dry bagasse contains 51.67% cellulose, 24.42% hemicelluloses, 10.23% soluble and 13.68% lignin. Thus, theoretically, 516.7 kg of cellulose can be obtained per tonne of bagasse. Whitened cellulose in México is MX$4.50 to MX$5.00 (US$0.30 to US$0.33) per kg. Comparing bio-ethanol and cellulose revenue: ethanol is MX$1200 (US$80.00) vs. cellulose MX$2583.50 (US$172.20) per tonne of dry bagasse. Possible cellulose production from Mexican sugarcane (2007–2008): milled cane 46 518 988 t; dry bagasse 6 977 848 t; yielding 3 605 454 t cellulose. Presently Mexico imports 80% of required cellulose. Not all cellulose fibres from bagasse can be efficiently used as fuel. With the new technology developed and tested by us, all long fibres can be converted into cellulose, and 94% of pith can be burnt. However, auxiliary fuel (3.9 litres of heavy bunker C per milled tonne of cane) is also required. It is important to establish laboratory methods to determine the real content of fibre convertible to cellulose and how biotechnology can help improve the quantity and quality of cellulose. These tests are to be performed at industrial laboratories and in accordance with official procedures.

Introduction

World sugar consumption is continuously increasing (Figure 1). However, a more detailed study of per capita consumption reveals cane and beet sugar consumption have decreased since 1980, when the corn sweetener (a composite of fructose, glucose and dextrose obtained from corn) replaced sucrose to some extent, Figure 2 (Jensen, 2005).

The sugar market is also affected by the instability of world market prices for sweeteners.

These facts resulted in severe economical crises for cane sugar industries, forcing them to look for new and alternative technologies and products to compensate for market price instability and per capita consumption decrease.
A typical flow diagram of a cane sugar factory is shown in Figure 3. There are various by-products in the process but only one commercial product, which is sugar; also, in some cases, alcohol. In order to improve the profitability of the sugar industry, by-products can become commercially feasible by applying new technologies or even by converting them to new products.

Diversifying options will be selected by each sugar mill. Local market and exporting opportunities are the factors to be considered.

The following 3 scenarios show and compare different uses of by-products: actual situation, conversion of all bagasse to ethanol, and cellulose production from bagasse.
Diversification options

There are various options for commercial utilisation of almost all the by-products in the sugarcane process. Some of them are still in a research and development stage, others need new technologies to be competitive, while others are used only in some countries.

Bagasse

Bagasse is the residue from sugarcane milling after the juice has been expressed from the crushed cane stalk. Average composition: 50% cellulose, 30% hemicelluloses and 20% lignin. Actual applications are:

1. Fuel in the sugar process. 91% of energy required in Mexican sugar mills is obtained from bagasse combustion, super heated steam generates electricity, and exhaust steam is used in the sugar process.
2. Cattle feed. Some communities are incorporating bagasse into the diet of different livestock, like cattle and chickens; reports and studies conclude no negative effect in the growth of the animals.
3. Paper and fibre board manufacturing. The old process used in industry to obtain cellulose from cane bagasse requires the chemical delignification and bleaching of the resulting paper pulp, being dangerous for health and environment; uses NaOH and chlorine (Hurter, 2001). A new biotechnology process is being developed by Mexican researchers, so that cellulose can be obtained from bagasse using some filamentous fungi species which are able to produce enzymes that can destroy the lignin and convert it to cellulose.
4. Biodegradable tableware. In China, some disposable tableware from bagasse is produced, replacing plastic or virgin paper. Tableware so produced has no plastic or wax lining applied and can be used for both hot and cold items.
5. As dye removal. Bagasse can be used for the removal of azo dyes by adsorption (Liew et al., 2005).
6. Dietary fibre. There is an industry in the United States selling milled and treated bagasse for use as an additive for human food, for thickening soups, for increasing the fibre content, and to improve the consistency of some precooked meals.

**Leaves**

In some countries, the leaves are still burnt in the field after harvesting, without any energy recovery. It is possible to burn leaves in the sugar mills’ boilers.

**Filter cake**

Used as fertiliser in the cane fields; for improving its effectiveness, some biochemical treatment and earthworms can be applied.

**Molasses**

Molasses contains sugar that can be used as a carbon source substrate for different biotechnology processes: citric acid (Garg and Sharma, 1991), acetic acid, ethanol, etc.; development of these technologies is in process around the world.

**Cases studies**

Comparing three different alternatives using bagasse, results are shown in Table 1:

1) Burning 100% bagasse in boilers (present situation)
2) Convert all obtained bagasse to ethanol, burning diesel and/or bunker C as fuel and
3) Convert all obtained bagasse to cellulose, burning diesel and/or bunker C as fuel.

Considered yields: 1.18 kilograms of dry bagasse per kg of sugar; 200 litres of EtOH per tonne of dry bagasse, 0.4 kg of cellulose per kg of dry bagasse; cellulose recovery efficiency considered to be 80%.

**Conclusions**

Commercial by-product utilisation is a very interesting alternative; much care should be taken to diminish risks when investing.

New technologies are a good opportunity, as by-products can achieve very high values, allowing the mills to increase sales and revenues. As a major labour generator, all alternatives are to be taken after a thorough analysis.

Even with high ethanol prices, cellulose applications are far more profitable.

MOTS-CLÉS: Canne à Sucre, Bagasse, Cellulose, Diversification.

Résumé

Les industries cannières font face à des crises financières aiguës. Pour augmenter leur profitabilité, elles doivent utiliser chacun des produits ou sous-produits de la canne. Comme un exemple du potentiel de diversification, une comparaison est faite entre l'éthanol et la cellulose. Au Mexique, le bioéthanol est évalué à 45 centimes américains le litre et quelques 200 litres sont obtenus d'une tonne de bagasse sechée. La bagasse sèche non traitée contient 51.67% de cellulose, 24.42% de hémicelluloses, 10.23% de produits soluble et 13.68% de lignine. Ainsi, théoriquement 516.7 kg de cellulose peuvent être produits d'une tonne de bagasse. La cellulose purifiée vaut au Mexique 4.50 à 5.00 dollars mexicains ou 30 à 33 centimes américains le kilo. En comparant les revenus de la cellulose et l'éthanol, on s'aperçoit que l'éthanol rapporte 1200 dollars mexicains ou 80.00 dollars américains par tonne de bagasse sechée contre 2583.50 dollars mexicains ou 172.20 de dollars américains pour la cellulose. La production potentielle de cellulose en 2007/08 au Mexique était de 3 605 454 tonnes à partir de 46 518 998 tonnes de canne et 6 977 848 tonnes de bagasse. Actuellement le Mexique importe 80% de ses besoins en cellulose. Pas toutes les fibres de cellulose de la bagasse peuvent être utilisées comme combustible. En ayant recours à la nouvelle technologie développée et évaluée par nos soins, toutes les longues fibres peuvent être converties en cellulose et 94% de la moelle peuvent être brulées. Toutefois un apport extérieur de fioul de l'ordre de 3.9 litres d'huile lourde est nécessaire par tonne de canne usinée. Il est important de mettre au point des procédés de laboratoire capables de déterminer la teneur réelle de fibre susceptible d'être convertie en cellulose et comment la biotechnologie pourrait aider à améliorer la quantité et qualité de cette cellulose. Ces procédés doivent être conduits dans des laboratoires industriels et selon les méthodes officiellement acceptées.
DIVERSIFICANDO LA CAÑA DE AZÚCAR: CELULOSA DEL BAGAZO

PALABRAS CLAVE: Caña de Azúcar,
Bagazo, Celulosa, Diversificación.

Resumen

La industria de la caña de azúcar atraviesa una severa crisis económica. Para incrementar su viabilidad económica debe utilizar cada producto ó sub producto de la caña. Como un ejemplo del potencial diversificador se comparan el etanol y la celulosa, ambos obtenidos del bagazo. En México el bioetanol cuesta acreedor de US$ 0.45 por litro y cerca de 200 litros pueden obtenerse por tonelada de bagazo seco. El bagazo seco no tratado contiene 51.67% de celulosa, 24.42% de hemicelulosa, 10.23% de solubles y 13.68% de lignina. Por tanto, teóricamente, 516.7 kg de celulosa pueden obtenerse por tonelada de bagazo seco. La celulosa blanqueada cuesta Mx 4.50 a Mx 5.00 (US$ 0.30 a US$ 0.33) por kg. Comparando los ingresos del bioetanol y la celulosa, el etanol vale Mx 1200 (US$ 80.00) vs. la celulosa a Mx 2583 (US$172.20) por tonelada de bagazo seco. La producción posible de celulosa de la caña de azúcar mexicana (2007–2008) es: caña molida 46 518 988 t, bagazo seco 6 977 848 t, rindiendo3 605 454 t de celulosa. En la actualidad México importa el 80% de la celulosa que requiere. No toda la fibra celulósica del bagazo puede ser utilizada eficientemente como combustible. Con la nueva tecnología desarrollada y comprobada por nosotros, toda la fibra larga puede ser convertida en celulosa y el 945 del bagacillo puede quemarse. Sin embargo, se requiere combustible adicional (3.9 litros de Bunker C pesado por t de caña molida).
**MAHANARVA FIMBRIOLATA INFESTATION IN SUGARCANE: IMPACTS ON ETHANOL PRODUCTION**

By

São Paulo State University – UNESP – Brazil

* mjrmut@fcav.unesp.br

KEYWORDS: *Saccharum* spp., Spittlebug, Cane Quality, Ethanolic Fermentation.

**Abstract**

The spittlebug (*Mahanarva fimbriolata*) has become an important pest of sugarcane in Brazil, causing stalk yield and cane quality losses. This research was conducted to evaluate the effects of spittlebug damage levels on ethanol production. The experiment was set in a sugarcane field with no trash burn, using the variety SP80-1842 (4th ratoon), four stalk damage levels (0, 15%, 30% and 60%) and two harvest dates (May/June and October). Batch fermentation was conducted with baker’s yeast, *Saccharomyces cerevisiae*, with 10 fermentation cycles. There was a reduction in juice sucrose content, total reducing sugars, purity and pH and an increase in total juice and volatile acidity. It was also observed that pest attack damage in sugarcane negatively influenced the fermentation process, with higher levels of acidity and residual reducing sugars and lower alcohol content in wines. Distillates presented higher acetaldehyde and lower ethanol concentration with increasing spittlebug stalk damage levels.

**Introduction**

The spittlebug *Mahanarva fimbriolata* (Stal, 1854) (Hemiptera: Cercopidae) has become a key pest of sugarcane in Brazil, because of the conditions resulting from mechanical harvesting with no trash burn. Nymphs suck roots resulting in nutrient deficiency and dry stalks, affecting both stalk and sugar yield.

Metabolic alterations take place in sugarcane in response to spittlebug infestation, producing a wide variety of biomolecules, which interfere with cane quality and processing, yeast metabolism inhibition during fermentative process, and alcoholic yield losses (Ravaneli *et al.*, 2006).

The damages may be severe on most genotypes, especially in middle and end-of-season varieties (Dinardo-Miranda *et al.*, 1999).

This research was conducted to determine the effects of *M. fimbriolata* damage levels in sugarcane on cane quality and on ethanol production.

**Materials and methods**

The variety used was SP 80-1842 (4th ratoon). The mean infestation observed was 5.32 nymphs/m. Cane was harvested at the end of the rainy season (May/June) and after the dry season (October). The stalk damage levels (15%, 30% and 60%) were compared to uninfested control (Gonçalves *et al.*, 2003).

Juice extraction was performed as described by Tanimoto (1964). Total soluble solids (T.S.S.) and sucrose content analyses were performed as recommended by Schneider (1979); pH, total Reducing Sugars (T.R.S) through Lane & Eynon’s (1934) method; Total Acidity by juice titration with NaOH 0.05N, Volatile Acidity as indicated by Vilella *et al.* (1973) and Total Phenolic Compounds through Folín and Ciocalteau’s (1927) colorimetric protocol.
To conduct ethanolic fermentation, juice was submitted to a clarification process. In the first harvest date, juice purity was diluted to 13° Brix. In the second harvest time, juice purity was diluted to 14° Brix, and pH 3.5 (± 0.3). Fresh baker’s yeast (Saccharomyces cerevisiae) was used at a concentration of 30g per liter of must. Batch fermentations were conducted in 1 L erlenmeyers, in a BOD incubator set at 32°C, monitoring the process with the help of a Brix densimeter. Ten fermentative cycles were conducted. Total residual reducing sugars (T.R.R.S.) (Lane and Eynon, 1934) and alcohol content were determined in wines. The distillates were submitted to volatile compounds analyses by gas chromatography.

**Statistical analyses**

For juice analyses, the experiment was arranged in a completely randomised design in a 4 x 2 factorial. Treatments corresponded to the spittlebug stalk damage levels (0, 15%, 30% and 60%) and harvesting times (May/June and October/2007). Analyses were performed in fifteen replications.

Wine and distillate data were analysed in completely randomised design in a 4 x 10 x 2 factorial. Treatments corresponded to the spittlebug stalk damage levels, fermentative cycles and harvesting times. Analyses were performed in three replications. Data were submitted to an ANOVA, and means were compared by Tukey test at 5%.

**Results and discussion**

*M. fimbriolata* infestation levels affected cane quality. Sucrose content, T.R.S. and juice purity were lower at higher damage levels. Losses were 8.76%, 3.14% and 6.95%, respectively (Table 1).

As spittlebugs attack sugarcane roots, limiting water, nutrient uptake, photosynthesis is expected to be affected, reducing sucrose accumulation (Dinardo-Miranda *et al.*, 2002; Ravaneli *et al.*, 2006). In addition, the reduction in sucrose levels may be a consequence of the biosynthesis of plant defence compounds, such as phenols (Buchanan *et al.*, 2000) and the attempt to produce new vegetative parts. Juice pH, total and volatile acidity were also affected by higher damage levels (Table 1), which indicates that cane was in a deterioration process.

**Table 1**—Effects of *Mahanarva fimbriolata* damage levels on technological parameters of sugarcane juice.

ns = non-significant; * = significant at 5% probability; ** = significant at 1% probability.
The damage levels of *M. fimbriolata* resulted in higher levels of total residual reducing sugars in the wine, reflected in alcohol yield decrease (Figure 1). The highest T.R.R.S. levels were found in the October harvest. This behaviour may be occurring as a result of yeast stress because of cane quality, which presents high levels of acidity and phenolic compounds (data not shown).

There were losses of 13.82% in alcohol content in wines at higher damage levels (Figure 1). Similar results were described in Ravaneli et al. (2006), which observed reduction of 7.2% in alcohol content when spittlebug infestation levels were higher than 2.5 nymphs/m. In distillates, there was higher acetaldehyde concentration when infested cane stalks were used. This behaviour is evident in the October harvest, although the highest means were found in the first harvesting season (Figure 2).

The opposite was observed in ethanol levels (Figure 2), which corroborates the juice quality results. Also, acetaldehyde levels indicate that the fermentation process itself may have been affected, because acetaldehydes are precursors to ethanol in the fermentation pathway. Therefore, *M. fimbriolata* attack results in incomplete fermentations because it affects cane quality and the fermentation process.

---

MOTS-CLÉS: Saccharum spp., Cercoped, Qualité de la Canne à Sucre, Fermentation d’Éthanol.

Résumé
MAHANARVA FIMBRIOLATA de la famille des Cercopidae, est devenu un ravageur important de la canne à sucre au Brésil, où il induit des pertes de rendements et de qualité. Cette étude a été réalisée pour évaluer les effets de différents niveaux d’infestations de Mahanarva fimbriolata sur la production d’éthanol. L’expérience a été réalisée dans un champ de canne à sucre sans brûlis, avec la variété SP80-1842 (4ème repousse), quatre niveaux de dommage des tiges (0, 15 %, 30 % et 60 %) et deux dates de récolte (mai / juin et octobre). Des fermentations en discontinues ont été menées avec de la levure boulángère, Saccharomyces cerevisiae, avec 10 cycles de fermentation. Il y avait une réduction de la teneur en saccharose du jus, des sucres réducteurs, de la pureté, du pH et une augmentation en jus total et des acides volatils. Il a également été observé que les dommages causés par l’infestation du ravageur ont une influence négative sur le processus de fermentation, avec des niveaux plus élevés de l’acidité ; des sucres réducteurs résiduels et une plus faible teneur en alcool dans les vins. Les distillats présentaient une plus forte concentration en acétaldéhyde et une plus faible concentration en éthanol, pour des dommages de niveaux croissants.

PALABRAS CLAVE: Saccharum sp., Spittlebug, Calidad de Caña, Fermentación Etanolica.

Resumen
EL SPITTLEBUG (Mahanarva fimbriolata) se ha convertido en una importante plaga de la cana de azúcar en Brasil, provocando pérdidas en el rendimiento de tallos de cana y en la calidad de la caña. Esta investigación se realizó para evaluar los efectos de los niveles del daño de este insecto en la producción de etanol. El experimento se localizó en un campo de caña sin quema de la paja, usando la variedad SP 80-1842 (4º retoño), cuatro niveles de daño en los tallos (0, 15%, 30% y 60%) y dos fechas de cosecha (Mayo/Junio y Octubre). Se realizaron fermentaciones en batch empleando levadura de panificación, Saccharomyces cerevisiae, con 10 ciclos de fermentación. Hubo una reducción en el contenido de sacarosa del jugo, en los azúcares reductores totales, la pureza y el pH, y un incremento en el jugo total y la acidez volátil. Se observó también que los daños por el ataque de la plaga en la caña de azúcar influye negativamente el proceso fermentativo, con más altos niveles de acidez y azúcares reductores residuales, así como menores contenidos de alcohol en los vinos. Los destilados presentan mayores aldehídos y menores concentraciones de etanol con el incremento de los daños de la plaga en los tallos de caña.
RHEOLOGICAL BEHAVIOUR OF VINASSES FROM A MEXICAN BIOETHANOL FACTORY

KEYWORDS: Rheology, Vinasses, Bioethanol, Viscoelastic, Energy Of Activation.

Abstract

THE KNOWLEDGE of the rheological behaviour of vinasses is very important for the operation and design of a sugarcane bioprocess. This study characterised rheological behaviour of residues from a bioethanol process that uses final molasses as the carbohydrate source. For this, we used a rotational rheometer Anton Paar MCR 301, concentric cylinder system, Peltier plate for temperature control and software Rheoplus for date capture. The temperature effect was compensated with an Arrhenius model, which measures the activation energy of vinasses in the range 298–310 K. The results showed an activation energy of 2.496 × 10³ Cal/g-mol, a non-Newtonian behaviour with viscoelastic characteristic, i.e. at low shear rate range (0–387 L/s) as fluid or viscous (pseudo plastic) flow. After this, there is an inflection point at high shear rate as solid or elastic flow (dilatant), because the vinasses presented a material restructure. This behaviour is due to the complex chemical composition of vinasse from final molasses, which is a by-product of the sugarcane process. To confirm this behaviour, it was compared with the rheological behaviour of vinasse from sugarcane juice as the carbon source that showed a dilatant behaviour, i.e. as a fluid flow. These results showed that, depending on the substrate chemical composition (complex/simple), similar rheological behaviour (complex/simple) is obtained.

Introduction

Residues and derivates from the sugarcane industry can be made into by products, with an economic value and avoid any environmental impact. This impact has a direct effect on the people, by particles emission, contaminant gases, solid residues or discharged fluids that affect environmental health, caused fundamentally by technological advances and low environmental education.

Vinasses from bioethanol production are classified as organic residues of main effect pollutants. From each hectolitre of ethanol produced from final molasses, 10 to 15 hectolitres of vinasse are obtained, with a Chemical Oxygen Demand-COD₅ between 60 and 70 g/L and a pH ca. 4.0. This vinasse is often discharged into rivers, booties and quays without treatment.

Rheology is a science that studies flow and deformation of material when subject to low external forces and depicts the fluids on a graph of stress strength versus shear rate, denominated rheogram (see Figures 1a and 1b). In contrast to fluid mechanics that studies how normal fluids behave, rheology shows how non-Newtonian fluids behave, i.e. that do not obey the Newton law, Equation (1) Bird et al. (2006):
\[\tau = \mu \cdot \dot{\gamma}\]  \hspace{1cm} (1)

where: \(\tau\) is a shear stress [Pa]

\(\mu\) is the dynamic viscosity [Pa·s]

\(\dot{\gamma}\) is the shear rate [sec\(^{-1}\)]

There are in industry other very complex non-Newtonian fluids such as viscoelastic fluids, located at the interface between solid and fluid behaviour.

The knowledge of the rheological behaviour of vinasses is very important to project, operate and design sugarcane bioprocesses, such as energy requirements during mixing and transport, friction losses in pipelines and accessories, and in other aspects of engineering. The rheological research gradually also finds applications in the following: kinetic reactions, chemical structures and components, concentration and distribution of molecular mass, Cantú-Lozano (1990).

**Methodology**

The vinasse samples were collected from two bioethanol factories, a Mexican and a Brazilian. The rheological characterisation was realised in an Anton Paar \(^\text{TM}\) rheometer model MCR301 with a Peltier plate for control of temperature (Figure 2). A concentric cylinder and parallel plates geometry and Rheoplus software for data capture were used with vinasse samples of 30 mL.
Rheological behavior of Mexican vinasse samples was characterised by Herschel-Bulkley model Equation (2) Morel et al. (2008)

\[ \tau = \tau_0 + K \dot{\gamma}^n \]  

where:

- \( \tau \) is a shear stress [Pa]
- \( \tau_0 \) is a yield stress [Pa]
- \( K \) is the consistence index [Pa\textbullet\text{s}^n]
- \( n \) is the rheological index [–]
- \( \dot{\gamma} \) is the shear rate [sec\(^{-1}\)]

The activation energy \((Ea)\) was calculated using the Arrhenius model equation (3), which correlates the apparent viscosity \((\eta_a)\) with temperature. In this case, vinasse samples were rotated in the rheometer at 200 rpm within a temperature range of 298–310 K.

\[ \eta_a = \eta_0 \cdot e^{\frac{E_a}{RT}} \]  

where:

- \( \eta_0 \) is initial viscosity [Pa\textbullet\text{s}]
- \( E_a \) is flow activation energy [Cal\textbullet\text{g-mol}^{-1}]
- \( R \) is ideal gases constant [Cal\textbullet\text{g-mol}^{-1}\text{K}^{-1}]
- \( T \) is absolute temperature [K]

Results

Rheological characterisation

Figure 3 shows the rheogram of behaviour of shear stress versus shear rate of a diluted Mexican vinasse sample and Table 1 shows the parameters of the Herschel Bulkley model from Mexican vinasse, performed with software Rheoplus, the values of: yield stress \( \tau_0 \) and consistency index, \( K_{HB} \), decreases with temperature increases. The flow behaviour index, \( n \), approaches Newtonian behaviour, \( i.e.\ n=1.0\).

Viscosity comparison

In Figure 4, we present comparisons of experimental data of viscosity apparent behaviour of a concentrated sample of Mexican vinasse that uses final molasses as a carbohydrate source with a concentrated sample of Brazilian vinasse that uses sugar juice as a carbohydrate source.

The Mexican vinasse presents non-Newtonian behaviour with viscoelastic characteristics at low shear rate (0–387 sec$^{-1}$), as pseudoplastic and, after an inflection point (387–2200 sec$^{-1}$), at high shear rate as dilatant flow with tendencies of solid behaviour.

The Brazilian vinasse presents a dilatant behaviour. These results showed that, depending on substrate chemical composition (complex/simple), similar rheological behaviour (complex/simple) is obtained.

![Fig. 4—Comparison of apparent viscosities of two concentrated samples, Mexican and Brazilian vinasses](image)

Effect of temperature

The effect of temperature was investigated with the Arrhenius model, Eq. (3). Figure 5 shows its linearisation with logarithm of viscosity against temperature reciprocal absolute. Equation (4) and Table 2 present the parameters of the Arrhenius model.
Fig. 5—Linearisation of Arrhenius model.

\[ \ln \eta_{ap} = -3.0074 + 1266 \left( \frac{1}{T} \right) \quad R^2 = 0.99109 \]  

(4)

Table 2—Parameters of Arrhenius model for Mexican vinasse.

Therefore the Arrhenius equation is defined, for these conditions, as follows:

\[ \eta_{ap} = 4.942 \times 10^{-2} Pa \cdot s \cdot e^{\frac{2496.55 \text{ Cal}/g\cdot\text{mol}}{RT}} \]  

(5)

Conclusions

The examined diluted Mexican vinasse, presents a non-Newtonian behaviour according to Herschel Bulkley model. With temperature increase, it approaches Newtonian behaviour (\( \tau_0 \to 0 \), \( n = 1.0 \) and \( K_{HB} \equiv \mu \)).

The examined concentrated Mexican vinasse presents a non-Newtonian behaviour with viscoelastic characteristic and high temperature, sensibility and shows a high Activation Energy Flow.

Depending on the chemical composition of the substrate (complex/simple), similar rheological behaviour (complex/simple) is obtained.

In a general way, Rheology of Vinasses is a useful tool to determine differences in: concentration, components and temperature sensibility.

PALABRAS CLAVE: Reología, Vinazas, Bioetanol, Viscoelástico, Energía de Activación.

Resumen
EL CONOCIMIENTO del comportamiento reológico de las vinazas es muy importante para la operación y diseño de un bioproceso de la caña de azúcar. Este estudio caracteriza comportamientos reológicos de residuos del proceso de bioetanol que emplean melazas como fuente de carbohidratos. Para esto empleamos un reómetro rotacional Antón Para MCR 301, sistema de cilindros concéntricos, platos Peltier para control de temperatura y software “Rheoplus” para la captura de datos. El efecto de la temperatura se compensó con un modelo de Arrenius, que mide la energía de activación de las vinazas en el rango 298-310 K. Los resultados muestran una energía de activación de 2,496x 10³ Cal/g-mol, un comportamiento no newtoniano, con características viscoelásticas i.e. en un rango bajo de efecto cortante (0-387L/s) como fluido ó flujo viscoso pseudo plástico). Después de esto, hay un punto de inflexión a altos efectos cortantes como sólido ó flujo elástico dilatante), porque las vinazas presentan una reestructuración material. Este comportamiento se debe a la compleja composición química de las vinazas de melazas, que son un subproducto del proceso azucarero. Para confirmar este comportamiento, se comparó con el comportamiento reológico de vinazas de jugos de caña como fuente de carbono, que mostró un comportamiento dilatante i.e. como un fluido fluido. Estos resultados muestran que, dependiendo de la composición química del sustrato (complejo/simple) se obtienen similares comportamientos reológicos (complejo/simple).
TECHNO-ECONOMICAL EVALUATION OF AN INTERACTIVE
DISTILLERY-SUGAR MILL TO GUIDE DECISION-MAKING
FOR THE BEST INCOME BALANCE

KEYWORDS: Sugarcane, Ethanol, Cogeneration, Economics.

Abstract

The world ethanol production has grown rapidly from the beginning of this decade, driven by its greater use as a fuel. For example, in 2001, 42% of the world ethanol production was directed to beverage, cosmetics and the chemical industry whereas, in 2008, this figure went down to only 20%, with 80% being used as fuel (bioethanol). In fact, the bioethanol production grew from 18 000 million litres in 2001 to an estimate of 66 000 million litres in 2008. This means that ethanol is today the main alternative liquid fuel and ethanol obtained from sugarcane is the only source that does not compromise food sources, and it induces a significant reduction in the green-house effect. The technological option of the combined production of ethanol from sugarcane juices and very high pol (VHP) sugars, with an additional contribution of surplus bagasse for electric co-generation, has great appeal. This paper presents a techno-economical evaluation, with an interactive model that can guide the decision making process in the sugar mill/distillery complex, to get the best income balance according to the sugar and ethanol prices prevailing in the world markets. A Cuban case study is presented.

Introduction

The changes in cane sugar production and electric co-generation, in addition to producing ethanol, establish the criteria for a new operational scheme that is being introduced in many countries (MECAS, 2008, 2009).

With the purpose of increasing the efficiency of ethanol production, to get higher competitiveness and better sugar quality, and diminishing dependence on crude oil, the economical impact of a new operational scheme is analysed for Cuban conditions.

In the case of the alcohol distillery, the molasses fermentation stage was found to be one of the most inefficient parts of the process, and some studies were carried out before the implementation of the designed scheme to improve the production technology.

The studies that were carried out indicated the need to employ an adequate yeast strain and supplementation with inorganic salts, all to get a lower blackstrap molasses consumption and a higher exhaustion of the fermentation substrate.

In the conventional scheme, not using the juices from the filters in the sugar production, around 90% of the cane juices are devoted to sugar production and only 10% are directed to ethanol synthesis.

When the system of ‘Two Massecuites’ is used in the sugar production and separating the juices from the filters for alcohol production, 82% of the extracted juices from the cane are used to produce sugar and 18% for ethanol, increasing the surplus bagasse from 36% to 42%.
With this new scheme, the amount of sugar obtained is reduced, because the juices from the filters are not used for that task; and because the ‘Two Massecuites’ alternative limits the sugar recovery up to the B molasses. Both elements had contributed to the increase in the quality of the raw sugar produced.

With the conventional way, a standard or medium quality raw sugar is obtained, with no more than 96 Pol; with the new scheme, it’s possible to obtain a raw sugar with no less than 97 Pol, having wide market opportunities, higher prices, and increasing the net income.

**Materials and methods**

In this study, the increase in the net income obtained when the new scheme is applied is evaluated, having as a reference a Cuban Standard Mill, with a milling capacity of 2520 t of cane per day, with a constant alcohol production per day.

An incremental income is obtained by improvements in the efficiency of the distillery, as well as the increase in the quality of the sugar produced and the higher electric availability.

In the calculations of the income under both schemes, the prices prevailing in the Cuban national market are used (MARC, 2008).

The term ‘extraction’ is used to mean the technological step of using the extraction of the juices from the vacuum filters as substrate for the bioconversion to ethanol.

**Results and discussions**

The results obtained with the New Scheme are shown in Table 1.

It must be taken into account that the raw material used in the substrate for the ethanol production—with the new scheme—is B molasses, a product of higher purity than the C molasses that obviously contributes to the increase in the efficiency of the ethanol production, reducing the unit input.

The production values obtained with both schemes are shown in Table 2 and Table 3. The bases for the calculations are represented in Table 4.

Source: ICIDCA Internal Reports

The surplus bagasse is increased by 1154 tonnes per day, which represents an increase of 6%, and gives opportunities for higher generation and sales of electricity, if this bagasse is used as fuel.

The electric balance is the figure obtained when the electricity consumption of the sugar-alcohol complex is deducted from the total electricity generated by the installation.

The electric balance of the sugar-alcohol complex during the season has two options: when the bagasse is burned as fuel or when not.

In the second case, the electric deficit drives an increase of the production costs as it is forced to buy electricity from the national grid; if burned, the complex is self-sufficient during the milling season, even having the possibility of selling electricity to the grid within the range of 2.51 to 2.98 MWh per day, for three or two massecuites respectively.

The alcohol remains constant in volume because there is no increase in the installed capacity. However, the need to transport molasses from other mills is dramatically reduced, because the ethanol plant can operate with its own molasses for a longer time, reducing the transportation costs of B molasses and giving a higher autonomy of production to the enterprise.

In Table 5, an increase in the total income of US$3m in the sugar-ethanol complex by the new scheme can be seen, when the bagasse is used as fuel to generate electricity.

Conclusions

The implementation of the proposed new scheme is in context with requirements and tendencies that are coming into force in world sugar industries. It allows an increase in the sugar quality, improving its commercialisation.

Additionally, a badly needed production flexibility is ensured in the sugar-ethanol combined manufacture, because the distillery can use juices and/or molasses and the whole range of their combinations, generating, at the same time, electricity, depending on the use of surplus bagasse as fuel.

It is a very promising way to give the cane sugar industry the opportunity to remain as an important economical component of sugar exporting countries.

REFERENCES

d’éthanol à partir de jus de canne, de sucre à pol très élevé (VHP) et la cogénération de l’électricité à partir de la bagasses de canne à sucre est très attrayante. Cette communication comporte une évaluation techno-économique, avec un modèle interactif qui peut guider la prise de décision dans le processus de rentabilité dans un ensemble industrielle usine de sucre-distillerie, pour obtenir un revenu optimal tenant compte les prix du sucre et de l’éthanol en cours sur les marchés mondiaux. PALABRAS CLAVE: Caña de Azúcar, Etanol, Cogeneración, Economía.

Resumen

La producción mundial de etanol ha crecido rápidamente desde el inicio de la actual década, promovido por su mayor empleo como combustible. Por ejemplo, en el 2001 el 42% de la producción mundial de etanol se dirigía a las bebidas, cosméticos y la industria química, pero en el 2008 esta cifra descendió hasta solo el 20%, con el 80% empleado como combustible (bioetanol).

De hecho, la producción de bioetanol creció de 18 000 millones de litros en el 2001 hasta un estimado de 60 000 millones de litros en el 2008. Esto significa que el etanol es hoy el principal combustible líquido alternativo y que el etanol obtenido de la caña de azúcar es la única fuente que no compromete fuentes alimenticias e induce una reducción significativa del efecto invernadero. La opción tecnológica de una producción combinada de etanol de los jugos de caña y azúcares de muy alto Pol (VHP), con una contribución adicional de bagazo sobrante para cogeneración eléctrica tiene un gran atractivo. Este artículo presenta una evaluación técnico-económica, con un modelo interactivo que puede dirigir el proceso de toma de decisiones en el Complejo Ingenio-Destilería de alcohol, para alcanzar el mejor balance de ganancias, en correspondencia con los precios prevalecientes en los mercados para el azúcar y el etano. Se presenta un ‘Estudio de Caso’ para un Complejo cubano.
THE YEASTS, THEIR ECONOMIC, TECHNOLOGICAL AND DIVERSIFICATION POTENTIAL—PRESENT AND FUTURE

KEYWORDS: Yeasts, Technologies, Nutrition, Flavour, Enhancers, Proteins, Pollution.

Abstract

A BRIEF look at the way yeasts and human beings met in ancient times, as well as an analysis of the primary and marginal yeasts such as baker’s yeast, fodder yeast from different agro-industrial residues, beer production, etc., with the possible alternatives for upgrading, are presented. The analysis of the yeasts propagation, as an established technology for the dramatic reduction of the polluting potential of distillery slops, with the simultaneous synthesis of a high quality fodder protein concentrate, as well as the evaluation of yeasts as a source of human nutrition complements, flavour enhancers, specific proteins and amino acids, organic pigments, plus the evaluation of the uses of the functional and thermal properties of yeasts, will complete the scope of this paper.

Introduction

Yeasts existed and influenced, from very early times. It is well known that there are no fossil yeasts. However, it is possible that they will be discovered soon (Poinnar et al., 1993).

Yeasts can be found in the most diverse environments, from the deserts (cactofic yeasts) to the Antarctic (criptococcus), as well as associated with insects, flowers, fruits, soils, plankton, etc.

Their unlimited ability to metabolise from hexose, pentose, and organic acids to hydrocarbons and their possibilities to synthesise from alcohols and fats to heterologous proteins gave the yeasts a distinguished active share in the ‘jump’ of life from the aqueous media toward superior forms.

About the history up to now

The yeasts and their ties with human beings are shown, from the very beginning, as faithful servants of the pleasure and the subsistence of our race (wine and bread).

The first to inform and systematise about it were the Egyptians who were in contact with yeasts but did not know their identity.

Sugarcane, in its long journey of 30 centuries from its origin in the Far East to the Caribbean was accompanied by the practice of fermenting its juices to obtain beverages of various characteristics and alcoholic content.

It was in America where the paradigmatic co-product of sugarcane was institutionalised: the Rum (Blanco, 1989).

In 1818, Erxleben established that the yeasts were living organisms, responsible for the fermentation. Finally, in 1857, Louis Pasteur demonstrated that their presence was essential for the fermentation process, giving the ‘final blow’ to the idea of the spontaneous generation. Hansen, in 1896, presented the first comprehensible taxonomic system for yeasts.
A landmark was when, at the end of the XVIII Century, fermentations were carried out to obtain solely yeasts. Between 1850 and 1870, an accelerated growth of baker’s yeast factories took place and, in 1867, A.L.G. Dehne invented and developed the well known ‘filter press’ for yeasts recovery, which is still in use.

The first producer of aerated yeasts was K.W. Howman, in England, in 1896. The first patent to backup the use of molasses as a substrate for yeasts production appeared in Austria in 1895, at the same time as the works of Delbrück started the use of the yeasts as a protein source in fodders, but also as a reliable option in human nutrition.

A solid development of aeration systems, with higher oxygen transfer rates and lower energy inputs, opened a new way for the genus *Saccharomyces*.

The food crisis during the World War I made it almost unavoidable to call on the *Torulopsis* and *Saccharomyces* as alternative sources of food for the population in Europe and also in the Caribbean. That stopped in 1918. Such experiences of massive production and use of SCP for human use favoured the come back in Germany in 1934–1936.

A new landmark in the evolution of biotechnology, that impacted on the massive production of yeasts, happened at the end of the World War II, with the required industrial production of penicillin. This forced the design and construction of big scale, highly aerated fermenters, for very pure cultures, which required efficient methods of agitation and aeration, accurate temperature measurement and control systems.

This was the milestone that marked the birth of the true biotechnology.

**Residual yeasts**

The *Saccharomyces* are used in an active form in the bakery industry, in the ethanol fermentation and other fermenting processes like the soya sauce (Luh, 1995).

Its inactive form, mainly in animal feeding and in human nutrition, is basically through its derivatives like the yeast extracts and autolises.

The high oil cost, plus the banning of oxygenating additives in gasoline, has driven an explosive expansion of ethanol production.

The residual slops of the distillation stage in the ethanol distillery is a highly contaminating stream. However, a technology has been developed that allows the aerobic fermentation of those slops, using a strain of *Candida* that metabolise the remaining organic matter to synthesise biomass. This depletes the BOD of the slops by 84% or more, and a highly valuable SCP dry concentrate of 45% protein content is obtained for fodder use.

**The yeasts as food**

The interest in the use of the yeasts as human and animal food corresponds basically to the following factors;

- The technological development reached about the baker’s yeasts that allows a deep knowledge of the biological mechanisms of their multiplication, as well as the necessary technological equipment for mass production. (Bergander, 1959)
- The availability of residual yeasts from other processes, mainly the production of ethanol.
- Abundant sources of raw materials of low cost, like the molasses from the production of cane sugar, vinasse from alcohol manufacture, starch, sulfite liquor, n-alkenes (Otero, 1989).
- The low availability or high prices of food, due to droughts, fuel shortages, etc.

Today, the protection of the environment has been added to the problems mentioned before. Yeasts production became a proved way to reduce the environmental contamination by some industries such as the ethanol industry.
The value of the yeasts as food

Foods must cover a series of requisites that make them acceptable. The FAO Organisation has established the pre and clinical tests that any food must undergo to be recognised as Gras (Generally Recognised as Safe).

**Digestion and absorption**

To be able to use the nutritive components of a food, they must be available at the digestion and during the absorption. Any additive like yeasts are forced to show, not only to be safe and nutritive, but also to have physical and chemical-physical properties that facilitate their use and ensure an attractive aspect of the final product. Among them are humidity, particle size, bulk density, palatability, and oxidation.

The yeasts are not only an ideal, safe, plastic source of high quality proteins, but also of badly required vitamins, oligoelements and essential amino acids

**The yeasts as a complement of human foods**

The yeasts as a complement in the human diet satisfy the concept of ‘functional food’, being able to produce beneficial metabolic and physiological effects, like the reduction of glycaemia, prevention of prostate cancer, etc.

In addition to the basic nutritional functions, the yeast cells could be considered as nutraceutics, as is the case of the different chromium and selenium complexes, etc. (Roberfroid, 1999).

The dry *Saccharomyces* cells are used as an optimum source of dietetic fibre and vitamins of the B complex. They also have eight essential amino acids required for healthy adults and arginine and histidine basic for children. Additionally, they supply essential minerals, especially chromium and selenium (Dziezak, 1987; Peixoto, 1996).

The essential amino acid composition of the yeasts has no difference in comparison with the FAO/WHO standard, except for the chemical score of the yeasts autolisate that reached 84% in relation to the sulfurous amino acids.

**The state of the art and some recent tendencies**

The last years of the 20th century and the beginning of the 21st show really interesting tendencies of special significance in the relation of yeasts with mankind.

Yeasts show even more abilities that, wisely used, have an indisputable space in health, nutrition and industrial production (Leimer and Finguerut, 2005).

An example is the possibility of accumulating significant amounts of minerals present in the culture media. It is the case of organic selenium used successfully because it resembles the way this mineral is present in nature.

A similar situation happens with chromium, a very active constituent of the glucose tolerance factor (GTF) that becomes a necessary cofactor to enhance the activity of insulin to transport the glucose from the circulatory tissues to the peripheral ones.

The strengthening of the immune system in animals is a new science and here also the yeasts are getting a special share.

Hydrogen, as an option to establish an ecologically friendly energetic alternative, is a place where yeasts will play a decisive role.

The impact of the yeasts in the solution of the basic problems that mankind is facing today: food, energy and the protection of the environment, is clear and evident; Yeasts will be surprising us every day.

Resumen

SE PRESENTA una breve visión del modo en que las levaduras y los seres humanos se encontraron en la antigüedad, así como un análisis de cómo las levaduras marginales y primarias, como las de panificación, forrajeras obtenidas de diferentes residuos agroindustriales, de la producción de cerveza, etc. pueden ser revalorizadas. La visión total de este trabajo se completa con el estudio de la propagación de las levaduras, como una tecnología establecida, para una dramática reducción del potencial contaminante de los residuos de las destilerías, con la síntesis simultánea de un concentrado proteico de alta calidad, así como la evaluación de las levaduras como fuente de complemento para la alimentación humana, potenciadores de sabor, proteínas específicas y aminoácidos, pigmentos orgánicos, a más de la consideración de los usos de las propiedades funcionales y térmicas de las levaduras.
DEMONSTRATION OF CELLULOSIC ETHANOL PRODUCTION FROM SUGARCANE BAGASSE IN AUSTRALIA: THE MACKAY RENEWABLE BIOCOMMODITIES PILOT PLANT

By

Queensland University of Technology, Brisbane, Australia
i.ohara@qut.edu.au

KEYWORDS: Lignocellulose, Bioethanol, Biorefinery, Biocommodities, Pilot Plant.

Abstract

The ready availability of sugarcane bagasse at an existing industrial facility and the potential availability of extra fibre through trash collection make sugarcane fibre the best candidate for early stage commercialisation of cellulosic ethanol technologies. The commercialisation of cellulosic ethanol technologies in the sugar industry requires both development of novel technologies and the assessment of these technologies at a pre-commercial scale. In 2007, the Queensland University of Technology (QUT) received funding from the Australian and Queensland Governments to construct a pilot research and development facility for the production of bioethanol and other renewable biocommodities from biomass including sugarcane bagasse. This facility has been built on the site of the Racecourse Sugar Mill in Mackay, Queensland and is known as the Mackay Renewable Biocommodities Pilot Plant (MRBPP). This research facility is capable of processing cellulosic biomass by a variety of pretreatment technologies and includes equipment for enzymatic saccharification, fermentation and distillation to produce ethanol. Lignin and fermentation co-products can also be produced in the pilot facility.

Introduction

As a result of the increasing scarcity of crude oil, rising oil prices and concerns about the geopolitical concentration of remaining oil reserves, many countries are now seeking alternative energy sources for transport fuels. The need for transport fuels that are renewable and sustainable and have low greenhouse gas emissions is also underpinning the development of new fuel production technologies.

Second generation biofuels utilise non-food feedstocks for bioethanol production. Materials considered for second generation biofuel production are generally lower value feedstocks, including crops grown on marginal agricultural land or underutilised biomass residues of existing agricultural crops such as sugarcane bagasse.

Sugarcane bagasse is a complex mixture of cellulose, hemicellulose and lignin with minor amounts of ash, proteins, lipids and extractives. The cellulose and hemicellulose components of sugarcane bagasse can be pretreated, hydrolysed and fermented with varying efficiencies into ethanol (IEA, 2004; Olsson et al., 2005).

Pilot plants are an essential tool for the development of new technologies, bridging the gap between laboratory research and commercial application. Pilot plants are used to optimise key process parameters such as yield, rate and efficiency at a scale much larger than that used for laboratory development and in equipment that mimics large scale industrial facilities.

These plants allow key process economics to be evaluated and provide information on both the robustness of the process and scale-up data for the design of the commercial facility.
Pilot plants also provide the opportunity to produce a significant amount of product for pre-commercial testing.

In Australia, the Queensland University of Technology (QUT) has constructed a pilot research and development biorefinery for the production of biofuels and other renewable biocommodities from biomass including sugarcane bagasse.

In a biorefinery, bagasse is typically fractionated into its major component streams and value is added to each component through the production of multiple co-products, such as bioethanol, compounds derived from lignin, specialty sugars, organic acids, fermentation products and energy products including biodiesel, hydrogen and methane (Figure 1).

![Figure 1—A typical concept drawing for a sugarcane biorefinery.](image)

The Mackay Renewable Biocommodities Pilot Plant

The Mackay Renewable Biocommodities Pilot Plant (MRBPP) has been funded jointly by the Queensland Government, the Australian Government and QUT. Queensland Government funding was provided through the Innovation Building Fund which was established to promote the development of research infrastructure for science and technology in Queensland. Under the Australian Government National Collaborative Research Infrastructure Strategy funding conditions, facilities are made available by the host organisations for both public and private sector research. The priority and cost of access is determined in accordance with an Access and Pricing Code, and access for meritorious, eligible research is provided at a subsidised rate to enhance facility usage.

The MRBPP has been built at the Mackay Sugar Limited (MSL) Racecourse Mill in Mackay, Queensland. Mackay is a major sugarcane producing region in Australia, with this region producing around 10 million tonnes of sugarcane per annum. Co-location on the site of a sugar factory allows the facility ready access to feedstocks for the process (bagasse, juice and molasses) and enables the utilisation of essential services from the Racecourse Mill site.

Key elements of the facility include site infrastructure consisting of the main factory building, office and laboratory facilities, plant and equipment and facility labour. Plant and equipment includes bagasse handling, pretreatment, saccharification, fermentation and ethanol purification and concentration. Laboratory process development units are available including a
Mettler Toledo RCe1 reaction calorimeter with on-line infra-red detection. This unit enables the development of comprehensive chemical reaction kinetic information.

Plant and equipment for the MRBPP facility has been selected to be capable of demonstrating a range of biorefinery processes (such as that shown in Figure 2). The major pretreatment reactor has been designed and manufactured by Andritz Inc and is a Hastelloy two-stage batch reactor capable of processing a range of biomass feedstocks, and demonstrating several pretreatment processes. These processes include pretreatment using both alkaline and dilute acid processes at temperatures up to 230°C and pressures to 26 bar. Further, the equipment will enable the fibrous material to be ‘exploded’ out of the reactor in the rapid depressurisation process known as steam explosion. Providing the flexibility to simulate a range of pretreatment processes maximises the value of the facility both to the research community and to potential industry partners.

Glucose and pentose fermentation to ethanol will be undertaken in a range of fermenters of varying scales up to 10 000 L. The MRBPP facility has been designed with an enclosed fermentation facility, capable of being certified to physical containment level 2 (PC2).

This containment level will enable the facility to trial a range of fermentation organisms, including recombinant organisms that have been modified for enhanced pentose fermentation capability. Ethanol produced in the pilot plant will be concentrated using a distillation column to produce a hydrous ethanol product.

One of the key co-products from the biorefinery is lignin – an aromatic polymer with many valuable properties. Research work at QUT and through the Cooperative Research Centre for Sugar Industry Innovation through Biotechnology (CRC-SIIB) has investigated a range of potential uses for lignin including as a phenol substitute in phenol-formaldehyde resins, as a water-borne barrier coating and as a component of lignin-PF films and biocomposite materials (Doherty et al., 2007).

The pilot plant includes equipment for both the delignification of biomass and the subsequent recovery and purification of lignin. The purified lignin is able to be produced in significant quantities to enable further product development and testing.

**Conclusion**

The MRBPP is valuable research and development infrastructure for both the international sugarcane research community and future biomass-based industries. This facility provides unique infrastructure for biomass utilisation research, particularly focussed upon the enzymatic conversion of cellulose into ethanol in an integrated biorefinery.
Additionally, the ability to produce novel co-products such as lignin allows opportunities for large scale product development and testing.

The MRBPP has sufficient flexibility to undertake trials on fermentation technologies based on sugar, molasses and bioethanol process streams to manufacture organic acids and other products. Further chemical derivatisation and transformations are also possible dependent upon process conditions.

Acknowledgements

The authors wish to thank the Australian Government Department of Innovation, Industry, Science and Research and the Queensland Government Department of Tourism, Regional Development and Industry, QUT and Mackay Sugar Limited for the on-going funding and support for the establishment of the MRBPP.

Resumen

La segura disponibilidad de bagazo de la caña en facilidades industriales existentes y la potencial disponibilidad de fibra extra por la vía de la recolección de los residuos agrícolas hacen de la fibra de la caña de azúcar la mejor candidata para una temprana comercialización de tecnologías de etanol celulósico. La comercialización de tecnologías de etanol celulósico en la industria azucarera requieren tanto el desarrollo de tecnologías novedosas, como el desarrollo de estas tecnologías a una escala pre-comercial. En el 2007 la Universidad Tecnológica de Queensland (QTU) recibió financiamiento de los Gobiernos de Australia y de Queensland, para la construcción de una instalación piloto de investigación y desarrollo para la producción de bioetanol y otros bioproductos renovables a partir de biomasa incluyendo bagazo de la caña de azúcar. Esta instalación se construyó en áreas del Reecourt Sugar Mill en Mackay, Queensland y es conocida como la Planta Piloto de Bioproductos Renovables de Mackay (MRBPP, en inglés). Esta facilidad investigativa es capaz de procesar biomasa celulósica mediante una variedad de tecnologías de pretatamiento e incluye equipos para sacarificación enzimática, fermentación y destilación, para producir etanol. Se pueden producir igualmente lignina y coproducios de la fermentación en esas facilidades piloto en Mackay.
SAN CARLOS ‘SUGAR CANE TO BIO-ENERGY—A SUCCESS STORY’

KEYWORDS: Bio-energy, Fuel Ethanol, Cogeneration, Biomass, Zero Discharge.

Abstract

THE FIRST commercial scale sugarcane to bio-energy (i.e. fuel ethanol and grid connected cogeneration) plant in Philippines commenced successful operation in January 2009. The integrated facility was set up by San Carlos Bio-energy Inc. (a joint venture of Bronzeoak Clean Energy Inc, United Kingdom) near San Carlos on Negros Occidental Island, Philippines. The technologies have been provided by Indian companies, ISGEC John Thompson (IJT) for the complete plant and KBK Chem-Engineering for ethanol. The facility comprises a raw syrup plant using state of the art energy efficient juice extraction, clarification and evaporation plant followed by fermentation, distillation and dehydration for production of fuel ethanol. After concentration of the vinasse, 75% is used for dilution of syrup and the balance 25%, along with the filter-cake, is used for bio-composting for organic fertiliser which results in zero effluent discharge. The Co-generation plant comprises an 8 MW extraction-cum-condensing turbo generating set and a 45 TPH, 67 kg/cm² (g) travelling grate single pass water tube IJT make boiler suitable for firing a wide variety of biomass, mainly bagasse, woodchips, eco-friendly cane trash and bio gas to facilitate year round cogeneration. The total process steam consumption for production of fuel ethanol is 350 kg/tonne of cane. The plant has achieved 110% capacity utilisation with all the efficiency parameters in the second month of the trial season. The plant is meeting World Bank standards of stack emissions through an electrostatic precipitator and zero effluent discharge through bio-composting of the vinasse. The plant is fully automated through a DCS-based control system with facility for remote operations. The surplus power export to grid is 60 kWh/tonne cane. This opens up a new avenue in the South East Asian region for profitable production of green energy.

Introduction

These days with increasing demand for fuel, ethanol blended with gasoline is the most widely used alternative fuel.

Replacing some petroleum use with renewable biomass resources and electricity is appealing but the approach brings with it important questions:

1. What is the best use of limited biomass resources?
2. How to replace litres of gasoline in a timely fashion, maximising the greenhouse gas emission reductions and accounting for energy security issues?
3. Can we achieve these goals without reaching technology limits?
Here is the answer and following benefits of converting sugarcane to bio-energy:

- Insulation from fluctuation of fossil fuel prices in the world market.
- Utilisation of alternative, clean and renewable fuels for energy without compromising food security.
- Promotion of countryside development and rural employment.
- Mitigation of toxic and greenhouse gas (GHG) emissions.

In view of examining ways to abate gasoline consumption by adopting alternative fuels and shifting of energy to the electricity grid, IS GEC John Thompson, INDIA, an EPC group has emerged with integrated sugarcane to ethanol plant including cogeneration of power.

Building on prior experience in the field of sugar machinery and ethanol, ISGEC John Thompson along with KBK were involved to design, develop, construct, erect and commission an integrated sugarcane to ethanol complex including power cogeneration at San Carlos Bioenergy Inc. in the Philippines near San Carlos on Negros Island (Figure 1.)

The plant is designed to produce 125 000 litres/day of anhydrous ethanol directly from cane juice with 8 MW power generation and it emits 50 tonnes per day carbon dioxide.

An anaerobic digestion plant with integrated waste treatment plant is installed to minimise the liquid and solid discharge from the plant.

The complete concept of design engineering, erection and commissioning of the plant is described in this paper.

Fig. 1—San Carlos Bio-energy Inc., Philippines ‘Powering the Future’.

**Concept of plant design**

**Energy security**

The plant is fueled entirely by indigenous biomass resources, particularly bagasse and eco-friendly cane trash and wood chips.

The ethanol plant is designed to produce 125 000 litres of anhydrous fuel grade ethanol per day and 30 million litres annually. 8 MW of energy will be produced through cogeneration, with approximately 4 MW available for export.

**Environment**

The ethanol plant conforms to World Bank emission standards. No NOx and SOx will be emitted. All liquid discharge is reused for the plant’s cooling systems and irrigation. Solids on the other hand are recycled as organic fertiliser.

Biogas produced and captured per day is utilised as additional fuel to the boiler.
Agro economy

Farmers cultivating biofuel feedstock, cane, will have a ready and viable market and will progressively increase their income. This facility provides numerous farm services and plant site employment opportunities. Stable energy supply in the area will encourage further agro-industrial development, resulting in improved socio-economic status of the local communities.

Main components of the plant

To meet local and international environmental and technical standards, the following are the main components of the plant:

- Cane handling and milling.
- Juice clarification and evaporation.
- Fuel ethanol Plant.
- Cogeneration plant.
- Carbon dioxide recovery plant.
- Anaerobic digestion plant.
- Bio-composting.

Flow processes

The flow processes and functions of the integrated bio-ethanol plant are described below.

Cane crushed through mills driven by energy efficient shaft mounted hydraulic drives (Figure 2).

The juice is clarified through a defecation process.

Juice Evaporation to 40° Bx in a state of the art fully-automated multi-effect evaporator station with all waste heat recovery system, condensate flash recovery for minimum steam consumption which is only 180 – 200 kg/tonne cane for raw syrup production to facilitate more power export (Figure 3).
Ethanol production from raw syrup.

The ethanol plant comprises three distinct stages: fermentation, distillation and dehydration. Syrup received from the raw syrup plant is diluted and fed to the fermentor for continuous fermentation (Figure 4).

In addition to production of relatively low alcohol feed to the distilling stage, fermentation results in the generation of carbon dioxide. This is a potential saleable byproduct for use in food and beverage industries. A CO₂ capture plant is installed.

The distillation plant is designed to operate under vacuum and use low-pressure steam from the cogeneration plant. Preheated fermented wash is fed at the top of the distillation columns. As the wash descends, vapours containing alcohol are separated.
Up to and about 75% of the spent wash is re-circulated to the fermentation plant in order to dilute the incoming cane syrup with the balance directed to the effluent treatment plant. This approach reduces both raw water make-up requirements and the resulting less effluent produced. However, it does increase effluent COD/BOD (chemical oxygen demand / biological oxygen demand).

Leaving the distillation stage, the separated alcohol vapours are sent to the dehydration stage where desiccant beds are used to remove residual water. The plant will have two 100% beds with one bed operating while the other is regenerated by steam from the cogeneration plant. Dehydration will result in ethanol with a concentration of 99.85%. Before leaving the plant, ethanol will be denatured.

It’s the responsibility of ethanol purchasers to blend the ethanol with gasoline to E5 or E10 grade before commercial sale at gasoline stations for common use in the Philippines.

The ethanol plant typically results in a high COD and BOD effluent. In view of modern practice, the first stage in treatment of effluent at S CBI is by anaerobic digestion. This substantially reduces COD/BOD with production of biogas, which is used as a supplementary fuel for the boiler.

Following anaerobic treatment, the effluent is directed to a membrane filtering system for separation into a permeate stream (low COD/BOD) and a concentrated stream (high COD/BOD) stream.

The SCBI design incorporates recycling of the permeate (relatively clean) stream within the facility. The main part of the concentrate stream will be used to aid bio-composting of the residual filter cake from the raw syrup plant to which boiler ash and anaerobic digestion solids are added. The resulting bio-compost will be returned to the fields for soil nourishment as organic fertiliser. In addition, any surplus liquid concentrate that is not used for composting will also be disposed by spraying onto cane fields.

Cogeneration

The cogeneration boiler is sized at 45 tonne/h and produces steam at 67 kg/cm² (g) and 480 ± 5°C. This steam drives an extracting-cum-condensing steam turbine to produce electricity, for in house consumption and facility for exporting surplus power (Figure 5). From an energy perspective, the plant is designed to be self-sufficient using bagasse from the mill and biogas from the anaerobic digestion plant. For longer operation wood chips can also be used.

Fig. 5—Cogeneration plant.
Depending on the availability of sugarcane, SCBI's operations will fall into two distinct modes: a) the on-season mode, the period when sugarcane is harvested and available for processing, b) the off-season mode, the period when no sugarcane is available. During on-season mode, the cane mill, raw syrup plant, ethanol plant and cogeneration plant with all associated services will be in operation. During the off-season mode, plant operations are limited to that of the cogeneration plant and associated services.

Over the course of a year, the plant will process over 450,000 tonnes of cane while producing 39 million litres/year of ethanol. The cogeneration plant will generate 7.5/8 MW during the on-season mode, allowing about 3.5/4 MW for export to grid. During the off-season, the cogeneration plant is predicted to increase export to 4 MW due to lower on-site consumption. Plant operation parameters are as follows:

<table>

</tbody>
</table>

Contract risks have been mitigated by the appointment of international consulting engineers, to manage the procurement and construction process during post-financial close project execution.

This company is registered as a CDM (Clean Development Mechanism) project and will earn additional revenue from the sale of CERs (carbon credits). These should accrue from four sources, a) displaced fossil generated electricity, b) displaced vehicle use of gasoline, c) methane captured by anaerobic digestion process, d) carbon dioxide captured and sold for commercial use. At the time of writing, the CDM process has received approval for source (a). The other sources are the subject of ongoing discussions and decisions by the UNFCCC (United Nations Framework Convention on Climate Change) methodology panel.

Since the cogeneration plant uses only biomass, only very low sulfur dioxide emissions will occur. The main control is for particulates using electrostatic precipitators. The design of the ethanol plant effluent treatment was both a technical and commercial challenge in terms of achieving the low standard for the final effluent quality and in terms of finding a cost optimised approach. The final solution results in zero effluent discharge to surface water by a combination of recycling, bio-composting and limited use of liquid effluent as a soil nutrient.
L’UNITÉ DE SAN CARLOS AU PHILIPPINES ‘DE LA CANNE À SUCRE À LA BIO-ÉNERGIE: UNE RÉUSSITE’

Par

Résumé

LE PREMIER complex industriel commercial à succès de la canne à sucre à la bio-énergie (c'est-à-dire bioéthanol et cogénération de l’électricité à la grille nationale), au Philippines a été mis en opération en janvier 2009. Cet ensemble industriel intégré a été institué par la San Carlos Bio-energy Inc. (une subsidiaire de Bronzeoak Clean Energy Inc, Royaume-Uni) près de San Carlos sur l’île de Negros Occidental, aux Philippines. Les technologies ont été fournies par les sociétés indiennes ISGEC John Thompson (IJT) pour l’ensemble industriel et KBK Chem-Engineering pour l’éthanol. L’installation comprend une unité pour produire du sirop à l’état brut à l’aide des technologies les plus avancées en matière d’efficacité d’énergie pour l’extraction, la clarification et l’évaporation suivie de la fermentation, de la distillation et la déshydratation pour la production de bioéthanol. Après la concentration des effluents, 75% est utilisé pour la dilution de sirop et la balance de 25% en mélange avec les écumes, est utilisé pour produire des engrais organiques par bio-compostage, ce qui se traduit par une absence complète de production d’effluents. L’unité de co-génération com prend un turbo alternateur extraction-cum-condensation de 8 M W et une chaudière à grille simple IJT de 45 TPH, 67 kg/cm² (g) pouvant être utilisée pour une grande variété de types de biomasse, principalement la bagasse de canne à sucre, des copeaux de bois, la paille de canne écologique et du biogaz qui permettent la cogénération pendant toute l’année. La consommation totale de vapeur pour la production de bioéthanol est de 350 kg/tonne de canne à sucre. L’ensemble industriel a atteint 110% de sa capacité tenant compte de tous les paramètres d’efficacité, au cours du deuxième mois de la saison d’essai. Le complexe industriel satisfait les normes de la Banque Mondiale pour les émissions à travers l’utilisation d’un filtre électrostatique et l’élimination totale des effluents par bio-compostage. L’ensemble industriel est entièrement automatisé par le biais d’un système de contrôle digitalisé (DCS) avec facilité pour des opérations de contrôle à distance. L’exportation du surplus de électricité à la grille est de 60 kWh par tonne de canne. Cela ouvre une nouvelle avenue pour une production d’énergie verte rentable dans le Sud-est Asiatique.

Resumen
LA PRIMERA planta a escala industrial en Filipinas para bioenergía (i.e. etanol combustible y cogeneración conectada a la red pública) comenzó su exitosa operación en Enero del 2009. La instalación integrada fue establecida por San Carlos Bio-energy Inc. (una inversión conjunta de Bronzeoak Clean Energy Inc., United Kingdom) cerca de San Carlos en la Isla Negros Occidentales, Filipinas. La tecnología fue suministrada por compañías indias, ISGEC John Thompson (IJT) para la planta completa y KBK Chem-Engineering para etanol. La instalación comprende una planta de sirope azucarero crudo empleando tecnología de “Estado del Arte” en cuanto eficiencia energética para la extracción del jugo, clarificación y evaporación, seguida de fermentación, destilación y deshidratación para la producción de etanol combustible. Posterior a la concentración del vinasse, 75% se emplea para la dilución del sirope y el balance del 25%, junto con los filtros, se utiliza para el biocomposteado para fertilizante orgánico, lo que resulta en una emisión cero de efluentes. La planta de cogeneración comprende un generador de extracción-condensación de 8 MW de capacidad y 45 TPH, 67 kg/cm² (g), parrilla móvil, tubos de agua IJT de un paso, hacen que la caldera sea capaz de combustionar una amplitud variedad de biomasa, principalmente bagazo, astillas de madera, residuos cañeros ecoamigable y biogas, todo para facilitar la cogeneración todo el año. El consumo total de vapor para la producción de etanol combustible es de 350 kg/t de caña. La planta ha alcanzado una utilización de 110% de su capacidad, con todos los parámetros de eficiencia en su segundo mes de la campaña azucarera de prueba. La planta también satisface los estándares de emisión de I Banco Mundial mediante un precipitador electrostático y cero descarga de efluentes por la biocompostación de las vinazas. La planta está to talmente automática mediante un sistema de control DCS con facilidades para la operación remota. La energía excedente exportada a la red pública, es 60 kWh/t de caña. Esto abre una nueva avenida en la región del sureste de Asia para la producción rentable de energía verde.
DESIGN, MANUFACTURING AND MAINTENANCE OF SUGAR MILL EQUIPMENT: ISSCT ENGINEERING WORKSHOP 2008 SUMMARY REPORT

By

G.A. KENT
ISSCT Engineering Section Chairman

KEYWORDS: Sugar, Mill, Sugar Mill Equipment, Design, Manufacture, Maintenance.

Abstract

The ISSCT Engineering Workshop 2008 in Brazil was well attended with 62 participants including 39 overseas visitors from 15 countries. The workshop addressed the theme Design, manufacturing and maintenance of sugar mill equipment. From the technical sessions, the following conclusions were drawn: several speakers articulated a shared vision of the future of the Brazilian sugar industry. This shared vision gives considerable confidence that the vision can become a reality; there is an increased focus on energy products. As a result, the reduction of factory energy consumption in order to maximise the energy available for products is also a focus; new equipment and products are being developed with reduced power consumption, lower capital and maintenance costs, and better performance. Methods presented for reducing maintenance costs included the use of a maintenance management system, condition monitoring and material selection. The workshop was held in conjunction with Piracicaba’s annual SIMTEC exhibition for the sugar and alcohol industries that provides a forum for technical presentations and discussion, and showcases products and services from manufacturers and service providers. In return for holding the workshop in conjunction with SIMTEC, SIMTEC provided sponsorship for the workshop, including paying travel and accommodation costs for two invited speakers, and organisation for the workshop. The ISSCT and SIMTEC technical programs were arranged so that their technical sessions did not clash, and the ISSCT program was extended a day to provide an opportunity for ISSCT participants to attend the SIMTEC exhibition. Informal feedback from workshop participants suggested that the arrangement between ISSCT and SIMTEC worked well. Site visits to two manufacturing facilities and two sugar mills were arranged as part of the workshop.

Introduction

An ISSCT Engineering Workshop was held in Piracicaba, Brazil from 30 June to 4 July 2008. The theme of the workshop was Design, manufacturing and maintenance of sugar mill equipment.

The workshop was held in conjunction with SIMTEC (Symposium and Technology Exhibition on the Sugar & Alcohol Industry). SIMTEC is an annual event held in Piracicaba that provides a forum for technical presentations and discussion, and showcases products and services from manufacturers and service providers. SIMTEC provided sponsorship for the ISSCT workshop and handled most of the workshop organisation.

To better integrate with SIMTEC, the ISSCT workshop was extended from its usual four days to five days. Technical sessions were held throughout the first day and on the mornings of the second and third days. SIMTEC started on the second day of the workshop and continued until the final day. SIMTEC was held in the afternoons and evenings of the second and third days so it did not clash with the workshop technical sessions. The afternoon programs for the second and third
days of the workshop were kept free for SIMTEC attendance so that ISSCT participants could attend the SIMTEC technical sessions and trade exhibition. Site visits were held on the fourth and fifth days of the workshop.

The workshop was attended by a total of 62 participants, including 39 overseas visitors from 15 countries.

Attendance included the ISSCT Factory Commissioner, Juliusz Lewinski, the author (Geoff Kent, ISSCT Engineering Section Chairman), and five members of the ISSCT Engineering Section Committee—Paulo Delfini, D.K. Goel, Adolfo Gomez, Dave Meadows and Boris Morgenroth.

Paulo Delfini from Brazil acted as Chairman of the Workshop Organising Committee in the lead up to the workshop while the other four members of the committee in attendance chaired the four main technical sessions.

Sponsorship

Financial support for the workshop was provided by SIMTEC, Dedini, TGM and WBA. In addition to the support provided in organising the workshop, SIMTEC paid the travel and accommodation costs for two invited speakers: Mr Alan Yarrow of Australia and Mr Manuel Enríquez of Mexico. TGM and Dedini provided lunch for the delegates during the two days of site visits.

Zuckerindustrie and International Sugar Journal provided a free one-page advertisement in their respective journals in advance of the workshop.

Opening session

The opening session of the workshop, chaired by the author, included presentations from the following invited speakers:

A welcome from Paulo Delfini, the Chairman of the Workshop Organising Committee.

The official opening of the workshop by José Francisco Calil, the Secretary of Economic Development for the City of Piracicaba.

An overview of the sugar industry in Brazil by Edgard Gomes Beauclair of STAB.

A welcome to SIMTEC from Alvaro Vargas, Directory of Industry Centre of Sao Paulo State (CIESP).

Edgard Beauclair’s presentation provided a good overview of the sugar industry in Brazil and its vision for the future. He stressed that the industry has been unfairly subjected to international criticism due to two misconceptions:

The production of ethanol from sugarcane is not replacing food production. Most new cane land was previously unproductive.

New cane land is not within the Amazon region of Brazil.

The Brazilian industry is focussed on the use of sugarcane as an energy crop. Products include ethanol from juice products, electricity, biodiesel and ethanol from sugarcane biomass.

Technical sessions

Introductory remarks

The conference included four technical sessions. The session topics and their respective chairmen are listed in Table 1.

Each session contained a keynote address that was intended to lead into a discussion of that topic. The keynote speakers are also listed in Table 1. Additional technical presentations were also given.
Table 1—Session topics and chairmen.

**Factory and factory system design and maintenance**

*Keynote address: Factory and factory system design (José Luiz Olivério)*

José Olivério outlined Dedini’s view for the evolution of the sugar industry in Brazil, focusing on sustainable development by producing biofuels and bioenergy from sugarcane. He described traditional factory configurations, current trends and a future vision.

The traditional factory configuration in Brazil produces sugar, bioethanol and bioelectricity. To maximise energy output, there is a need to minimise factory energy consumption. A traditional factory can maximise energy output by replacing turbine drives with electric or electro-hydraulic drives, generating high pressure (100 bar) steam, producing low, low pressure steam, improving process control and biogasification of dunder.

Considered as an energy source, 1 tonne (dry basis) of cane in the field (made up of one-third sugar, one-third bagasse and one-third trash) has equivalent energy to 1.2 barrels of oil. Bioelectricity can be produced from bagasse, trash and dunder. Bioethanol can be produced from bagasse and trash. Biodiesel can be produced from an integrated sugar and bioethanol mill. He outlined a range of technologies under development that would help to achieve this vision.

The presentation also covered environmental sustainability and the need to reduce water consumption. His vision included the export of water and the production of fertiliser from concentrated dunder and filter mud.

*On line devices for process monitoring and control of the sugar production – the purity analyser (Mathis Kuchejda)*

Mathis Kuchejda indicated that the demand for on-line instrumentation came from the desire to maximise productivity through direct process control. On-line instrumentation is of great benefit in process control.

The on-line purity analyser measures purity according to the ICUMSA laboratory method. It consists of a process refractometer for measuring brix and a Polatronic NIR polarimeter for measuring pol. The NIR method does not require the juice to be clarified before measurement. The analyser can be used on process streams with brix from 15 to 85. Higher brix materials are diluted by a factor of four before measurement.

The instrument takes about 10 minutes to process a sample. It is intended that samples from multiple streams be processed by this one instrument. The system is cleaned as part of the measurement cycle in readiness for processing a different stream.

**Factory equipment design and manufacture**

*Keynote address: Factory equipment design and manufacture (Boris Morgenroth)*

After listing a range of emerging technologies for sugar mill equipment, Boris Morgenroth focussed on evaporator designs. He discussed the evolution of the evaporator, with falling film plate evaporators being the most recent type to gain acceptance. He indicated that this type of evaporator offered better heat transfer coefficients and less sucrose inversion but required higher juice velocities.
Concept for an energy efficient 6000 t/day cane sugar factory (Boris Morgenroth)

Boris Morgenroth described a range of technologies that he believed should be incorporated into a new cane sugar factory in order to achieve high energy efficiency. The technologies he recommended were:

- Diffuser technology and the return of clarifier underflow to the diffuser.
- Falling film plate evaporators.
- Increased fifth effect vapour temperature from 0.15 bar(a) to 0.55 bar(a).
- Vapour bleeding from all effects.
- All pans supplied with vapour 3 (about 100°C).
- Continuous pans for A, B and C products.
- A-seed cooling massecuite plant.
- Stepwise flashing of condensates and reuse of flash vapours.
- Using condensate for pre-heating of limed juice.
- High g-factor continuous centrifugals.
- High pressure boiler and turbo-alternator.
- High level of automation.

Simple innovative, proven equipment and processes for improving energy efficiency in sugar factories (Bruce Moor)

Bruce Moor discussed a range of relatively simple changes that could be made to an existing factory to improve energy efficiency. His baseline for improvement was a typical co-generating factory considered efficient in the 1980s. The technologies he discussed were:

- High steam pressure and temperature boilers.
- Continuous pans using vapour 2 or vapour 3.
- Diffusers.
- Mud recycling to diffuser.
- Electric drives on shredder and mills.
- Boilers with increased boiler efficiency (better air heaters and economisers) and less excess air.
- Direct contact heaters.

Long tube rising film evaporators, particularly for first and second effects.

Design, manufacturing and maintenance of sugar mill equipment (Simon Trancart)

Simon Trancart reported on a range of designs available from Fives Cail aimed at reduced maintenance costs and higher energy efficiency. These designs were:

- The in-line shredder which contains no knives and reduces power consumption by 15% to 20% as a result.
- The MillMax three-roll mill configuration that achieves 12% lower capital cost, 40% lower maintenance cost and 30% lower power consumption than an equivalent four-roll mill.
- A falling film tube evaporator that achieves high heat transfer coefficients, low residence time and low temperature drop.
- Two designs of continuous vacuum pan (one with vertical tubes and one with horizontal tubes) that can operate on vapour 2 or vapour 3, with low temperature drops.
- Batch centrifugals that consume 30–40% less power than earlier designs.
Main results of the application of planetary gear boxes to drive cane sugar mills (Paulo Rogério Vizin)

TGM have developed a range of planetary gearboxes for mills than enables in-line roll drives. The drives have been used to completely replace turbines or to provide assist drives to increase mill power through providing additional power on one roll. They can also be used to replace conventional gearing on turbine driven mills. The planetary gearboxes are more efficient than traditional mill gearing.

Characteristics of the Mexican industrial sugar plant – some innovations introduced (Manuel Enríquez Poy)

Manuel Enríquez outlined a range of technologies being introduced into the Mexican sugar industry to improve factory performance. These technologies were:

- 35 t trucks for cane transport.
- Heavy duty shredders.
- Hydrostatic mill drives and rope couplings instead of tailbars.
- Automatic roll arcing, including the pre-season application of picots for increased grip.
- Increased automation of the factory.
- Rotary juice screens.
- Bagasse bins.
- Automatic bagasse feeders for boilers.
- Higher pressure boilers.
- Low residence time clarifiers.
- Plate juice heaters.
- Pan automation.
- Continuous vacuum pans.
- Vertical crystallisers.
- Larger batch and continuous centrifugals.
- Cane separation for separate processing of pith and rind.
- Alcohol distilleries.
- Molasses storage in underground plastic liners.
- Liquid sugar and amorphous sugar.
- Bulk sugar road transport.

He also outlined a vision for a future mill that included ethanol production, cogeneration, use of vinasse for irrigation and mill mud for composting.

Computational modelling for the design of sugar mill equipment (Geoff Kent and Ross Broadfoot)

Geoff Kent and Ross Broadfoot provided a range of examples where the use of computational fluid dynamics had been used to improve the design of sugar mill equipment.

Specific examples included:

- Boilers.
- Juice clarifiers.
- Robert evaporators.
- Syrup clarifiers.
- Batch and continuous vacuum pans.
Development of pinionless mill for energy efficiency and low maintenance (D.K. Goel)

ISGEC John Thompson has developed a range of pinionless mills for up to 340 t/h cane rate. D.K. Goel outlined the design steps in developing the design and some of the design features of the mill.

The design included finite element analysis of the headstock, bearings and top roll assembly. The pinionless drives result in lower stresses in the components than in a conventional four-roll mill.

Other advantages include 15% lower cost, 15% lower power consumption, reduced lubricant consumption, more even top roll lift and reduced maintenance costs. One feature of this design is that the electric motors are vertically mounted to reduce the bending moment on the top roll shaft.

Design, manufacturing and maintenance of electro-hydraulic drives (Bo Ljung)

Bo Ljung described the characteristics of the electro-hydraulic drive. The drive has good speed control and full torque available over the entire speed range, up to the limit of the electric motor.

The maximum torque is determined from the size of the motor and the allowable hydraulic pressure. The maximum speed is determined from the capacity of the hydraulic pump.

Hydraulic motors have application in sugar mills as mill drives, conveyor drives, crystalliser drives and winch drives.

The drive features and maintenance requirements were described.

High pressure cogeneration in sugar plants (A.K. Subramanian)

A.K. Subramanian outlined the features of the high pressure boilers available from ISGEC John Thompson. He indicated that 32% higher power generation per tonne of bagasse could be achieved by increasing the boiler pressure from 45 bar to 105 bar.

The main features of the high pressure boiler are:

- Pressurised feedwater (220°C).
- Travelling grate to handle alternative fuels such as coal and woodchip.
- Electrostatic precipitators.
- On-line steam and water analysers.

In increasing the boiler pressure from 65 bar to 105 bar, the capital cost of a boiler increases by only 10%, due to the need to only change the design of the pressure parts. All boilers with a pressure greater than 45 bar require a dedicated water circuit.

Efficient cooling crystallisation – design and practice (Reinhold Hempelmann)

Reinhold Hempelmann described BMA’s oscillating vertical crystalliser design. The main feature of this design is that the cooling banks within the crystalliser move up and down by 1 m due to the action of hydraulic cylinders. This movement increases heat transfer and improves the flow of high-viscosity masssecuite. The crystalliser achieves plug flow, resulting in a well defined and consistent residence time.

Selection, use and maintenance of process pumps in sugar industry (Michael Yang)

Michael Yang described the selection criteria that should be used to select a centrifugal pump to minimise whole-of-life costs. These criteria include:

- Selection of the pump material and shaft sealing arrangement.
- Pumping efficiency (energy use).
- Maintenance costs.
- Quality.

Capital costs are only a significant part of whole-of-life costs for small pumps (less than 10 kW). Capital costs are almost negligible for pumps over 150 kW. Given the relative significance
of maintenance costs in the whole-of-life costs, stainless steel pumps with dynamic seals were recommended in most applications.

**Factory equipment maintenance**

*Keynote address: Condition monitoring (Alan Yarrow)*

The purpose of condition monitoring is to achieve a reduction in maintenance costs by only maintaining equipment that needs to be maintained. It assists to identify potential failures before they fail in order to reduce the incidence of breakdowns.

Alan Yarrow categorises items of plant as critical, moderate or convenient. Failure of critical plant could cause a major loss of production. Failure of moderate plant would cause some loss of production. Failure of convenient plant is not expected to cause a loss of production. The sampling frequency is highest for critical plant and generally only monitored at the end of the season for convenient plant (to determine if an overhaul is required during the maintenance season).

Typical techniques used for condition monitoring are:
- Vibration analysis.
- Oil analysis.
- Grease analysis.
- Use of a magnetic chip collector and filter debris analysis.
- Wear debris analysis.
- Thermography.

*Formalising maintenance processes with a traditional Australian sugar milling environment to develop a culture based on improvement (Steve Scott)*

Steve Scott outlined the process being undertaken at Harwood Mill in Australia to implement a maintenance management system in order to improve the operation of the plant and to reduce overall maintenance costs.

The process involved:
- Identifying the problems with the current maintenance system that expended all resources on immediate maintenance needs.
- Developing a maintenance management system.
- Formalising the control of maintenance work through work flow control.
- Analysing the effectiveness of maintenance in order to modify maintenance practices to increase the amount of scheduled maintenance and reduce the amount of unscheduled maintenance.
- Optimising maintenance schedules to minimise the amount of maintenance required.

*Wear mechanisms on shredder hammer tips (Geoff Kent)*

Geoff Kent described the results of an investigation to identify the wear processes in white iron and tungsten carbide shredder hammer tips. He reported that the main wear processes for white iron tips were matrix removal by plastic deformation, brittle fracture of the eutectic carbides adjacent to the surface and pull-out of eutectic carbides and secondary carbides adjacent to the surface. For tungsten carbide tips, the main wear processes were selective removal of the cobalt binder phase, loss of entire tungsten carbide grains and cracking and chipping of individual tungsten carbide grains.

*Sintered-tungsten carbide technology (Joydeep Duttagupta)*

Joydeep Duttagupta reported on a manufacturing process used by IMCO for manufacturing shredder hammer tips. The process involves producing a sintered carbide consisting of tungsten carbide blended with fused ceramics in a chrome matrix to form an alloy powder block. The arrangement was reported to increase crack resistance and extend life.
While the focus of the presentation was on shredder hammer tips, the technology has also been applied to leveller knives, trash plates, and shredder grid bars.

**Novel and unconventional equipment designs**

*Keynote address: Novel and unconventional equipment designs (Dave Meadows)*

Dave Meadows described the process for developing novel equipment designs. He indicated that there was a need for innovation to reduce costs, increase performance and increase safety. Design techniques include computer aided design, computer simulation and model validation using physical measurements. Design concepts were challenged, including whether large sizes and continuous processes are always better. The design process was described, including examples using current equipment designs.

*SRI swirl spreaders for improved boiler performance at increased loads (Geoff Kent)*

Geoff Kent described SRI’s swirl spreader that improves the distribution of bagasse over the furnace grate, increasing steam generating capacity by improving bagasse drying and reducing grate deposition. The design increases boiler capacity by at least 10%, improves flame stability and reduces the sensitivity to bagasse moisture content variations.

*The Siftek membrane technology (Normand Bernier)*

Vaperma have developed a revolutionary membrane system for alcohol distilleries. This system replaces the conventional rectification column and dehydration process and reduces energy consumption by up to 50%.

The technology is quite new, with two demonstration plants using corn-based feedstock and one demonstration plant now constructed in Brazil using sugarcane feedstock.

The system offers additional revenue from electricity due to the lower energy requirements for the plant, a continuous process and a flexible system allowing the production of both hydrous and anhydrous alcohol.

*The use of a novel jigger system to improve vacuum pan performance (Ross Broadfoot)*

Ross Broadfoot described a new jigger system for batch and continuous pans that uses incondensable gases injected in the base of a calandria to improve circulation and heat transfer.

He reported improvements in average circulation rates of up to 20%, a reduction in calandria pressure of 20 kPa to 40 kPa, improvements in heat transfer coefficients from 5% to 30%, reduced average steam flow and shorter cycle times.

The system is simple to install, requires little operator intervention and no special cleaning requirements.

*Development of cane dry cleaning in Brazil (Paulo Delfini)*

Paulo Delfini described the development of a dry cane cleaner in Brazil. Early experience found that it was difficult to predict the air flows within the cleaner, resulting in less than desired performance. Through the use of computational modelling, improvements were made.

To meet desired energy production requirements, Paulo Delfini indicated it is desirable to have trash contents in cane of about 13%. It is easiest to transport this trash with the cane and then separate the trash at the factory. Once separated, the trash can be washed if desired and returned to the process. Several examples of dry cleaning installations where the trash was returned to the process before the final mill and mixed directly with final bagasse were described.

**Closing session**

The author gave a brief summary of the outcomes from the workshop in the closing session. In particular:

- Several speakers articulated a shared vision of the future of the Brazilian sugar industry. This shared vision gives considerable confidence that the vision can become a reality.
There is an increased focus on energy products. As a result, the reduction of factory energy consumption in order to maximise the energy available for products is also a focus.

New equipment and products are being developed with reduced power consumption, lower capital and maintenance costs and better performance.

Methods presented for reducing maintenance costs included the use of a maintenance management system, condition monitoring and material selection.

Site visits

The workshop included four site visits:

1. TGM. The visit included TGM’s gearbox manufacturing plant and turbine manufacturing plant. The gearbox manufacturing plant produces a wide range of conventional and planetary gearboxes of 85 kN.m to 4000 kN.m capacity. The turbine manufacturing plant produces a wide range of turbines of capacity up to 250 MW.

2. Usina Mandú. This sugar factory and distillery processes about 12 000 t cane per day. There are a large number of TGM gearboxes on the milling train.

3. Usina Da Barra. This large white sugar factory and distillery processes 38 000 t cane per day. It produces a range of white crystal, amorphous and liquid sugar.

4. Dedini. The factory visited is one of Dedini’s six large manufacturing facilities, specialising in the design and construction of complete sugar factories and distilleries, in addition to individual items of plant. It also services other industries such as breweries, mining and steel.
CONCEPTION, MANUFACTURE ET MAINTENANCE DES ÉQUIPEMENTS

Par

G.A. Kent
Président de la Section d'Ingénierie de ISSCT

MOTS-CLES: Sucre, Mill, Appareils d'Usine de Sucre, Conception, Fabrication, Maintenance.

Résumé
L’ATELIER de la section Engineering de l’ISSCT a eu lieu au Brésil; 62 délégues étaient présents, 39 représentant des visiteurs de 15 pays. Le sujet a été «Conception, manufacture et maintenance des équipements». On a conclu comme suit: plusieurs auteurs ont présenté une vision pour le future de l’industrie au Brésil; on pense que cette vision peut se réaliser; l’énergie et son utilisation pour d’autres produits sont des sujets très importants. Il faut réduire son utilisation à la sucrerie; on développe des équipements et des produits nouveaux pour réduire la demande d’énergie, les coûts et pour augmenter l’efficience. On a présenté des systèmes pour réduire le coût de la maintenance. L’atelier a eu lieu pendant l’exhibition annuelle SIMTEC pour l’industrie sucrière et celle de l’alcool; cela a permit des discussions et présentations techniques et des démonstrations de matériel industriel. SIMTEC a contribué en aidant financièrement et en organisant l’atelier. Les programmes techniques de SIMTEC et de l’ISSCT ont été organisés pour faciliter la participation des délégues aux sessions techniques des deux organisations. On a ajouté une journée au programme de l’ISSCT pour permettre aux délégues de visiter l’exhibition SIMTEC. Les arrangements entre SIMTEC et ISSCT ont été appréciés par les délégues. Deux manufactures et deux sucreries ont été visitées.
ISSCT WORKSHOP DE INGENIERÍA 2008. DISEÑO, MANUFACTURA Y MANTENIMIENTO DE EQUIPOS DE INGENIOS AZUCAREROS

Por

G.A. KENT
Presidente de la Sección de Ingeniería ISSCT

PALABRAS CLAVE: Azúcar, Mill, Aparatos de Molino de Azúcar, Diseño, Fabricación, Mantenimiento.

Resumen

El WORKSHOP de Ingeniería ISSCT 2008 en Brasil contó con la asistencia de 62 participantes incluyendo 39 visitantes extranjeros de 15 países. El evento se orientó al tema Diseño, manufactura y mantenimiento de equipos para ingenios azucareros. Las siguientes conclusiones se obtuvieron de las sesiones técnicas: Varios conferencistas articularon una visión compartida del futuro de la industria azucarera de Brasil; Esta visión compartida da confianza en que la visión pueda volverse realidad; Hay un creciente interés en productos energéticos. Como resultado, también hay gran interés en la reducción del consumo de energía en la fábrica para maximizar la energía disponible para productos. Equipos y productos nuevos están siendo desarrollados con menores consumos de potencia, menores costos de capital y de mantenimiento y con mejor desempeño. Los métodos presentados para la reducción de costos de mantenimiento incluyeron el uso de sistemas de gestión de mantenimiento, monitoreo del estado de equipos y selección de materiales. El Workshop se desarrolló conjuntamente con la exhibición anual de SIMTEC en Piracicaba para la industria de azúcar y etanol y se generó un foro para las presentaciones técnicas y las discusiones así como una oportunidad para las demostraciones y ofertas de servicios de los fabricantes y proveedores de equipos. Como contrapartida, SIMTEC brindó patrocinio para el evento, incluyendo viaje y alojamiento para los presentadores. Los programas técnicos de ISSCT y SIMTEC se organizaron de tal manera que las sesiones no entraran en conflicto y el programa de ISSCT se extendió un día para brindar a los participantes la oportunidad de asistir a la exhibición de SIMTEC. Una evaluación informal con los participantes sugirió que la asociación de los eventos de ISSCT y SIMTEC funcionó bien. Se efectuaron visitas a dos instalaciones de fabricación de equipos y a dos ingenios como parte del evento.
SUGAR MILL OPERATION WITH INDIVIDUAL DRIVES

By

JULIUSZ LEWINSKI¹, PAULO GRASSMANN² and TOMAS KALLIN³

¹Consultant: jlewin@prodigy.net.mx
²Hagglunds Drives, Brazil: paulo.grassmann@br.hagglunds.com
³Hagglunds Drives, Sweden: tomas.kallin@se.hagglunds.com

KEYWORDS: Hydraulic, Mill, Drive, Independent, Torque, Speed.

Abstract
THE TERM ‘Individual drives’ refers to the process of separately moving each roll of the mill with independent drives. This way of mill operation is rather new and knowledge regarding how to set and operate the mills with individual drives is very limited. This paper describes tests made with a complete tandem (four mills) driven by electro-hydraulic independent drives. The first mill was driven at a constant top roll speed, and the feeding was adjusted automatically to keep the chute level within the determined range. The rest of the mills were automatically changing speed, keeping the chute level of the corresponding mills within the pre-established range. Three scenarios were analysed in the first tests: speed ratio between side and top rolls varied to keep the same pressure in all hydraulic systems (torque distribution 50, 25, 25% between top, cane and bagasse rolls respectively), speed ratio to keep the same peripheral speed for each roll and rotational speed ratio equal to 1 as is often the case with conventional drives. For each scenario, the torque and power distribution were measured. The main conclusions found were that the total torque required doesn’t depend on the speed of the mill for constant mill pressure and that the distribution of the torque in the four-roll mill can be 50, 25, 25 for higher speed of the cane roll and lower speed of the bagasse roll than the top roll speed. This scenario is best from a mechanical and operational point of view.

Introduction
The term ‘Individual direct drives’ refers to the separate propulsion of each mill roll by a drive placed directly on the shaft of each roll.

The first mill drive using this method was reported in Cuba (Abon, 1986) where the torque distribution between the rolls, depending on the relative speeds of the side rolls compared to the top roll, was presented.

This installation was the result of the collaboration of MINAZ (Ministry of Sugar) and the Hägglunds company, starting with the introduction of the first high torque hydraulic motors in Cuba in 1976.

For that first installation, the drive was formed by combining Hagglunds hydraulic motors with two-stage planetary gearboxes of the Thyssen company.

This concept gave rise to the ‘Hydrodrive’ of the Mannesmann Rexroth company, where high speed hydraulic motors and three-stage planetary gearboxes were combined.

A similar installation was analysed in Mexico 10 years later (Muñoz and Lewinski, 1996) and important research about the torque distribution in three-roll sugar mills was carried out in Australia (Kent and McKenzie, 2001).

In the 1980s, Hägglunds developed higher torque hydraulic motors, allowing mill rolls to be driven individually, and eliminating the need for planetary gearboxes.
At the same time, the German company Flender, well known manufacturer of gearboxes, presented a ‘Hydrex – Planurex’ system, combining a high torque hydraulic motor of their own manufacture and a one-stage planetary gearbox.

These high torque hydraulic motors, with and without planetary gearboxes, were very well received in the marketplace, due to the following advantages:

1. Partial or full elimination of conventional gears and crown gears.
2. Elimination of the tail bar.
3. Less space required.
4. Reduction of loads on roll shafts.
5. No foundation required.
6. Maximum torque over the full speed range; from zero to maximum speed.
7. Reversible movement.
8. Continuous speed variation in each roller.
9. Protection against overloading and almost immediate interruption of mill operation.
10. Simplifies automation of the milling process.
11. Measurement of the torque for each roller.
12. Easy maintenance.
14. Power savings (high efficiency in transmission, use of electric power, load reduction in journal bearings).
15. Increased extraction (optimisation of the extraction process).

The main advantage is the independent variable speed of each roll, which allows for the optimisation of the mill’s operation from a mechanical (torque distribution) and operational point of view (extraction, pol in bagasse, moisture in bagasse) (Lewinski, 2005; Vivas et al., 1998)

A more recent alternative for fitting individual drives to sugarcane mills has been the use of planetary gearboxes engaged directly to or through the cardan shaft with AC electric and variable frequency motors, a well known solution in the sugarcane industry for driving cane conveyors.

Currently the following options are commercially available for mill operation on an individual basis.

1. Electro-hydraulic drive – high torque, low speed hydraulic motor
2. Electro- hydraulic – mechanical drive (high torque, low speed hydraulic motor connected to a one-stage planetary gearbox)
3. Electro – hydraulic – mechanical drive (medium speed hydraulic motor with a two-stage planetary gearbox)
4. Electro – hydraulic – mechanical drive (high speed hydraulic motor with a three-stage planetary gearbox)
5. Electro mechanical drive (planetary gearbox driven by an AC variable frequency electric motor.

At present, options 1 and 5 are the most common ones in the market.

Although 20 years experience has been gained operating mills with direct, individual drives, there is no published information on how to operate these mills (torque distribution, speed distribution, mill adjustments, etc.). This work aims to answer some of these questions.

**Description of the testing methodology**

Tests were conducted on a mill tandem driven by high torque electro-hydraulic drives, without planetary gearboxes.
Each mill was driven by four high torque hydraulic motors of the same size, directly placed on the mill’s rolls (two motors on the top roll and one on each side roll) (Figure 1).

Each hydraulic motor was powered by an electric motor which drove a variable flow hydraulic pump, allowing for the operation of the motors at rated torque over the whole speed range. The flow was transmitted to the motors through piping, which allowed for great flexibility of positioning for the power units (electric motor, pump and accessories) in relation to the hydraulic motors. The tandem was made up of four mills and was located in the Santa Isabel sugar mill, in Brazil (Figure 2).

Mill 1 had a length of 2134 mm and the remaining mills were 1981 mm in length. The mills were set for a cane rate of 550 t/h and operated at constant first mill speed, usually 6 r/min. The tandem was automated (Figure 3).

The feed of mill 1 was controlled to maintain the level of the chute in the determined range and the other mills varied their speed automatically to maintain the level of their chute within the predetermined ranges. Measurements included the torque on each mill’s shaft (continuous pressure measurement for each hydraulic system) and speed (sensors placed directly on the hydraulic motors).
Desired results were:
1. Torque distribution.
2. Speed distribution (ratio of speed of the side rolls in relation to the top roll).
3. Distribution of power on the mill’s rolls.
4. Total power consumed by each mill.

In the first tests carried out in 2008 in Santa Isabel Sugar Mill, three different scenarios were analysed for the mill settings defined by the manufacturer.
1. Distribution of torque 50%, 25%, 25% between the top, cane and bagasse rolls respectively - providing optimal capacity performance of the hydraulic motors (equal pressure on all hydraulic systems of the mill). For this scenario, the speed ratios were experimentally determined).
2. Equal peripheral speeds for all mill rolls – a case considered by several researchers as optimal for mill operations.
3. Equal rotational speed for all mill rolls – as is often the case of mills with conventional transmissions equipped with pinions.

Further tests were carried out in 2009 in Santa Isabel for the purpose of measuring the torques and powers in all mills of the tandem. These tests were conducted for the first scenario of equal pressures in all hydraulic systems.

Results
Measurements were taken during two test periods, identified as Test 1 and Test 2. Within these periods, each of the three scenarios was used. The periods for the individual measurements are shown in Table 1.

Laboratory results for the day in which Test 1 and Test 2 were conducted were as follows: cane rate 572 t/h and extraction 95.65%.

The first scenario where the speed ratio was adjusted to keep the same pressure in all hydraulic systems was assessed to be the most suitable, taking into account the optimal use of the drives, as well as the distribution of speed. In this tandem, the cane roll always rotates at a higher speed helped by the better feed and the bagasse roll usually rotates at a lower speed. The torque on
the top roll was generally constant, independent of the speed variations of the mill and the speed ratios and, as a result of the control scenario, was 50% of the total torque generated.

Table 4 presents results of measurements carried out in Santa Isabel in 2009. Both tests used scenario 1 with equal pressure in all hydraulic systems – torque distribution 50, 25, 25.

Figure 6 shows the mill 1 results for Test 2 and Figure 7 shows the mill 4 results for Test 2.

**Fig. 6**—Mill 1 Test 2 results from the 2009 tests.
Fig. 7—Mill 4 Test 2 results from the 2009 tests.

The laboratory results demonstrated higher milling capacity (cane rate 591.3 t/h) and higher extraction (96.76%) in comparison with the 2008 results with very similar or even slightly lower total power consumed by the tandem. The extraction only from the Mill 1 was close to 84%. In comparison with 2008, all the rolls were machined reducing their diameter by 30 mm, the mill pressure was kept at the same level, and the settings of the mills were made very close to the values from the year 2008. The mill rotational speed was higher to maintain similar tangential speed of the rolls as in 2008 (Sato, 2009).

Conclusions

With the individual drives, mills can be operated at different speed distributions, giving the possibilities to drive the mill with the same tangential speed of the rolls, the same rotational speed as in conventional mills and changing the ratio between side and top rolls looking for the higher cane roll speed (for better feeding) and lower bagasse roll speed (for lower reabsorption).

This last option was achieved for similar mean pressures in all hydraulic motors, resulting in the same torque applied on the end of all the shafts. For this option all hydraulic drives can be operated at their maximum capacity, maximising the mill torque, avoiding the hydraulic system overloading, giving the same stresses on the end of all the shafts.

At Santa Isabel Sugar Mill, the use of the equal pressure control scenario helped to give better milling results than the previous year. The tandem of four mills is now achieving a cane rate close to 600 t/h and extraction of 97%, with extraction from mill 1 close to 84%. These better results were achieved with total mill power consumption about the same as in the previous year.

Acknowledgements

The authors would like to express their gratitude to the companies Hagglunds Sweden and Hagglunds Brazil for the interest in this research and the corresponding economical support. Thanks to Santa Isabel Sugar Mill people for their support and great cooperation in making possible this
research. Thanks to Mr Mario Sato for the permission to use his settings in Santa Isabel Sugar as reference. Special thanks to Geoff Kent for his very valuable comments and observations and for great help in interpreting the results and preparation of the last version of this paper.

Résumé

Le terme « commande individuelle » indique que chaque rouleau du moulin est conduit indépendamment. Ce mode de fonctionnement est nouveau et les connaissances le concernant sont très limitées. Ce document décrit les tests réalisés sur un tandem complet (quatre moulins) conduit par des moteurs indépendants electro-hydrauliques. Le premier moulin a été conduit à une vitesse constante pour le cylindre supérieur et l'alimentation a été ajustée automatiquement pour maintenir le niveau de la goulotte dans la plage déterminée. Le reste des moulins modifient leurs vitesses automatiquement pour maintenir le niveau des goulottes correspondantes dans les plages préétablies. Trois scénarios ont été analysés dans les premiers tests: le rapport des vitesses cylindres de côté et supérieur est varie pour maintenir la pression constante dans tous les systèmes hydrauliques (distribution du couple 50, 25, 25% entre les rouleaux supérieur, canne et bagasse respectivement), rapport de la vitesse sélectionne pour conserver la même vitesse périphérique pour chaque rouleau et le rapport de la vitesse de rotation égal à 1 comme c'est souvent le cas avec les conduites conventionnelles. Pour chaque scénario, le couple et la distribution de la puissance ont été mesurés. Les principales conclusions trouvées étaient que le couple total requis ne dépend pas de la vitesse du moulin à une pression constante et que la répartition du couple dans un moulin avec quatre cylindres peut être 50, 25, 25 pour une vitesse supérieure du cylindre canne et une vitesse inférieure pour le cylindre bagasse compare à la vitesse du cylindre supérieur. Ce scénario est le meilleur d'un point de vue mécanique et opérationnel.
OPERACIÓN DE MOLINOS DE CAÑA CON ACCIONAMIENTOS INDIVIDUALES

PALABRAS CLAVE: Hidráulica, Molino, Accionamiento, Torque, Velocidad.

Resumen

EL TÉRMINO accionamiento individual se refiere al movimiento de cada maza de un Molino de caña con accionamientos independientes. Esta forma de operación es relativamente nueva y el conocimiento sobre cómo ajustar y operar estos molinos es limitado. Este trabajo describe las pruebas efectuadas con un tándem completo (cuatro molinos) movido por accionamientos electrohidráulicos independientes. El primer molino fue accionado a velocidad constante de la maza superior y la alimentación se reguló automáticamente para mantener la altura de la caña preparada en la tolva del molino dentro del rango determinado. El resto de los molinos operaron con velocidad variable para mantener la altura de bagazo en la tolva de cada Molino dentro del rango especificado. Tres escenarios fueron analizados en las primeras pruebas: la razón de velocidades entre maza superior y las inferiores se varió para mantener la misma presión en todos los sistemas hidráulicos (distribución de torque de 50, 25, 25% entre mazas superior, cañera y bagacera respectivamente), la razón de velocidades para mantener la misma velocidad periférica para cada maza y razón de velocidades igual a 1 como es a menudo el caso en accionamientos convencionales. Para cada escenario, se midieron el torque y la distribución de potencia y las principales conclusiones encontradas fueron que el torque total requerido no depende de la velocidad del molino para presión de molienda constante y que la distribución porcentual del torque en un molino de cuatro mazas puede ser 50, 25, 25 para relaciones de velocidad entre maza cañera y superior mayores que 1 y entre maza bagacera y superior menor que 1. Este escenario es el mejor desde un punto de vista mecánico y operacional.
THE IMPLEMENTATION OF SOUTH AFRICAN SUGAR TECHNOLOGY:
THE WORLD’S LARGEST SUGARCANE DIFFUSERS

By

I. VOIGT
Bosch Projects (Pty) Ltd, 203 North Ridge Rd, Durban
voigti@bproj.co.za

KEYWORDS: Diffusers, Extraction, Brazil,
Technology, Chainless, South Africa.

Abstract
Cane diffusion gained popularity in South Africa in the 1960s and 1970s using European technology. Local research and developments led to the development of locally designed diffusers and to the South African industry achieving the highest extraction rates in the world. The largest diffusers in the South African industry were installed at Felixton 2 in 1984, being 12 metres wide and rated (conservatively) at 350 t/h. The first real change to the fundamentals of diffuser design since then took place when Bosch Projects introduced the ‘chainless diffuser’ concept in 2006. Of the nine chainless diffusers to be installed in Brazil between 2008 and 2010, two are similar in size to those at Felixton and six are larger. The first of the 12 metre diffusers (at UNP and rated at 500 t/h) was commissioned in September 2008. The diffusers at Brenco, Cosan Jatai and Meridiano are 15 metres in width, are rated for 98% extraction at 625 t/h and will be the largest cane diffusers in the world. The diffusers in Cosan and Meridiano will ultimately process 875 t/h. The successful sales of the chainless diffuser in Brazil is evidence that South African sugar technology and engineering continue to play a leading role, even in the most competitive sector of a fast-changing world industry.

The history of cane diffusers
It is reported that cane diffusion has been in use for over 100 years, first in batch form and more successfully as a continuous process. Continuous diffusers were well accepted in the beet industry before they made their way into the cane industry. Their acceptance in the cane industry became more common in the 1960s, first as bagasse diffusers (where one or two mills preceded the diffuser) and then later as cane diffusers.

As an indication of the increasing interest in this alternative extraction technology at the time, the proceedings of the 12th Congress of the ISSCT in Puerto Rico in 1965 contains numerous papers by researchers and engineers reporting on early continuous diffusers around the world.

- The Diaz-Compain diffuser, from a Puerto Rican designer, was working in a factory in East Pakistan. (Diaz-Compain, 1966). The principle of operation was to fully submerge the cane in a very large slat conveyor, and rates of extraction of over 99% were claimed.
- The first DDS cane diffuser had been operating for a few months at TPC in Tanganyika (Weng and Bruniche-Olsen, 1966). It was based on the DDS beet diffuser and consisted of twin screw conveyors that transported the bagasse counter-current to the juice. Clarifier mud was recycled to the diffuser.
- A Silver Ring diffuser was reported as operating in its second season in Hawaii (Townsley and Cheatham, 1966). This was a hugely successful installation and their understanding of the important requirements for successful diffusion was years ahead of its time, as reported by Payne (1968).
E. Gulbaran (Turkey) proposed his diffuser for cane and beet (Gulbaran, 1966).

The operating results from three 150 tch bagasse diffusers at Nag Hamadi in Egypt were presented, while a 200 t/h unit was under construction. (Tantawi, 1966). The Egyptian diffusers were of the style that ultimately became popular in South Africa, using a stationary perforated plate floor; chains for the conveyance of bagasse inside the diffuser; a 1–2 m bed depth at 0.7–1.5 metres per minute; and independent juice collecting tanks below the screen.

In South Africa, diffusion started in 1927 when Duncan Fletcher supplied a diffuser to the Tinley Manor factory (Buck, 1965). In 1966, Union Co-operative installed a BMA bagasse diffuser in their new sugar factory based on the very promising performance of the Egyptian diffusers, and De Smet diffusers were installed at Entumeni and Nchalo (Buck, 1965). In 1967, a BMA diffuser was installed at Empangeni mill and a De Smet diffuser at Malelane. (This was a period of substantial growth in the industry, and new milling tandems were commissioned at Amatikulu, Noodsberg and Sezela) (Perk, 1966).

By 1974, there were seven diffusers operating (or under construction) in the industry as follows (Fitzgerald and Lamusse, 1974):

- Union Co-op: 60 t/h BMA bagasse diffuser (1966).
- Empangeni: 205 t/h BMA bagasse diffuser (1967).
- Malelane: 225 t/h De Smet bagasse diffuser (1967).

By 1984, there were 10 cane diffusers and four bagasse diffusers in the SA industry out of 21 extraction plants, accounting for 54% of cane processed (Lamusse, 1985). In these early days, the motivation for installing diffusers was the lower capital cost and lower costs of maintenance and operations (Fitzgerald and Lamusse, 1974), rather than improved extraction, since the early extraction benefits were small.

An interesting historical phenomenon is that, while the installation of new diffusion plants and their successes are well documented, the reasons for their failures are not so well recorded. Of the list of seven diffusers in 1974, only Amatikulu remains. The bagasse diffuser at Union Co-op was replaced with a cane diffuser; the Entumeni and Empangeni factories were ultimately closed; Malelane now has a BMA cane diffuser, as does Pongola; and Umfolozi has a De Smet diffuser.

**Diffuser development in South Africa**

In the early days of this boom in diffusion, South African engineers contributed significantly to the success of the technology, whereas a lack of engineering innovation seems to have doomed diffusers to failure elsewhere. Renton and van der Riet (1971) reported on the improvements made to the 225 t/h BMA diffuser at Huletts’ Empangeni mill, which was installed to replace the third and fourth mills of their six mill tandem. Huletts pioneered the use of:

- lifting screws to overcome the problems of flooding in the area of press water return;
- tracer testing of juice percolation using NaCl and the adjustment of stage troughs;
- the use of stage sprays in place of overflow troughs;
- windows for internal observation of the diffuser;
- the elimination of press water clarification;
- the use of two dewatering mills in parallel with each other;
- the use of scraper slats on diffuser chains;
using water as ballast in the press roller;
• an improved understanding of cane preparation requirements.

In the mid-1970s the FS/van Hengel diffuser was developed, claiming advantages of:
• modular construction allowing for incremental capacity increases;
• lower residence times;
• increased sucrose extraction;
• reduced floor area.

Huletts engineers contributed significantly to the theoretical understanding of the diffusion process. Rein (1974, 1995) and Love and Rein (1980):
• quantified the relationship between cane preparation and extraction;
• studied percolation patterns and juice hold-up;
• quantified the effect of stage juice recirculation, imbibition water rate, temperature and residence time on extraction;
• developed a means of controlling diffuser flooding by measuring the juice level inside the bed;
• quantified the proportion of work done by lixiviation versus molecular diffusion.

The diffusers developed by Tongaat Hulett incorporated some unique features (Moor, 2001 a,b):
• Diffuser dry feeding, eliminating the problematic segregation of fines which was caused by conventional sluiced feeding.
• The elimination of draft juice screening.
• The use of direct contact heating of unscreened press water.
• the introduction of fully adjustable juice sprays (replacing weirs).
• and juice level measurement for automatic spray positioning.

In 1996, Bosch Projects rekindled interest in the old idea of clarifier mud recycling (and branded it ‘Filtrafusion’). Tongaat Hulett trialled the process at its Maidstone factory (Meadows et al., 1998). This proved successful and has since become the standard for diffusers in South Africa.

As a result of many years of focus on the optimisation of diffuser design and operation, the extraction achieved by Southern African mills exceeded all previously accepted norms. The average extraction of diffuser factories in South Africa frequently exceeds 98% over the entire season.

**The advantages of diffuser extraction over milling**

The rapid adoption of diffusers in South Africa was as a result of many benefits (Rein, 1995; Koster, 1995; Hoeskstra, 1995). Compared to milling, diffusers:
• achieve better extraction results;
• have a lower capital cost;
• are cheaper to maintain and operate;
• absorb less power;
• result in a factory with lower HP steam demand, making more HP steam available for the generation of electrical power.

**The limitations of diffusers**

Despite the remarkable success achieved in South Africa, diffuser technology never made a lasting impact elsewhere. Cane diffusers were installed far and wide – both BMA and De Smet were very successful internationally. However, although the technology was introduced in most growing sugar industries, it never reached the point of domination over milling extraction, as it had
in South Africa, despite the obvious benefits of improved extraction, lower capital cost, lower maintenance and operational costs and improved energy efficiency. The reasons for this vary from country to country and can be fairly difficult to establish. However, the following anecdotal reasons have been given:

- The cane preparation requirements are more demanding for diffusers than mills, and a heavy-duty shredder is essential. This adds to the initial cost of cane preparation equipment and also to the absorbed power for cane preparation.

- It is widely believed that diffusers require higher imbibition water rates than mills, and hence additional exhaust steam demand and evaporator capacity. This is probably because of the high rates used in South Africa, but does not consider the fact that South African imbibition water rates can be high because of excess available bagasse due to long milling seasons, good time efficiencies, high fibre content in cane and the reduced demand for HP steam because of the diffusers in operation.

- In South Africa, we take for granted the sharing of experiences through forums such as the annual SASTA Congress; research performed for the industry by the SMRI; and the constant drive for improved factory efficiencies to compensate for low agricultural yields. In this environment, technological advances in one factory are rapidly communicated and adopted in others, with a good probability of further improvements. Not all countries have a similar structure and culture. For example, in Brazil, factories have traditionally been owned by family concerns and the promotion of new technologies is largely through equipment suppliers. In India, a large proportion of factories were traditionally co-operatives or state-owned, with few incentives to develop technology.

- In countries with milling seasons shorter than that of South Africa, the cane crop is not necessarily large enough to justify the capital expense of more than four mills in a tandem. In these cases, the capital cost of a four mill tandem is compared with that of a diffuser and two de-watering mills, and the economic benefits become more marginal. Not considered is the fact that a smaller and cheaper diffuser could be used for extraction equivalent to four mills.

- The concern that, once a diffuser has been built, its capacity is determined. Any future expansion of the capacity is difficult and costly.

The latter point is, in the experience of the author, the most oft-quoted reason for diffusion not being more readily accepted in industries that have experienced growth.

The reason for the limited expandability of moving bed diffusers rests in the fact that a diffuser’s capacity is related to its dimensions—a larger diffuser can process more cane than a smaller diffuser at the same extraction performance. However, the length of a diffuser is constrained by the limit of chain tension allowed.

Also, any extension to a diffuser’s length will normally require the repositioning of cane preparation equipment or de-watering mills. The height of a diffuser is limited by the depth of prepared cane through which juice can practically percolate. The variable dimension is thus the width of a diffuser, and diffuser capacities are determined by their width. In Brazil, a very simple rule-of-thumb is used to define a diffuser’s capacity: 1 metre of width = 1000 tonnes of cane per day (assuming 100% availability).

(The discussions regarding expandability are generalisations. The diffuser at Triangle in Zimbabwe was expanded to operate at 1800 mm bed depth, and the diffuser at Amatikulu was lengthened by 9.5 metres. However, it is quite obvious that, in both cases, further expansions in capacity are unlikely.)
Every moving bed diffuser has a head shaft at the discharge end of the diffuser. The headshaft drives the diffuser chains and is a rather heavy piece of engineering. (The headshaft of a 12 metre wide diffuser has a mass of about 100 tonnes.) More than any other, this is the component that limits the expandability of diffusers since, for any increase in the width of a diffuser, the headshaft must be replaced with a longer shaft. The economics thereof generally make such an expansion infeasible. Furthermore, in all traditional diffuser designs, the return of the chains is beneath the diffuser, which thus requires a substantial bridging structure, the extension of which is extremely costly.

**How wide should a diffuser be?**

As previously stated, the capacity of a diffuser depends on its size. The parameters considered for a specified performance are:

- Screen area/tonnes fibre per hour. For extraction performance of 98%, this parameter is in the range of 11–12 m²/t fibre/h.
- Bagasse retention time. For top performance, 70–80 minutes is considered suitable.

Given an assumed bed depth and an assumed bed speed, these parameters determine the diffuser length and width. The chainless diffusers have a standardised length of 60.25 m, a bed speed of 0.75 m/min and a bed height of 1.5 m. Given these parameters, the conventional width of a chainless diffuser is 5.4 t fibre/h per metre width or 4 t fibre/h per module. Other diffuser designers have different parameters.

**How the chainless diffuser eliminates size constraints**

The chainless diffuser concept was developed in 2006 when it was installed into the existing BMA diffuser at UCL (Schröder et al., 2007).

The chainless diffuser eliminates the need for chains and a diffuser headshaft. Instead, the diffuser screen (floor) consists of 750 mm wide modules that run the entire length of the diffuser. Each of these modules moves independently of each other, and by employing the correct sequence of movement the cane is conveyed through the diffuser. These individual modules are actuated by hydraulic cylinders and a specialised control system.

There are additional advantages. Since the diffuser structure no longer needs to allow for the return of the chain below the juice trays, supporting columns can be employed beneath the diffuser. The transverse steelwork beneath the diffuser screens, previously unsupported except at their ends, is supported at 3 m intervals in the chainless diffuser. Thus these components are no constraint to the width of diffusers.

The next possible limitation is the transverse beams that suspend the lifting screws. Since they are above the diffuser bed, they cannot be supported midway. With each lifting screw having a mass of around one tonne, the size of these beams becomes quite large. However, it is a simple problem of structural engineering and, in the 15 m wide chainless diffusers, they consist of plate girders 1.45 m deep. Similarly, the dewatering drum and the discharge kicker need to span the entire width of the diffuser, supported only on the bearings 15.9 m apart. Again, these are relatively simple engineering designs.

In trying to determine the maximum practical width of the diffuser, the final consideration is the feed into the diffuser. It is generally accepted that the bed of cane in a diffuser must be as level as possible in both directions. To achieve a level bed across the width of a 6 or 9 m diffuser may be relatively easy, but what is the practical limitation? The 12 m diffusers at Felixton use scraper conveyors to feed the prepared cane into the diffuser. These conveyors rake the top of the bed and ensure that it is perfectly flat, and the excess cane is returned to the infeed end through a system of conveyors. This concept is also generally used in Brazil. The drawbacks are that these scraper conveyors absorb more power; require additional installed conveyors to return the excess cane; and reduce the ability of operators to easily vary bed depth in the diffuser.
All the more recent diffuser designs, however, use conventional infeed carriers with one of two arrangements. Either the carrier is oriented at an angle to the back plate of the diffuser, or it has adjustable mitre floor plates. In this latter design, which is used in the chainless diffuser, as long as the cane supply into the infeed carrier is evenly distributed over its entire width, the design inherently allows for an even spread across the width of the diffuser. Of course, the wider diffusers require a wider infeed carrier so that the angle of the mitre can be maintained, and a 2.4 m wide infeed carrier for up to 15 m wide diffusers has been selected.

Given that the conventional constraints have been removed and that the possible constraints mentioned above are manageable through diligent engineering, Bosch Projects decided to develop a design for diffusers 15 m wide.

**Expandability of the chainless diffuser**

As mentioned earlier in this paper, one of the reasons given for the slow adoption of diffusers in other cane sugar industries is that a diffuser cannot have its capacity easily expanded. The alternatives are to build a second diffuser to process additional cane or to process the additional cane through the same diffuser at a reduced rate of extraction.

Since the chainless diffuser consists of 750 mm wide modules that move independently, it is a relatively simple exercise to add more modules. What is required is to:

- Extend the transverse structural steel beams below the moving floor, adding additional supports if necessary.
- Extend the juice trays. The juice trays of the chainless diffuser are based on the arc of a cylinder and are easy to extend.
- Extend the lifting screw beams.
- Move one side wall to its new position.
- Add more screen modules.

The probable expansion of diffusers is assumed during the design stage, unless a client specifically declines this option. To accommodate the future expansion, all of the components listed above are provided with bolted connections on the side of the diffuser that will be extended in future.

**Operating results of existing installations**

At the time of writing, two chainless diffusers are in operation. The first installation was a retrofit of a BMA diffuser at the UCL factory in South Africa in 2006 (Schröder et al., 2007) which has since completed 3 seasons of operation.

The second is the 500 tch diffuser constructed by Dedini at Usina Noroeste Paulista in Brazil which was commissioned in September 2008. Since the latter has been in operation for less than 12 months, there has been insufficient time elapsed for an objective evaluation of the performance of the diffuser. However, some aspects of the performance of the UCL diffuser can be regarded as representative.

The first season of operation at UCL was carefully documented by Schröder et al. (2007) and shortcomings in the original design were identified. Many of these were addressed after the first season, and the regular maintenance costs for the subsequent two seasons may be considered.

**Hydraulic systems maintenance**

The reciprocating diffuser screens are driven by two hydraulic systems, one at the feed end of the diffuser and one at the discharge end. The cost of maintenance of these systems has been recorded. The maintenance consisted of parts replacement and repairs (e.g. filters, seals, hoses and fittings) and the inspection of the condition of the systems during the off-crop; and a service contract with a service provider for a 2-weekly inspection of the systems during the crop period. The maintenance costs were as shown in Table 1.
Table 1—Hydraulic systems maintenance costs of the UCL diffuser: 2007–2008 ($).

Wear strips maintenance

The reciprocating diffuser screens are supported on wear strips manufactured from a synthetic polymer material which has low friction co-efficient properties as well as withstanding the elevated diffuser temperatures. The average rate of wear of the thickness of these strips per season has been measured at 1 mm (out of a total useable thickness of approximately 14 mm). During the past three seasons, no wear strip replacements have been carried out due to excessive thinning.

Perforated screens maintenance

The perforated diffuser screens reciprocate with a stroke length of 1 metre. On the forward stroke, there is no relative movement between the diffuser screens and the sugarcane. However, when a diffuser screen retracts, it slides underneath the sugarcane bed and some wear of the perforated screen plates may be anticipated. During the past 3 seasons of operation, no replacement due to wear of perforated screen plates has been required, and no thinning has been measured.

Diffusers in Brazil

With the modern trend toward energy-efficient factories and the sale of electricity, cane diffusion is becoming more popular in Brazil. In 2004, there were eight diffusers in an industry of 347 factories. By 2007, this number had grown to 22 out of 393 factories representing 14 new diffusers in 46 new factories (Oliverio, 2007). The few diffusers in Brazil up to that time were mostly of the stationary screen type manufactured by Sermatec, including four with rated capacities of 12 000 t cane/d. However, the trend in Brazil is for larger units of operation which can process four million or more tonnes of cane per season, preferably in a single preparation/extraction line. Suppliers of mills claim capacities of up to 1250 t cane/h, but investors are aware of the disadvantages of milling tandems – higher power consumption, capital and maintenance costs, and the logistical challenges of getting mill spares from industrial centres located far from their estate operations. In light of this, there is a demand in Brazil for diffusers with capacities approaching those claimed for mills.

The Brazilian cane crop is forecast to grow from 562 million tonnes in 2008/09 to 829 million tonnes in 2015/16. This presents an interesting opportunity for diffuser suppliers who can overcome the size constraints of conventional diffusers.

The first chainless diffuser commissioned in Brazil is 12 m in width, the equivalent to the largest diffusers installed anywhere. It is located at Usina Noroeste Paulista in the state of Sao Paulo, and is designed to process 500 t/h (65 tonnes fibre per hour) and achieve 98% extraction. It is expandable to 625 t/h, or 15 m wide. This diffuser was commissioned in September 2008. Table 2 lists the chainless diffusers currently under construction Brazil.

In considering the list, the following points are relevant:

- The first diffuser was commissioned very successfully in September 2008.
- The first of the 15 m diffusers will be commissioned in September 2009. This will provide immediate answers to the question of cane distribution over the width of a 15 m diffuser.
- Cosan is the largest sugarcane processor in Brazil, with 18 current factories which processed 44 million tonnes of cane in 2008/09. The Jatai factory, in the state of Goias, plans to process four million tonnes per annum.
- Brenco is a biofuels company newly established in Brazil. Ultimately they aim to establish 14 identical cane-to-ethanol plants.
- The diffusers for Cosan and Meridiano are special cases. Although perfectly sized for their initial duties, these diffusers will be expected to process cane at a rate of 875 tonnes per hour in the future at reduced rates of extraction. The diffusers will operate with a design bed level of 1.6 m and a speed of 0.92 m/min, giving a retention time of 65 minutes. The extraction is expected to be 96.5–97%.

In addition to this list, Mozambique Principle Energy Ltda has commissioned the design of a 440 t/h chainless diffuser for their Dombe Ethanol and Co-Generation plant. This diffuser will have the largest rated capacity in the Southern African region.

Conclusions

The development of diffusers in the cane sugar industry accelerated during the 1960s and 1970s, and diffusion is now the accepted technology in South Africa. The fact that diffusers are less well accepted elsewhere in the cane sugar world is possibly attributable to the ability of South African sugar technologists and engineers to overcome the problems initially associated with diffusion, whereas those elsewhere were less successful. The improvements made to the technology in South Africa have become universally accepted. However, the fundamental principles of cane transport through diffusers remained largely unchanged, until the chainless diffuser was developed in 2006. Since then, the chainless diffuser has been successfully sold into the Brazilian cane industry, where it meets the industry’s requirements of high capacity and low capital and maintenance costs and low power consumption. It is anticipated that, in trying to meet the demand for ever-increasing capacities, diffusers larger than 15 m wide will be developed within the next few years.

It appears that technological innovations from South Africa are as relevant to the world sugar industry as ever.

Résumé
LA DIFFUSION s’est établie en Afrique du Sud à partir de 1960 et 1970, à l'aide de la technologie européenne. La recherche locale et l'expérience ont permis le développement de diffuseurs conçus localement et l'industrie sud-africaine a atteint des taux d'extraction les plus élevés dans le monde. Les plus gros diffuseurs de l’industrie sud-africaine ont été installés à Felixton 2 en 1984, mesurant 12 mètres de large et capable de traiter au moins 350 t/h. En 2006, le premier changement réel des principes fondamentaux de conception a été introduit par Bosch Projects grâce au concept de 'Diffuseur sans chaîne'. Des neuf diffuseurs sans chaîne a être installé au Brésil entre 2008 et 2010, deux ont une taille similaire à ceux de Felixton et six sont plus grands. Le premier diffuseur de 12 mètres (à UNP avec une capacité de 500 t/h) est entre en service en septembre 2008. Les diffuseurs à Brenco, Cosan Jatai et Meridiano sont de 15 mètres de largeur, peuvent atteindre une extraction de 98 % à 625 t/h et seront les plus gros diffuseurs de canne à sucre du monde. Les diffuseurs de Cosan et Meridiano traiteront finalement 875 t/h. La vente de diffuseurs sans chaîne au Brésil est la preuve que la technologie sucrière sud-africaine continue à jouer un rôle de premier plan, même dans le secteur le plus compétitif d'une industrie mondiale, aux changements rapides.

LA IMPLEMENTACIÓN DE TECNOLOGÍA AZUCARERA SURAFRICANA: LOS DIFUSORES PARA CAÑA MAS GRANDES DEL MUNDO

Bosch Projects (Pty) Ltd, 203 North Ridge Rd, Durban
voigt@bproj.co.za

PALABRAS CLAVE: Difusores, Extracción, Brasil, Tecnología, Sudáfrica.

Resumen
LA DIFUSION de caña ganó popularidad en Sudáfrica en las décadas de 1960 y 1970 usando tecnología europea. Investigación y desarrollos locales llevaron a difusores diseñados localmente y la industria sudafricana alcanzó los niveles de extracción más altos del mundo. Los difusores más grandes fueron instalados en Felixton 2 en 1984 con 12 metros de ancho y tasados conservativamente en 350 t/h. El primer cambio real a los fundamentos del diseño de difusores tuvo lugar cuando Bosch Projects introdujo el concepto del difusor sin cadena (‘Chainless Diffuser’ ) en 2006. De nueve difusores sin cadena a ser instalados en Brasil entre 2008 y 2010 dos son similares en tamaño a los de Felixton y seis son mayores. El primero de los difusores de 12 metros ( en UNP con capacidad nominal de 500t/h) fue puesto en operación en Septiembre 2008. Los difusores de Brenco, Cosan Jatai y Meridiano son de 15 metros de ancho diseñados para 98% de extracción a 625 t/h y serán los difusores mas grandes de caña en el mundo. Los difusores de Cosan y Meridiano finalmente procesarán 875 t/h. Las exitosas ventas del difusor sin cadenas en Brasil son evidencia que la tecnología azucarera y la ingeniería sudafricanas continúan jugando un papel de liderazgo aun en el sector más competitivo de una industria que cambia rápidamente.
HYDRAULIC MOTOR OF HIGH TORQUE
WITH CYLINDERS AND CRANKSHAFT

By

G. ARIAS-POLO
Cuban Sugar Research Institute
gariaspolo@yahoo.com.mx

KEYWORDS: Hydraulic Motor, High Torque Motor,
Multi Cylinder Motor.

Abstract
THE PAPER describes a new design of hydraulic motor for high torque and low speed applications. This design involves no speed reduction between the motor and the driven equipment. The motor is simple to manufacture as it uses components of common technology, with low cost and little complexity. It consists essentially of three double effect hydraulic cylinders and a rotary flow valve, all supported on a frame. It has the patented novelty that the three hydraulic cylinders carry out useful work in both directions, giving it a higher torque/mass density. A prototype motor has operated during one season in Havana Libre Sugar Mill of Cuba, with very promising results. The design of a new more robust model, promising better performance than the experimental prototype, is also presented.

Introduction
In the late 1970s, the Swedish company ‘Hägglunds’ introduced their High Torque, Low Speed (HTLS) hydraulic motors into Cuba (Per-Owe, 1981). The motors did not require any speed reduction between the motor and driven equipment. These motors have been used in the sugar industry in applications such as sugar crystallisers, cane conveyors, winches, mills crushing trash, big lathes and cane mills.

The main advantages of these motors were reported by Arias-Polo (2008b), Lewinski (2002a), Lewinski (2002b), Lewinski (2006) and Ljung (2006):

a) Direct coupling of drive to equipment without speed reduction.
b) Low assembly costs. Foundation is not needed.
c) Decrease of power loss in transmission.
d) Decrease of the required space. High torque/mass density
e) Wide speed range without gear ratio change.
f) Full torque at zero speed for indefinite time.
g) Can cope with frequent starts and stops.
h) Energy saving since power is not consumed unless required.
i) Low inertia (1% of conventional drive). The over loads and impact loads are controlled by a simple relief valve.
j) Long life, high technical reliability and low maintenance.
k) Reverse direction simple way achieved.

In several applications such as cane conveyors, pumps and fans, the working load has significant variability during its duty cycle. HLTS motors have advantages in these applications to achieve a considerable energy saving and softness in operation as described by Lewinski (2006) and Ljung (2006). These advantages are achieved by means of an automatic closed loop that controls the speed irrespective of the load. The low inertia mentioned above allows faster automatic control
than other alternatives that use mechanical speed reduction steps. When frequent stopping and starting are required, particularly in combination with high loads, hydraulic drives are the most suitable. These advantages of hydraulic drives have been demonstrated by Hägglunds in Cuba over more than 28 sugar harvest seasons.

Financial difficulties in the sugar industry have limited the further uptake of this valuable technology. With the objective of finding an economically viable and technically feasible alternative to existing HLTS motors, the author developed a novel hydraulic motor of high torque and low speed that is presented in this paper.

**Background to the invention**

The author carried out a literature search to look for solutions that met the objective of an economically viable and technically feasible alternative to existing HLTS hydraulic motors. One partial solution was identified, consisting of a two cylinder hydraulic motor applied to vertical crystallisers as described by Cameco Industries (1997), DDS Crystalliser (1995) and Groupe Fives-Lille (2002). From these references and the well-known classical steam engines, the author has improved the basic layout by using an odd number of cylinders to smooth the delivered power to the driven equipment.

Additionally, to increase the reliability of the new invention and its compactness, the author investigated the use of flow directional rotary valves that are widely used by companies such as Ebara Man. Co. (1998), Kawasaki Hydraulic Products (1999) and SAI s.p.a. (2004), and adapted this technology to the new design. This adaptation, to allow the cylinders to produce useful work in both directions, is not widely known.

**Description of invention**

This new hydraulic motor design has been patented (Arias-Polo, 2006). The design concept is shown in Figure 1.

![Fig. 1—Simplified drawing of the invention.](image)

The invention is a three cylinder hydraulic motor with a common point of action of forces 5. The hydraulic fluid, supplied by a pump, enters the directional rotary valve 1 at entrance E. This rotary valve 1 moves together with the crank 6, controlling the flow of fluid to the three cylinders 3 and, consequently, the sequence of operation and synchronisation of the cylinders. The fluid enters and leaves the cylinders through the lines 2. The stroke of the cylinders is transferred into rotational motion through the connecting rods 4. The ends of connecting rods are articulated in 8 and 5,
causing the rotation of the crankshaft 6, rotating the driver shaft 7 where useful torque is applied to the driven equipment with the angular speed $\theta$. The return of hydraulic fluid to the oil tank is also controlled through the rotary valve 1 through the exit S.

The patented technological novelty of this invention is that cylinders carry out useful work in both directions of their stroke. This feature enables the invention to achieve a higher torque to mass ratio compared to similar motors, with the additional advantages of smaller size, weight and cost.

**Experimental development under industrial conditions**

Based on the design presented by Arias-Polo (1998), a prototype was built by TANACEN in Cuba, a manufacturing plant belonging to the Cuban sugar industry. The prototype was installed in Havana Libre mill in Cuba, on a Blanchard Crystalliser of 34 m$^3$ rotating at a speed of up to 2 rpm (Figure 2), with promising results (Table 1). The equipment processed C massecuite successfully at different speeds (0.5, 0.75, 1.0 and 2.0 rpm), having to stop, after more than 300 operating hours, because of the end of the harvest season.

**Design improvement**

After the operational experiences of the first prototype, the author developed a new design (Arias-Polo, 2002), to increase robustness and to achieve the maximum possible torque within the same motor casing). The diameter of the pistons and connecting rods, the driver shaft and the diameter of the shaft at the end of the three connecting rods were the most important parts updated.
The new design also incorporated a shrink disc coupling that doesn't require keys or splines, allowing quicker assembly and higher strength.

A full mathematical model and the corresponding software for the motor design and performance were described by Arias-Polo (2008a). Applying the model to the new design, new design parameters were obtained. A graph of available motor torque $T_1(\theta)$ vs. $\theta$ (rotation angle in radians) is presented in Figure 3. The average value $V_M$ is also shown. Table 2 shows the design specifications, based on the minimum torque shown in Figure 3.

Comparison of new design with current market leaders

From Hägglunds motor data, as presented by Hägglunds Drives (2002) and Lewinski (2002b), the author built performance curves, like that shown in the Figure 3, for four motor models.

A summary of the results, compared to the new design is presented in Table 3. Figure 4 shows the torque vs mass relationship. Interpolating the relationship for the Hägglunds motors, one can observe that the new design weighs about 30% less (1360 kg) than a Hägglunds motor design matching the torque of the new design (1975 kg).

Further improving the available torque

The available torque can be increased by reducing the torque fluctuations through a revolution of the shaft, such as shown in Figure 3. To achieve this objective, an increase in the number of pistons is proposed, using two motors applied to the driven equipment, with different phases, as shown in Figure 5. Figure 6 shows the resulting performance.

Fig. 4—Comparison between the new design and the leader in market.

Fig. 5—Two motors applied in each extreme.
The available torque for two motors (the minimum value in Figure 6) with 95% torque efficiency is $T = 445\,880$ N·m. The torque for each motor is now $T/2 = 222\,940$ N·m, 23.85% higher than the 180 000 N·m shown in Table 2.

**Conclusions**

A new design of High Torque Low Speed hydraulic motor has been developed, with the patented novelty that cylinders carry out useful work in both directions of their stroke. That performance enables the invention to achieve a higher torque to mass ratio than existing motor designs, with the additional advantages of reduced size, weight and cost.

A prototype design was tested under industrial conditions in the Havana Libre Mill in the Republic of Cuba.

With the acquired experience, a new design was developed that modelling has shown has a mass that is less than 70% that of similar motors in the market.

In order to improve the torque to mass ratio further, a configuration is offered by increasing the number of pistons using two motors, with different phases. In this configuration, the torque for each motor will be 23.85% higher than when only one motor is used.

The simple mechanical construction allows the motor to be manufactured in a shop belonging to the Cuban Sugar Industry.

MOTRE HYDRAULIQUE DE COUPLE ELEVE
AVEC CYLINDRES ET ARBRE

Par

G. ARIAS POLO
Institut de Recherche Sucre Cubain
gariaspolo@yahoo.com.mx

MOTS CLEFS: Moteur Hydraulique,
Couple Élevé, Cylindres Multiples.

Résume
ON PRÉSENTE un moteur hydraulique d’une nouvelle conception; le moteur donne un couple élevé et des vitesses réduites. Il n’est pas nécessaire de réduire la vitesse entre le moteur et l’appareil qu’il conduit. La construction du moteur et sa technologie sont simples ; les coûts sont réduits. Le moteur comprend trois cylindres hydrauliques a effet double avec une vanne rotative, le tout bâti sur un châssis. Les trois cylindres hydrauliques travaillent dans deux directions, une idée nouvelle qui a été brevetée; cela permet un rapport couple/densité plus fort. Un moteur prototype a opère pendant une campagne a la sucrerie Havana Libre Sugar Mill de Cuba ; les résultats ont été très bons. Le papier donne aussi des détails sur un model plus robuste, promettant une performance supérieure comparée a celle du moteur prototype.
MOTOR HIDRÁULICO DE ALTO TORQUE
CON CILINDROS Y CIGUEÑAL

Por

Cubano Instituto de Investigación de Azúcar
gariaspolo@yahoo.com.mx

Resumen
EL ARTÍCULO describe un nuevo diseño de motor hidráulico para las aplicaciones de alto torque y baja velocidad de rotación. Estos diseños no necesitan reducción de velocidad entre el motor y el equipo a mover. El motor es simple de construir y utiliza componentes de tecnología común, con bajo costo y pequeña complejidad. Consiste esencialmente en tres cilindros hidráulicos de doble efecto y una válvula de flujo rotatoria, todo soportado por un bastidor. Tiene la novedad patentada que los tres cilindros hidráulicos realizan trabajo útil en ambas direcciones de la carrera, resultando una superior densidad de torque/masa. Un prototipo de este motor ha operado durante una Zafra en el ingenio Habana Libre de Cuba, con resultados muy prometedores. También se presenta el diseño de un nuevo modelo más robusto, el que promete mucho mejor desempeño que el prototipo experimental.
COMPARISON OF DIFFUSION AND MILLING
AT A CANE SUGAR PLANT

By

NARENDRANATH MULLAPUDI
The Andhra Sugars Ltd.
Tanuku 534 215, India
asltnk@vsnl.com

KEYWORDS: Diffusion, Energy Efficient Extraction, Low Operation and Maintenance Cost, Exportable Electricity.

Abstract

With the advent of the diffusion technology and its improvement, diffusers have replaced mills for juice extraction at a few cane sugar plants due to their better extraction efficiency, lower manpower needs, lower power consumption, low operating and maintenance cost, increase in exportable electricity, and better operation flexibility. The performance of a cane diffuser at The Andhra Sugars Limited, Sugar Unit – II at Taduvai has been elucidated and a comparison done between diffusion and milling. Taduvai achieves a reduced milling extraction (RME)\(^1\) of 98.4% and pol in bagasse (%) of 0.84 and has 51% lower manpower, 18% lower power consumption and 60% lower operation and maintenance costs compared to a milling tandem. The vacuum filter station has been eliminated. With a cane diffuser, 2616 kW more electricity can be exported than with a milling tandem.

Introduction

‘In the sugar factory, diffusion is therefore the phenomenon by which the cells of the beet or the cane, immersed in water or a solution of lower concentration than the juice which they contain, give up to that water or to that solution a part or all of the sugar forming the excess of concentration of their juices’, quoted Hugot (1986).

In diffusion, sugar extraction from cane is effected by rupturing the cane cells and then washing the ruptured cells with water or juice. So it is necessary that the preparatory index of around 90% be achieved to obtain a RME of 98% or higher. This process of extraction of sugar from cane offers several advantages over milling.

Percolation type diffusers are widely used in the cane sugar industry. There are two types of percolation diffusers in use – the fixed screen and the moving screen.

The cane sugar industry has used milling for juice extraction. With the advent of diffusion technology and its improvement, this process has replaced mills at the juice extraction station in a few cane sugar plants; particularly due to its better extraction efficiency, lower manpower needs, lower power consumption, lower operating and maintenance costs, increase in exportable electricity and better operating flexibility.

In 1969, a moving screen percolation type bagasse diffuser was installed at The Andhra Sugars Limited, Sugar Unit – I, at Tanuku in Southern India. Satisfied with its performance, a second moving screen percolation type bagasse diffuser was installed in 1977 and a moving screen percolation type cane diffuser was installed in 1997 at Sugar Unit – II at Taduvai.

This is the only cane sugar company with diffusers, producing direct consumption plantation white sugar of around 30 IU colour. All information presented in this paper is from the Taduvai plant (see Table 1).

---

Cane diffusion

Cane is prepared by a fiberiser or a shredder to a preparatory index of 90% or higher and passed through the diffuser with no mills before the diffuser and only one dewatering mill after the diffuser; see Figure 1.

Initially diffusers at most cane sugar plants were bagasse diffusers, where the existing mills were used as primary and dewatering mills.

With the advent of improved fiberisers and shredders that achieve 90% and higher preparatory index, cane diffusion became popular, doing away with the primary mill, resulting in multiple savings as mentioned in the abstract and introduction.

![Fig. 1—A diffuser.](image)

There are a few aspects to be borne in mind when considering the use of diffusion at a cane sugar plant:

- Compared to milling, diffusion requires 2 to 3% more low pressure steam, to heat the prepared cane to the operating temperature of 80°C, using vapour bled from the 2\(^{nd}\) effect evaporator. This extra 3% steam is first used to generate electricity and then used to heat the prepared cane.
- Imbibition of 45% on cane is given at the diffuser, requiring slightly more evaporator capacity.
- Experience shows that addition of the clarifier underflow (mud) into the diffuser made a minor difference in quantity of ash or on the calorific value of the bagasse.

\(^2\) ICUMSA Method GS2/3-10
Operation of a cane diffuser at the Taduvai Sugar Plant

The cane diffusion process has three major operations:

Cane preparation

A heavy duty swing hammer type horizontal fiberiser with 144 hammers (each weighing 17.5 kg) driven by a 1865 kW steam turbine is being used at Taduvai. An auto-feed arrangement is used to have a uniform bagasse mat feeding the diffuser. The power consumed for cane preparation is 1790 kW though 2242 kW is installed.

Juice extraction

Juice extraction is by a moving screen, percolation type cane diffuser of 5000 t/d capacity. It is like a long rail box wagon, with its bottom having a horizontally moving screen running the full length of the diffuser. Below the moving screen are 15 recirculation trays, 2 scalding juice tanks and 1 draft juice tank. At the top, fixed just below the roof of the diffuser are 15 distributors located throughout the length of the diffuser at the centre of the recirculation trays. The screen moves slowly from the feed to the discharge end, carrying a bagasse mat of uniform thickness. Imbibition at 45% on cane is added on to this mat at the discharge end of the diffuser. Press juice is added on to the mat at the second last compartment from the discharge end of the diffuser. This press juice is heated from 60 to 85°C, using 3rd vapour in a direct contact heater.

Pumps at the recirculation trays pump the percolated liquid through the distributor above the preceding tray. The liquid percolates through the bagasse mat and collects in the recirculation trays below. The liquid moves from the discharge end to the feed end of the diffuser gradually increasing its concentration by taking up the soluble matter, resulting in a counter current extraction. It takes 60 minutes for the bagasse mat to traverse the length of the diffuser, while the liquid takes 20 minutes. The juice goes to the process house, with the flow being controlled by the level of the juice in the scalding juice tank. The juice from the diffuser passes through a screen before being sent to the process house. This quantity is around 110 to 115% on cane.

At the discharge end of the diffuser, the bagasse drops on to a rake carrier, which transports it to the dewatering mill. To avoid blocking of the bagasse mat by fine particles, 2 sets of lifting screws are provided, one after the feed end and the other before the discharge end of the diffuser, facilitating proper drainage of the liquid.

The liquid distribution system automatically adjusts (Rein et al., 1992) by sensing the liquid level in the bed using a differential pressure transmitter through a DCS (distributed control system) to have better percolation of liquid through the bagasse mat. With this arrangement, the point of application of the liquid moves forward or backward, adjusted by means of a pneumatic cylinder. The power used at the diffuser is 448 kW though 574 kW is installed. Table 2 shows the diffuser performance data.

To have a better extraction and to minimise microbial activity in the diffuser, the temperature inside the diffuser is maintained at around 80°C. To achieve this, a fully automated and controlled injection of 1st vapour is provided. To raise the temperature of the bagasse to the operating temperature, the juice from the scalding juice compartment is heated in two multi-pass vertical juice heaters and spread over the bagasse mat at the feed end of the diffuser.

At this stage, milk of lime is added to maintain the pH between 5.8 and 6.0. As the temperature of the juice in the diffuser is maintained at around 80°C, inversion is minimal. Figure 2 shows the concentration (°Brix), pH, temperature (°C) and reducing sugar (RS) per 100°Brix of the juice at the various compartments of the diffuser at Taduvai indicating that there is minimal inversion in the diffuser. The clarifier underflow (mud) is pumped into the diffuser near the first row of lifting screws, at a point of matching concentration, eliminating the vacuum filter station and the need for disposal of the filter cake. The mat of bagasse acts as a filter, removing the mud particles in the underflow (mud) of the clarifier and the suspended particles in the diffuser juice
Addition of the clarifier underflow (mud) into the diffuser has not negatively affected the boiler. It has in fact resulted in:

- Power saving of 112 kW.
- Increase in recovery by 0.06% on cane.
- Steam saving of 1%, as there is no cake washing.

Performance data for the diffuser at Taduvi are presented in Table 2.

Fig. 2—Graph of concentration (°Brix), pH, Temperature and RS/100°Brix at various compartments of the cane diffuser at Taduvai.

**Dewatering of bagasse**

The moisture content of the bagasse discharged from the diffuser is around 80%. It passes through a 991 mm × 1982 mm mill with a TRPF (toothed roller pressure feeder). The moisture content of bagasse at the outlet of the dewatering mill is around 50.5%. This bagasse is passed through a flash dryer bringing the moisture down to 42%, thus improving the efficiency of the boiler. This has enabled each of the 40 t steam/h boilers to produce 5 t/h more steam. The power consumed at the dewatering mill is 507 kW, though 1082 kW is installed.

**Advantages of cane diffusion over milling** (5000 t/d capacity, and a 150 day season)

**Better extraction efficiency**

While the RME at many mills is about 96% and pol in bagasse (%) is about 2, at Taduvai the RME is around 98.4% and pol in bagasse (%) is 0.84, gaining 0.374 in recovery (% on cane), while elimination of the vacuum filter station contributes 0.06 (% on cane) to the recovery. The sugar so gained is approximately US$1.95 per tonne of cane processed. Recovery gains for diffusion and milling are presented in Table 3.

**Table 3**—Calculated recovery gain with a diffuser.

</tbody>
</table>

There is a saving of 659 kW power with a diffuser. With the elimination of the vacuum filter station this saving increases to 749 kW. While a RME of 98% and higher is achieved with a diffuser, to achieve this RME with a milling tandem, two more sets of mills are needed, requiring an additional installed power of 1268 kW.

**Lower operation and maintenance costs**

The operation and maintenance cost at a diffuser and a milling tandem for a 150 day operation is shown in Table 6.

</table>

Clarification and filtration

The bagasse mat in a diffuser acts as a filter for the juice. The suspended solids in the draft juice from the diffuser are around 80 ppm, while it is about 2000 ppm with a milling tandem. With the addition of the clarifier underflow (mud) into the diffuser, the pol loss in the filter cake is ‘0’. ‘No’ recirculation of filtrate to draft juice results in lower suspended impurities in the draft juice, better floc formation and better clear juice transmittance, as seen in Figure 3.

Fig. 3—Colour of draft, sulphited and clarified juice at Taduvai.

There is a notion that as the diffuser draft juice is higher in colour, use of a diffuser is not conducive to produce direct white sugar. Figure 3 shows the juice colour achieved at the cane diffuser, while Table 1 and Annex 1 show the quality of sugar produced at Taduvai.
Lower unknown losses

As diffusion takes place in enclosed equipment, at a temperature of 80 to 85°C, microbial activity is minimal. In milling, extraction is done in the open, at ambient temperature, so most of the unknown loss is due to microbial activity, loosing eight parts of sucrose to one part of lactic acid, while it is only two parts of sucrose to one part of lactic acid in a diffuser (Mackrory et al., 1984).

Increase in Exportable electricity

A cane sugar plant with a boiler at 4.5 Mpa and 420°C and a diffuser would export about 2616 kW more electricity than with a milling tandem as seen in Table 8.

</tbody>
</table>

Better operating flexibility

A diffuser can be operated from 20 to 100% of its rated capacity without significant loss in efficiency by merely varying the thickness of the bagasse mat and the screen speed.

Conclusion

Diffusion has a definite advantage over milling due to higher extraction, lower manpower needs, lower power consumption, lower operating and maintenance costs, increase in exportable electricity and better operating flexibility. For a cane sugar company considering setting up a new sugar plant, it would be advantageous in the interest of a better bottom line to use diffusion for juice extraction.

Dr. Rainer Mogele
COMPARAISON DE LA DIFFUSION ET DES MOULINS DANS UNE SUCERIE

Par

NARENDRANATH MULLAPUDI
The Andhra Sugars Ltd.
Tanuku 534 215, India
asltnk@vsnl.com

MOTS-CLEFS: Diffusion, Energie et Extraction, Coûts de l’Opération et de la Maintenance, Exportation d’électricité.

Résumé
AVEC l’avènement de la technologie de diffusion et de son amélioration, les diffuseurs ont remplacés les moulins pour l’extraction du jus dans des sucreries. Comparée aux moulins la diffusion donne une meilleure efficacité d’extraction, demande moins de main d’œuvre, et consomme moins d’énergie; les coûts de maintenance et de l’opération sont plus faibles. Elle permet aussi d’exporter plus d’électricité et donne une opération plus flexible. Les performances d’un diffuseur de canne à The Andhra Sugars Limited, Unit Sugar-II à Taduvai ont été éucidées et une comparaison effectuée entre la diffusion et les moulins. Taduvai réalise une extraction réduite (RME) de 98.4%, un pol % bagasse de 0.84, une maintenance réduite de 51%, une consommation d’énergie réduite de 18%, et 60% de réduction pour les coûts d’opération et d’entretien par rapport à un tandem. La station de filtre a été éliminée. Avec un diffuseur on a augmenté l’exportation de l’électricité par 2616 kW, compare aux moulins.

COMPARACIÓN ENTRE DIFUSIÓN Y MOLIENDA EN UNA PLANTA DE AZÚCAR DE CAÑA

Por

NARENDRANATH MULLAPUDI
The Andhra Sugars Ltd.
Tanuku 534 215, India
asltnk@vsnl.com

PALABRAS CLAVE: Difusión, Energía, Extracción, Mantenimiento, Costos, Cogeneración.

Resumen
CON la aparición de la tecnología de difusión y su mejoramiento, los difusores han reemplazado los molinos para la extracción de jugo en algunas fábricas debido a su mejor eficiencia de extracción, menores requerimientos de mano de obra, menor consumo de energía, menores de operación y mantenimiento, incremento en cogeneración y mayor flexibilidad de operación. El desempeño del difusor en la Unidad II de Andhra Sugars Limited, en Taduvai ha sido evaluado y se comparado con la tecnología de molienda. Taduvai alcanza una extracción reducida de 98.4% y pol en bagazo (%) de 0.84 y tiene 51% menos mano de obra, 18% menos consumo de potencia, y costos de operación y mantenimiento 60% menores si se lo compara con un tren de molinos. La estación de filtración fue eliminada y con este difusor pueden exportarse 2616 Kw más que con un tándem de molinos.
FACTORY CONCEPTS FOR VERY LOW STEAM DEMAND
AND STATUS OF IMPLEMENTATION

By

B. MORGENROTH and S. PFAU

IPRO Industrieprojekt GmbH, Celler Straße 67, 38114 Braunschweig, Germany
Morgenroth@ipro-bs.de

KEYWORDS: Co-generation, Steam Efficiency,
Energy Benchmarking.

Abstract

THE EXPORT of power from cane sugar factories allows the production of ‘green energy’
and proves nowadays as a substantial source of revenue as well. Looking to the co-
generation potential of the cane sugar industry, the power export is in fact still at a very
early stage. The report gives an overview about concepts and measures that are required
to achieve a low steam demand and high electrical power export for different factory
concepts. The impact of sugar extraction by mills and diffusers as well as the option of
producing refined sugar in an attached refinery is investigated. The factory models
investigated allow steam demands to reduce to the range of 26–34% steam on cane.
Such factory concepts are not theoretical any more but have been implemented and
successfully proven in several plants in India, Brazil and Pakistan in the last five years.
The report gives an overview about the actual achievements.

Introduction

While saving of process steam has not been very attractive for many cane mills in the past,
the situation has turned in the last decade substantially since electrical power can be sold for
reasonable prices, in many cane processing countries, to the national grid or directly to external end
consumers. The carbon credit trade has acted to some extent as a catalyst to accelerate this process
and has proven to be a most welcome add-on to boost the electrical power production of cane sugar
factories. Electrical power prices of 50–60 €/MWh in countries like Brazil and India make power
exports more attractive. The market price for each tonne of carbon dioxide substituted by the
production of electrical power from bagasse is approx. 5–15 €/t CO2 and this adds to the revenues.

Taking into account that, with well proven technologies, electrical power exports of 100–
125 kWh/t cane are already possible today, the potential to create ‘green energy’ is huge. In the case
where bagasse gasification is applied, even 200 kWh/t cane would be possible in the future (Turn,
1999). Considering sugarcane production in more than 100 countries worldwide with approx. 1800–
2000 sugarcane and bio-fuel (ethanol) factories processing approximately 1558 million t cane/year
(FAOSTAT, 2008), the power production potential amounts to 156–179 TWh/year. In other words,
20 MW power export capacity would have to be installed in each cane processing factory in order
to match the actual potential.

Another trend observed is producing better sugar qualities locally with a tendency to white
(refined) sugar production of less than 45 ICUMSA units in back-end refineries.

This report gives an overview about energy efficient process schemes employed in the cane
sugar industry and typical benchmark numbers that can be achieved.

Base concepts

There are various configurations possible to process sugarcane to sugar. Mill and diffuser
extraction concepts compete, with diffusers gaining more ground on an international basis today.
While in most countries a three-stage crystallisation scheme with an eventually attached back-end refinery is typical, in Brazil usually approximately half of the sucrose in cane is converted to sugar and half to ethanol. A diffuser and mill-based plant concept with and without back-end refinery have been chosen to benchmark the steam demand and the power export. Sub scenarios have been created in order to show, for example, the effect of different imbibition rates. In Table 1 the main input variables for the subsequent calculations are summarised.

Table 1—Base data for the process calculations.

</tbody>
</table>

An important aspect is a very high sugar recovery of 89.5–90.5%. Many sugar factories compromise on this important benchmark figure and there are many factories achieving sugar recovery efficiencies from 80–85% only. For the calculation of the different process models, the ‘Sugars’ program was employed.

**Technologies employed**

In the following, the most important technologies considered for the concept evaluation are summarised:

- Diffuser plus dewatering mills or milling tandem (6 mills)
- Recycling of clarifier underflow in case of the diffuser models
- Defecation in the juice purification
- Partly direct contact heaters and plate or platular heaters for liquid/liquid applications
- Optimum usage of heating with condensate
- Falling film evaporators
- Stepwise flashing of condensates by ‘condensate cigars’
- CIP (clean in place) system for heaters and evaporators
- Minimisation of evaporator condenser loss
- Batch pans for seed massecuite and refinery products R1, R2 and R3
- Continuous pans for the raw house operation
- Syrup/molasses wash layer system for A sugar
- Crystal seed technology in the raw house
- High pressure boilers with 109 bar and 535°C
- Extraction/condensing turbo alternators
- Fully electrified drives (no steam turbines)

Apart from the mentioned core technologies, it has been assumed that modern equipment is employed and the factory is well designed having good automation.

Arguments for the selection of diffuser versus milling tandem technology have been summarised by Rein (1995, 1999), Mullapudi (2006) and many other authors. In the subsequent chapters, additional background information about some of the aforementioned technologies is given.

**Impact of defecation and sulfitation**

For the production of refined white sugar the defecation process is preferred. If sulfitation is applied in the juice purification stage and eventually for syrup sulfitation, the sugar quality in the raw house can be improved from approx. 350–600 IU to 70–100 IU. This is important for factories producing plantation white sugar for local consumption.

There have been fears in the past that sulfated juices are not suitable for the operation of falling film evaporators as a harder and thicker scale formation could be expected on the evaporator heating surfaces.

This cannot be confirmed. Falling film tubular as well as Falling film plate evaporator trains are operating successfully nowadays with either defecation or sulfitation systems in factories in Brazil, India and Pakistan (Avram et al., 2007).

**Tube/plate heaters versus direct contact heaters**

In order to minimise the process steam demand, indirect and step-wise heating of process flows with tubular or plate heaters is required. However, there are arguments to employ direct contact (DC) heating where applicable because:

1. DC heaters are inexpensive and easy to integrate with low space demand.
2. Allow an approach temperature of 0.5–2 K while tubular or plate heaters require 4-8 K.
3. Almost no cleaning or down time.
5. High load flexibility with minimum performance change.

The juice dilution by injected vapour is of course a drawback of DC heaters. The set-up is crucial as one has to consider that the vapour and the juice system are directly connected and safety measures are required to avoid juice carry over to the condensate system and sugar losses.

The steam on cane demand can be further reduced by 2–3% when only indirect heating with tubular or plate type heaters is employed.

Especially plate heaters require a disciplined and rigid cleaning regime and often do not show the expected performance stated by the suppliers.

For the calculated concepts, direct contact heaters have been considered for raw and limed juice heating as well as clarified juice heating.
It has to be considered that employing DC heaters shifts the requirement for heating surfaces from heaters to the evaporators. The overall investment does not change substantially. It is the operating cost and process performance that favour the DC heaters.

**Evaporator technology**

The most widespread evaporator technology in the cane sugar industry is still the Robert type evaporator with some Kestner applications in selected countries. The process steam demand on cane is limited in these cases to usually 36–40% on cane in the case of raw sugar factories or 45-55% on cane for factories with back-end refineries.

Experience has been gained (Avram et al., 2007, Bhagat, 1996, Journal, 2005, GEA, 2009) in the last 20 years with falling film tubular and later also plate type applications especially in cane sugar mills in Brazil, India and Pakistan with units usually employed in the 1st and 2nd effect (approx. 250–300 units to date). During the past five years, full trains of falling film type evaporators have been introduced.

The authors have been involved in the design of eight plants where exclusively falling film tubular or falling film plate evaporators have been employed. The right evaporator and process engineering design are a crucial aspect here.

The automation of such plants is relatively simple but a well adapted CIP process is required. Good training for local personnel is required to adapt to such new technologies but overall the predicted results have been achieved after an initial learning curve.

Figure 1 displays the k-values (thermal evaporator performance) for Robert, rising film plate, falling film tubular and falling film plate evaporator types (Morgenroth, 2002) in the typical range of applicability in the cane sugar industry.

The k-value is displayed here dependent on the juice viscosity as this parameter is a function of Brix and juice temperature. The plate evaporators show far better efficiencies resulting in less required heating surface and therefore usually less investment.

![Fig. 1—Evaporator performance (k-value) for different viscosities and evaporator types.](image)

On first view, the k-values of Robert and falling film tubular evaporators are not very much different. This is true as long as high temperature differences and high steam consumptions can be accepted.

Figure 2 (Morgenroth, 2002) shows the impact of the specific heat flow density that is correlated to the effective temperature difference. The smaller the specific heat flow, the lower will
be the temperature difference. In the case of rising film evaporators the \( k \)-value does not only depend on the juice viscosity. It depends also very much on the available delta-T or specific heat flow density. If the specific heat flow drops below 7 kW/m\(^2\) heating surface, the thermal performance deteriorates very rapidly.

This is not the case for falling film evaporators where the specific heat flow has practically no impact on the performance. In the case where the overall temperature difference in an evaporation plant is decreased from 125–60°C to 125–90°C, it will not be commercially viable to employ Robert or rising film plate evaporators.

![Fig. 2—Influence of the specific heat flow on the evaporator performance (k-value).](image1)

Figure 3 gives an example for a complete falling film tubular evaporation plant recently installed.

![Fig. 3—Five effect falling film evaporation train in AlMoiz, Pakistan.](image2)
Discontinuous versus continuous pans and other pan house features

Employing continuous pans in the case of low steam demands is not an absolute prerequisite but can offer further optimisation potential.

Actually, continuous pans show their highest benefit when operated with steam pressures in the calandria of 70–90 kPa(a). In this case, the low massecuite head and use of stirrers allow good and smooth performance. The other benefit is the reduction of vapour demand fluctuations because of the constant load profile. However, well designed batch pans equipped with stirrers and operated with low massecuite heads can also be employed without problems with pressures down to 90 kPa(a) without loss in performance.

A new development is the Spray Continuous Pan (SCP) that follows similar lines in comparison to the BMA type VKT with a vertical arrangement (Verma, 2009). Up to now, 14 units of this type are in operation or under construction (Figure 4).

Continuous pans are considered for the concept evaluation for operation with 4th and 5th effect vapour with pressures from 70–100 kPa(a) depending on the scenario.

A high-grade or ‘white’ molasses wash layer system has been considered for the A batch centrifugal station in the raw sugar house. This technology allows reducing the sugar crystal loss from typically 15–25% to 8–12%, thus reducing the steam and power demand of the process. The white molasses used for this purpose does not dissolve much sugar whereas 1 kg wash water dissolves approximately 3 kg of sugar.

A cooling seed crystal system has been considered as well in order to form a uniform seed material for the raw house products. This is especially important for the C-Massecuite seeding as with this technology less high purity material is introduced to the C pans and subsequently lower final molasses purities can be achieved.

Fig. 4—Vertical continuous pans (SCP).
High pressure boilers and turbines

The increase of boiler pressure (and steam temperature) above 4500 kPa(a) does require an improvement of feed water quality and no sugar traces can be accepted any more. Care has to be taken that condensate with a temperature of approximately 120°C is stored under pressure and continuously analysed for sugar traces by flame photometry (potassium based measurement) or TOC (Total Organic Carbon) based on on-line sensors in order to avoid any potential contamination. Typical boiler pressures vary around 6500 kPa(a)/520°C, 9100 kPa/520°C or 10 900 kPa(a)/535°C. Recently, in India, new boiler installations shifted to 10 900 kPa(a) steam pressure, while the highest pressures in Brazil are 9200 kPa(a) nowadays. The selection is influenced by the availability of experienced local boiler manufacturers as well as on the availability and performance of locally or internationally available steam turbines.

Results

The results of the calculations for the different process models are displayed in Tables 1 and 2. The process steam requirement lie in a range of 26–34.2% on cane for the different scenarios.

The diffuser models require approximately 2.5–4% steam on cane more than the milling scenarios. The additional process steam demand for refined sugar production varies from 4.2–5.7% process steam on cane.

The specific power export to the electrical grid varies from 100–122 kWh/t cane.

The diffuser based model offers the advantage of approximately 13–14 kWh/t cane more electrical power export compared to the milling tandem based model.

With the diffuser concept scenarios, it is possible to produce approximately 700–1200 t sugar/year more than with the milling concept scenarios. The reason is the return of the clarifier underflow to the diffuser, eliminating the sugar losses in the filter cake. However, the suitability of this arrangement depends on the cleanness of the cane and requires a multi-fuel boiler because of the higher ash content in the bagasse.

</tbody>
</table>

The imbibition rate was varied from 35–44% on cane resulting in a difference in sucrose extraction rate between 97 and 98%. The power export is affected only by 2–3 kWh/t cane and this shows clearly that usually it is more economic to improve the sugar recovery instead of compromising on the imbibition rate. However, this requires of course sufficient evaporator capacity.

An amount of approximately 5% of the available bagasse has been considered for starts/stops and steam losses. This bagasse can also be partly used for power production but this has not been considered here.

Approx. 1.7% on cane bagacillo has been considered to be lost with the filter mud. In the case of very good cane qualities, the bagacillo amount can drop to less than 0.8% on cane. Often, cane trash is burnt in modern multi fuel boilers today in addition to bagasse.

This can add substantially to the power production and should always be considered for a power plant concept. The evaporation operation scheme for Scenario 4 is displayed as an example in Figure 5.
Fig. 5—Evaporation plant operation Scenario 4.
One of the most important differences between a conventional evaporation set-up and the given scenarios is the small effective delta-T with special regard to the last two effects. It has been stated in the past that the higher temperatures in the last effects could cause high sugar losses or colour formation.

Practical experience has shown that this is not the case and supports the known facts of slower sucrose degradation and colour formation (Vukov, 1965; Vukov and Patkai, 1981) in the case of juice temperatures below 110°C.

The juice residence times in a falling film evaporation plant are approx. 25–35 minutes compared to Robert-based trains where often more than 60 minutes residence times can be observed (Morgenroth, 2002). This allows operation at slightly higher temperatures in the initial effects that are more sensitive concerning sugar losses.

There are cases where an investment into high pressure boilers might not be viable. However, bagasse itself is nowadays a valuable product that can be sold for good prices. Therefore, it makes sense to optimise the process.

Conclusions

A steam on cane demand from 26–34% steam on cane (260–340 kg steam/t cane) can be considered nowadays as a benchmark for a modern cane sugar factory supplying also ‘green power’ to the electrical grid. Electrical power exports of 100–120 kWh/t cane to the power grid can be considered as technically and economically feasible.

It might be assumed that a modern factory concept requires higher investment cost. In our experience, this has not been proven as the reduction in steam demand–compared to conventional designs–of approx. 20% on cane or ~ 40% in total reduces the investment in boilers and turbines substantially allowing additional investment in other areas.

First experience has been gained with such innovative designs in a few mills in Brazil, India and Pakistan and especially the success of the falling film evaporator technology has been proven very well under quite different operating conditions.

MOTS-CLEFS: Cogénération, l'Efficacité de la Vapeur, Normes d’Energie.

Résumé

L'EXPORTATION d’énergie des usines de canne à sucre permet la production ‘d’énergie verte’ et s'avère aujourd'hui comme une source importante de revenu. En vue du potentiel de cogénération de l'industrie, l'exportation d'énergie est en fait à un stade très précoce. Ce rapport donne un aperçu sur les concepts et les mesures qui sont nécessaires pour obtenir une faible demande de vapeur et une forte exportation de puissance électrique avec des usines différentes. L’impact de l’extraction aux moulins ou avec une diffusion ainsi que l'option de production du sucre raffiné dans une raffinerie attachée à la sucrerie sont étudiés. Les modèles étudiés permettent de réduire la demande de vapeur vers une plage de 26–34% sur la canne. Ces concepts ne sont plus théoriques, mais ont été mis en œuvre et éprouvées avec succès dans plusieurs sucreries en Inde, au Brésil et au Pakistan au cours des cinq dernières années. Le rapport donne un aperçu des résultats obtenus.

CONCEPTOS PARA UNA BAJA DEMANDA DE VAPOR EN FÁBRICA Y ESTADO DE IMPLEMENTACIÓN

PALABRAS CLAVE: Cogeneración, Eficiencia Energética, Vapor, Benchmarking

Resumen

LA EXPORTACIÓN de energía eléctrica desde los ingenios cañeros permite la producción de ‘energía verde’ y se manifiesta también como una fuente sustancial de rentabilidad. Observando el potencial de cogeneración de industria de la caña, la exportación de energía eléctrica se encuentra aún en una etapa muy primaria. Este trabajo presenta un repaso sobre conceptos y medidas que se requieren para lograr una baja demanda de vapor y alta capacidad de cogeneración para diferentes conceptos de fábrica. Se investiga el impacto de la extracción con molinos y difusores también como la opción de producir azúcar refinado en una refinería anexa. Los modelos de fábricas investigados permiten demandas de vapor %caña de 26–34%. Tales conceptos de fábrica no son teóricos ya y han sido probados exitosamente en plantas de India, Brasil y Pakistán en los últimos cinco años. Se presenta un reporte de los logros reales alcanzados.
ENGINEERING PROPERTIES OF SUGARCANE FIBRES

By

J. RODRIGUEZ RAMIREZ and L. MENDEZ LAGUNAS
Instituto Politécnico Nacional, CIIDIR Unidad Oaxaca, Hornos 1003 Sta. Cruz Xoxocotlan, Oaxaca Mexico
jrodrigr@ipn.mx

Abstract

THE PHYSICAL properties and the mass and heat transfer coefficients for sugarcane bagasse were determined to provide information for process design and manufacturing of products. In this report, true density ($\rho_s$) and apparent density ($\rho$) were measured by the pycnometer method. Superficial area ($A_s$) and pore size distribution of fibres were determined by nitrogen adsorption and mercury porosimetry. Equilibration cells were used in order to obtain sorption isotherms. Water content and surface temperature of the sugarcane fibres were monitored using a modified Thermal Gravimetric Analyzer (TGA). The method of slope was used to calculate the effective water diffusion coefficient. The mass ($h_M$) and heat coefficients ($h_H$) were determined by experimental data, and then compared with one convective transfer correlation. The results showed that the parameters of the GAB equation adequately represent the experimental data. The order of magnitude of $D_e$ of fibres was $10^{-10}$ m$^2$/s. The value of $h_H$ was 40 W/(m$^2$ °K) and $h_M$ was 0.045 kg/(m$^2$.s). The fibre is a porous material consisting of macropores and its internal structure differs from that of the pith. The experimental values of $h_H$ were more elevated than those calculated with correlations due to the effects of conduction and radiation. The principal mass transfer mechanism was the internal resistance, $D_e$ increased with temperature in an Arrhenius type function.

Introduction

Bagasse is the residue left after the crushing of sugarcane for juice extraction. The largest and most traditional use of bagasse is burning it in boilers to generate process steam (Nassar et al., 1996).

A revision of the published results and industrial experience realised by Atchison (1971, 1974) and Pilgrim (1989) has shown the viability of satisfying the energy needs of a sugar factory with half of its residual bagasse. Then, the remainder can be used in more than 40 applications; the most important are paper pulp and cellulose pulp production, animal food, ethanol, and furfural.

In order to expand the use of bagasse, it is essential that information on fibre characteristics and the factors which affect the performance of that fibre be available.

Specific knowledge of the bagasse material is useful to predict its behaviour during transformation processes. Physical properties involved in the heat and mass transfer, such as density and porosity, play an important role in the design, the estimation of other properties, the characterisation of materials, and the prediction of heat transfer operations during processing and handling.
The engineering properties are important in the process design and manufacturing of products. The mathematical models are fitted using data as a function of one or more experimental parameters, such as temperature, water content, porosity, heat, and mass transfer coefficients or others. In order to do this, the aim of the present work is to describe physical characteristics, adsorption capacity, mass and heat transfer coefficient and water diffusivity of bagasse.

**Materials and methods**

**Material preparation**

The sugarcane bagasse provided by sugarcane factories in Zacatepec, Morelos, Mexico was depithed while wet, dried, sieved, and classified by size manually using a stereoscopic microscope. The highest frequency fractions (9.62% and 7.53%) of fibre (12 to 14 and 20 to 24 mesh screen/sieve, respectively) were used for all tests. A vernier caliper was used for measuring the length and diameter of the selected fibres. Volume and area were calculated using these data. Physical characteristics are shown in Table 1.

**Heat and mass transfer convective coefficient**

A heat and mass balance expressed by equation 1 (Vaccarezza et al., 1974) was used to determine the experimental convective heat and mass coefficients. All symbols are described in the Notation section at the end of this paper.

**Equation 1**—Heat balance equation.

\[
\Delta H_v \frac{dX}{dt} = h \cdot A \cdot \Delta T
\]

Experiments were conducted to measure the moisture lost during drying. The rate of moisture lost \( \frac{dX}{dt} \), determined in the period of constant-rate drying, and fibre surface temperature data were used for determine the convective coefficients of heat and mass transfer. It is assumed the heat of water vaporisation is constant and equal to the heat of water vapour condensation.

A correlation presented by Eckert and Drake (1959) was used for the calculation of the local heat transfer coefficient around the periphery of thin cylinders in the laminar region for flow of a fluid with constant thermophysical properties. For Reynolds numbers 0.1 to \( 10^5 \) and Prandtl numbers of 0.7 to 1500, the heat transfer coefficient correlation is expressed by equation 2.

**Equation 2**—Heat transfer coefficient correlation,

\[
Nu = 0.43 + 0.532 \cdot Re^{0.5} \cdot Pr^{0.31}
\]

The Nu and Re numbers were calculated with the fluid properties measured at the mean temperatures of the solid and of the fluid.

An analogous expression for the mass transfer coefficient is shown in equation 3.

**Equation 3**—Mass transfer coefficient correlation.

\[
Sh = 0.43 + 0.532 \cdot Re^{0.5} \cdot Sc^{0.31}
\]
Calculation of the effective moisture diffusivity

The effective moisture diffusivity \( (D_e) \) in solids is a physical property of the system and can be estimated from drying rate data. Assuming that the drying process is entirely controlled by internal mass transfer resistance (falling rate drying period), uniform initial moisture distribution and negligible external resistance, the solution of Fick’s diffusion equation developed for particles with cylinder geometry by Crank (1975) for a series of six terms is applicable and is in the form of equation 4.

**Equation 4**—Solution of Fick’s diffusion equation for a cylinder.

\[
W = 2 \cdot \sum_{i=1}^{5} \int^{1}_{0} f_0\left( \alpha_i \cdot r \right) \, dr \cdot \exp \left( -F \alpha_i \cdot \alpha_i^2 \right)
\]

The effective moisture diffusivity was calculated using the slope method (Perry et al. 1984)

Physical properties

**True and apparent density**

The true density was calculated from the volume measured by a gas pycnometer. A dried, pre-weighed sample was placed in an autopycnometer (MicroMeritics AccuPyc 1330). Helium was used as the displacement fluid. The apparent density of the totally-dried fibres was determined by measuring their dimensions and weight.

**Surface area and pore size**

The size, area and pores distribution were measured by nitrogen adsorption and mercury porosimetry methods, respectively. A nitrogen adsorption surface area analyser (Micromeritics, ASAP-2000) and standard methods ASTM D 3663-92 and ASTM D 4222-91 were used to evaluate the surface area and pore size, and adsorption and desorption by nitrogen isotherms. A mercury porosimeter (Poromaster, Quantachrome) was used between 0 and 60,000 psi for measured macropores. The pore volume distribution over pore diameter is expressed in terms of the distribution function \( F_v \) (eq. 5):

**Equation 5**—Pore volume distribution function.

\[
F_v = \left[ \frac{dV}{d\log D} \right]
\]

where \( V \) is pore volume. The function is such that area under the function in any pore diameter range yields volume of pores in that range.

**Sorption isotherms**

Sorption isotherms were determined gravimetrically at 25°C and 70°C. Triplicate samples of fibres dried at 90°C, sieved on sieves mesh number 16–14 (1.19–1.41 mm) and weighed, were transferred to vacuum desiccators.

Sulfuric acid solutions at different concentrations were used to achieve the internal, relative humidity in desiccators (Iglesias and Chirife, 1982; Molnár, 1995) over the range of 4% to 80% water activity \( (a_w) \). The criterion for the stable state was that water content of the samples (dry basis) did not change more than 2 mg/g during three consecutive days.

The Guggenheim-Anderson-DeBoer (GAB) equation (eq. 6) was used in modelling water sorption (van den Berg and Bruin, 1981):

**Equation 6**—The Guggenheim-Anderson-DeBoer (GAB) equation

\[
X = \frac{X_m \cdot C \cdot K \cdot a_w}{(1-K \cdot a_w) \cdot (1-K \cdot a_w + C \cdot K \cdot a_w)}
\]
The water activity, $a_w$, is defined as the ratio of the partial pressure, $p_w$, to the vapour pressure of water $p_w(0)$ at equilibrium (Rao and Rizvi, 1986). Temperature dependent GAB constants $C$ and $K$ were calculated with the following equations:

**Equation 7**—Temperature dependent GAB constant.

\[
C = C_0 \cdot \exp\left[\frac{\Delta H_C}{R \cdot T}\right]
\]

\[
K = K_0 \cdot \exp\left[\frac{\Delta H_K}{R \cdot T}\right]
\]

**Results**

**Fibre dimensions**

Surface area, pore and diameter volume measured by nitrogen adsorption and mercury porosimetry are shown in Table 2. True density of fibres was 1.331 g/cm$^3$. The order of magnitude is consistent with those of some natural fibres and similar to jute, banana, kenaf, coconut, and sisal (Eichhorn et al., 2001; Biagiotti et al., 2004). Porosity, calculated from true density and pore volume was 0.714. The pore distribution is shown in Figures 1 and 2 for the two measurement methods used.

![Fig. 1—Fibre pore distribution (mercury porosimetry).](image)
The distribution of pore sizes was represented by the logarithmic derivative of the cumulative intrusion of mercury volume V (dV/dlogD) vs pore diameter (D). The nitrogen absorption method shows lower results than the mercury porosimetry method. The difference is explained by the measurement range of each method. The first method has a range of micropores to mesopores of between 10–500 Å while the second method has a range of mesopores to macropores greater than 500 Å.

The pore volume distribution over pore diameter is expressed in terms of the distribution function Fv. The fibres reveal two pore distributions, one in the range of 0.1 at 1 μm and one in the range 4–100 μm with pore diameter maxima of 0.5774, 5.387 and 29.85 μm. This material mainly contains macropores >0.05 μm.

Fig. 2—Fibre pore distribution (nitrogen adsorption method).

**Sorption isotherm**

The values of GAB constant and the correction factors are presented in Table 3. The water adsorption isotherm results plotted for the fibre were carried out at 25°C and 70°C and are presented in Figure 3.

The isotherm presents a sigmoid or S-shape. For the same moisture content, water activity increased with temperature. This behaviour is frequently observed in cellulose-based materials (Jonquières and Fane, 1998).

The high level of moisture adsorption is caused by the high hydrophilic nature of the sugarcane fibre compared to other natural fibres, like the agave fibre which shows a low adsorption of 0.3 g water/g dry fibre at 0.8 a_w (Bessadok, 2009).

Cane fibre has a high cellulose composition of 32–48 % (Rowell et al., 2000) and therefore a number of accessible –OH groups that are responsible for the negative charge and the best characteristics of sorption.

Mass and heat transfer

The experimental heat and mass transfer coefficients were larger than those typically used in correlations. This could be explained because other factors like thermal conduction and radiation are involved in the experimental tests (Table 4).

The values of effective diffusivity for different experimental conditions are presented in Table 4. These values are within the general range of $10^{-11}$ for dry food materials and lower than the reported values of $3.92 \times 10^{-12}$ m$^2$/s for sisal at 30% relative humidity (Alvarez et al., 2004).

The mass transfer Biot number values were higher than 50. Therefore, the controlling mechanism of mass transport is the internal resistance to the transfer of humidity. Both internal and external resistance are important for heat transfer (Biot less 50).

Conclusions

The dimensions of the fibre, physical properties, and mass and heat transfer coefficients of cane fibre bagasse were studied. The fibres are made up mainly of macropores distributed essentially in two pore diameters.

The analysis of the water sorption indicates that the fibre is highly hydrophilic. This behaviour is a result of its high cellulose composition and is consistent with other cellulose fibres. The GAB model gives a good fit to the water adsorption data.

The heat and mass transfer coefficients, determined by experimental tests and correlations, show differences. The explanation of this behaviour would be the effect of thermal conduction and radiation.

The controlling mechanism of mass transport is the internal resistance to humidity transfer and, for heat transfer, internal and external resistance are important.

MOTS-CLEFS: Propriétés Physiques, Fibres de Canne a Sucre, Coefficients de Transfert Massique et Thermal.

Résumé
LES PROPRIÉTÉS physiques de la bagasse et les transferts de masse et de chaleur ont été déterminés afin de fournir des informations pour les processus de conception et pour la fabrication de produits. Dans ce rapport, la densité réelle ($\rho_s$) et la densité apparente ($\rho$) ont été mesurées avec un pycnomètre. La superficie (As) et la distribution de taille des pores de fibres ont été déterminées par adsorption d'azote et par porosimétrie. Des cellules d'équilibre ont été utilisées afin d'obtenir des isothermes. La température de surface et la concentration d'eau de la fibre ont été déterminées avec un Thermal Gravimetric Analyzer (TGA). La méthode de pente a été utilisée pour calculer le coefficient de diffusion de l'eau. Les coefficients de masse ($h_M$) et de chaleur ($h_H$) ont été déterminés par les données expérimentales et puis comparées par corrélation. Les résultats montrent des valeurs $\rho_s$ de 1231 kg/m$^3$, $\rho$ de 466 kg/m$^3$ et As de 1300 m$^2$/kg. La fibre de canne est constituée principalement par des macro pores d'un diamètre moyen de 0.0385 μm. Les isothermes de sorption sont du type II sigmoïde, un formulaire qui est compatible avec les structures macro pores. Les résultats montrent que les paramètres de l'équation de GAB représentent convenablement les données expérimentales. L'ordre de grandeur pour le $D_e$ des fibres est $10^{-10}$ m$^2$/s. La valeur de $h_H$ était 40 W/(m$^2$.°K) et celle de $h_M$ 0.045 kg/(m$^2$.s). La fibre est un matériau poreux, composé de macro pores et sa structure interne diffère de celle de la moelle. Les valeurs expérimentales de $h_H$ étaient plus élevés que celles calculées par corrélations due aux effets de conduction et rayonnement. Le mécanisme principal du transfert de masse était la résistance interne, $D_e$ a augmenté avec la température en fonction de l’équation d’Arrhenius.

PALABRAS CLAVE: Propiedades Físicas, Fibras de Caña de Azúcar, Coeficientes de Transferencia de Calor y Masa.

Resumen
SE DETERMINARON las propiedades físicas y los coeficientes de transferencia de calor y de masa del bagazo para suministrar información para diseño de proceso y fabricación de productos. En este trabajo se midieron la densidad real (ρs) y aparente (ρ) con el método del picnómetro. El área superficial (As) y el tamaño y distribución de fibras se determinaron por adsorción de nitrógeno y la distribución de los tamaños de poros de las fibras se determinó por adsorción de Nitrógeno y porometría de Mercurio. Para la obtención de las isotermas de adsorción se usaron celdas de equilibrio. El contenido de agua y la temperatura superficial de las fibras de caña se monitoreó con un Analizador Termogravimétrico modificado (TGA). El coeficiente efectivo de difusión de agua se calculó por el método de la pendiente. El coeficiente de transferencia de masa (hM) y el coeficiente de transferencia de calor (hH) se determinaron con datos experimentales y se compararon con una correlación de transferencia convectiva. Se obtuvieron valores de ρs de 1231 Kg./m3, ρ de 466 kg/m3 y As de 1300 m²/Kg. Las fibras de caña están formadas principalmente por micropores con un diámetro promedio de 0.0385 μm. Las isotermas de adsorción son del tipo II de forma sigmoide, consistente con las estructuras macroporosas. Los resultados mostraron que los parámetros de la ecuación GAB representan adecuadamente los datos experimentales. El orden de magnitud para el De de las fibras fue 10⁻¹⁰ m²/s. El valor de hH fue 40 W/(m².°K) y hM fue 0.045 Kg./(m².s). La fibra es un material poroso formado por macroporos y su estructura interna es diferente de la de la médula. Los valores experimentales de hH fueron más elevados que los calculados con correlaciones debido a los efectos de conducción y radiación. El principal mecanismo de transferencia de masa fue la resistencia interna, y De se incrementó con la temperatura en una función del tipo Arrhenius.
CANE PREPARATION—OPTIMISED TECHNOLOGY

By

S.T. INSKIP

Fives Fletcher Limited, Derby, England
steve.inskip@fivesgroup.com

KEYWORDS: Shredder, In-Line, Preparation, Cane.

Abstract

FIVES CAIL has developed and improved its cane preparation technology to meet the requests of modern cane sugar and ethanol factories who either want to upgrade their factories or build new ones; the major concerns being investment, performance, energy and operation. Fives Cail now has more than 30 installations of the in-line shredder in Africa, Asia and the Americas, and has continually improved and developed the design to extend the range up to a capacity of 825 tonnes cane crushed per hour, while at the same time simplifying the original designs of feed drum, rotor, hammers and anvil plate and increasing the capacity for a given carrier width. The in-line shredder technology consists of two main pieces of equipment; a cane leveller (or carding drum) and the shredder assembly, which allows for a very simple and uncomplicated installation that can be either incorporated into an existing cane carrier or installed in a new one. Its construction is modular with a small footprint. The in-line shredder will process either whole stick or billeted (short) cane or any combination of the two, and can operate in all possible conditions including the preparation of washed cane, and also cane containing a high quantity of sand or rocks. All results shown have been obtained directly from the factories, either through official channels or from personal visits by Fives Group personnel. As with all results collected under non-laboratory conditions, some approximation may be assumed; however, they tend to show fairly consistent figures. It can therefore be concluded that after several years of continual development and improvement, research and results show there are several genuine benefits, both direct and indirect, to be gained from incorporating the in-line shredder technology into a factory in order to upgrade the cane preparation performance. Benefits can be seen in terms of reduced installation costs, reduced maintenance costs, and reduced overall power consumption over more conventional cane preparation equipment.

Introduction

Cane preparation is often overlooked in a factory’s quest for general improvement in efficiency and performance when in actual fact, in the factory environment, it is probably one of the most important factors in achieving both of these. In terms of improving and increasing overall factory output, it is very probably one of the cheapest ways to do so. By improving the cane preparation from say a preparation of 75% to a preparation index above 90%, the increase in throughput, overall extraction and reduction in pol % bagasse is similar to the figure that would be expected when adding an extra mill to the crushing line, at approximately 60% of the equipment price (more if civils and drives are taken into account).

Historical

There have been few major developments in cane preparation since the introduction of the heavy duty gravity-fed shredders in the late 1960s. In order to achieve a preparation index above 90%, a typical cane preparation station for long cane comprises the following:
• 1 × leveller (1st) knife set (50 mm pitch)
• 1 × heavy duty (2nd) knife set (25 mm pitch)
• 1 × cane kicker
• 1 × gravity shredder

The cane knives are required to prepare and more importantly chop the whole-stick cane to a suitable condition to feed into a gravity shredder in order to avoid choking.

A typical installation drawing is shown in Figure 1.

![Fig. 1—A typical whole-stick cane preparation station with gravity-fed shredder.](image)

To obtain consistent preparation, the 1st knives would be positioned on an auxiliary carrier approximately 250 mm from the surface of the slats to prepare the top half of the cane bed. The part-prepared cane would be tumbled onto a 2nd (main) carrier passing through a set of heavy duty knives preparing the remaining cane to a preparation index of around 65%, before feeding into a heavy duty shredder from a height of 6 m to 7 m.

The shredded cane would then be transported to the 1st mill. The Fives Fletcher recommended installed powers in order to guarantee a preparation index of over 90% with this specification would be as follows:

- No.1 knives 11 kW.h/t fibre
- No. 2 knives 14 kW.h/t fibre
- Cane kicker 30 kW
- Gravity shredder 45 kW.h/t fibre

So, typically for a 2135 mm wide carrier and considering a cane rate of 400 t/h at 15% fibre content, the total installed preparation power would be 4230 kW.

**Contra-rotating knives**

Several manufacturers produce contra-rotating cane preparation devices, fitted with either swivelling hammers or fixed knives, and operated with a washboard. These devices can be fitted in place of the No.2 knife set to reduce the installation requirements in terms of the number of carriers required and hence overall space. Contra-rotating knives are especially useful in areas with rock problems as they tend to chip away the rocks. However, the installed power does increase as shown below.

- No.1 knives 11 kW.h/t fibre
- Cane preparator 25 kW.h/t fibre
- Gravity shredder 45 kW.h/t fibre

Again, for a 2135 mm wide carrier and considering a cane rate of 400 t/h at 15% fibre content, the total installed preparation power would be 4860 kW and the configuration is shown in Figure 2.
The requirements of a modern sugar and ethanol factory

Increasingly for the front end, clients are looking for the following advantages:

- Reduction in overall energy consumed
- Increased productivity and throughput
- Reduction in downtime
- Reduced maintenance periods and costs
- Increase in factory performance
- Cost effective changes

In-line shredder

Fives Cail developed and installed some of the first in-line shredders in the 1990s, and these designs have been constantly updated, re-designed and further developed into the present range of shredders.

The in-line shredder has been designed to process either long or short cane (in any ratio) and without the need for pre-preparation, so no cane knives are required prior to the shredder.

The shredder assembly consists of three main components, the feed drum, the shredder rotor and the anvil plate (Figure 3). In addition to these, two auxiliary pieces of equipment are required to ensure consistent feed of cane to both the shredder and No.1 mill; a carding drum and a shredded cane kicker (see Figure 4).
Carding drum
The carding drum contra-rotates against the cane flow and is responsible for two operations
- Metering flow: The carding drum acts as a metering device, holding back excessive amounts of cane in the carrier and ‘filling-in’ sparse areas, therefore providing a consistent flow of cane at the calculated carrier speed and cane density to maintain a consistent crush rate.
- Increasing compaction: The density of long cane fed into a carrier normally averages between 125 kg/m³ and 150 kg/m³. The carding drum is designed to be set at a specific height, based on carrier speed and cane throughput, to achieve the required cane compaction after the drum. The resulting cane mat is therefore at a consistent density which ensures the correct approach angle can be achieved of the cane mat relative to the feed drum. For 100% short cane, the carding drum would be used to ‘wipe-off’ the cane bed to achieve the correct calculated height for the capacity required. No additional compaction would take place.

Only one carding drum is normally required to obtain the required compaction for installation on carriers from 0 to 10 degrees. Two carding drums are recommended at angles in excess of 10 degrees and also in situations where the cane feeding is difficult to control, for instance if substantial manual and unmonitored cane feeding is allowed after the feed tables.

Feed drum
The feed drum co-rotates with the cane flow and is responsible for providing positive feed of the cane mat into the rotor and also increasing the compaction of the cane to avoid the whole stalk being swept into the anvil. The drum ‘traps’ the mat of cane against the carrier slats, increasing the compaction of cane to between 280 kg/m³ to 350 kg/m³, thus allowing the rotating hammers to ‘wipe-off’ a section of cane from the long stalks. It is most important to keep the cane entry to the drum at a good angle, to maximise throughput while keeping the carrier speed as low as possible for the required capacity. Excessive entry angles can create cane feed problems and results in drum judder which would ultimately cause increased peak loads on both drives and bearings, leading to premature failure. The peripheral speed of the feed drum is set higher than the linear speed of the carrier to provide positive feed of cane to the hammers.
Rotor

These shredders are available with two types of rotor design, either six-row or eight-row; both types incorporate alternately staggered profiled plates. The six-row design has a swept hammer diameter of 1680 mm while the eight-row swept hammer diameter is 1900 mm. Figure 6 shows capacities for both types of rotor. All the rotors should have in excess of 100% full coverage of the hammers and ideally use high grade stainless steel tie rods and hammer bars for extended life expectancy and strength. The tie rods should be tightened to specific torque ratings using hydraulic tensioning devices.

Hammers

Hammers are manufactured from 55 mm or 60 mm thick high strength, low alloy structural steel plate preferably cut along the grain of the steel. Hard facing is applied to the hammer extremities to a minimum 3 mm thickness on the facing to give a wear resistant layer of material. The specification for the weld deposit is dependent on the operating conditions expected at site; (excessive sand or rocks would dictate different materials). Normal weight for the hammers on a Fives Cail shredder is 22 kg and life expectancy is dependent on many things, but normally 14 days between hammer changes is a reasonable expectation.

Anvil plate

The entry distance between the rotor and anvil is normally fixed at around 40 mm, with adjustment at the exit side of the anvil plate being possible as required. The anvil plate adjustment bars are also fitted with shear pins to protect the rotor and grid bars in case large objects should pass through the shredder. The angle of wrap is approximately 75 degrees.

Kicker

The shredded cane is very dense and wet when it is deposited back onto the cane carrier, and tends to stick to the slats at the head end and causing uneven feed onto the resulting conveyor or carrier. To overcome this uneven feed, the installation of a shredded cane kicker is always recommended if at all possible. This kicker breaks up the cane mat, reducing the shredded cane density, and improving the consistency feed into No.1 mill intercarrier.

A typical installation is shown in Figure 5.

![Fig. 5—A typical cane preparation station with in-line shredder.](imageurl)
Again, for a 2135 mm wide carrier and considering a cane rate of 400 t/h cane at 15% fibre content, the total installed power would be 3180 kW.

**Capacity**

Fives Cail manufactures in-line shredders of both six-row (1680 mm diameter) and eight-row (1900 mm diameter). Figure 6 below shows the general capacities for the two diameters of shredder when compared with the width of the cane carrier.

The blue line represents the theoretical capacity of the 1680 mm diameter shredder rotor and the red line represents the theoretical capacity of the 1900 mm. These figures are approximate and based on cane containing 15% fibre. Every proposed installation, however, should be treated on an individual basis.

![In line shredders](image)

**Tip speed**

The calculated tip speed for the shredder is set between 88 m/s and 99 m/s, which gives a good compromise between cane preparation and hammer life.

On the 1.9 m diameter rotor, both 50 Hz and 60 Hz electric motors can operate at synchronous speed (at either 900 r/min or 1000 r/min) with no need for gear reduction.

The 1.68 m diameter rotor operates within the desired range at 60 Hz (88 m/s) and, although the tip speed is slightly slow when operating at 50 Hz (80 m/s), good results have been obtained. Turbine drives should be designed to operate with a minimum tip speed of 90 m/s.

**Performance**

Results were obtained from a random selection of factories, either sent to Fives Cail by the factory technicians or from the collection of results directly from site by Fives Group engineers, and the results collated into the graphs shown in Figure 7.
From these graphs, it can be seen that the absorbed power for the in-line shredder is normally around 40 kW.h/t fibre. Only three installations are operating in excess of 50 kW.h/t fibre; significantly all operate at less than 80% of their intended capacity and so it appears preferable to operate the machines and drives under load and close to their design capacities to prevent inefficiencies occurring. The drive split for the factories shown below is approximately 50/50 turbines and electric motors.

**Advantages of the in-line shredder**

- **One-stop cane preparation:** No pre-preparation is required.
- **Retro fitting:** A huge advantage with the in-line shredder is the ability to fit the shredder and carding drum into an existing carrier layout, (the shredders are supplied complete with all casings to match with the existing carrier sideplates). Normally, the installation can be achieved with a minimum of modification and incorporating most of the original equipment including carrier drives and drive positions, slats, etc (although the slats have to be operated in a ‘reversed’ direction to work successfully with the contra-rotating rotor). For factories that operate year-round, the shredder and carding drum can be positioned around existing knives and leveller equipment so that the new installation can be built and commissioned within two to three weeks.
- **Space:** Only 1 × carrier and 1 x conveyor are required to transport cane from the feed tables to No.1 mill.
- **Simplicity:** Fewer cane carriers mean there are significantly reduced costs in terms of material stocks and off crop maintenance for slats, drives, chain etc.
- **Installation costs:** In any project, in addition to the overall cost of the equipment, any civil works must also be considered. The in-line shredder cuts installation costs because it requires a very much smaller footprint regarding civil foundations, and a lower height requirement. The design requires a reduced quantity of machinery and with fewer drives.
• Versatility: In-line shredders will operate in almost all conditions, with washed or dry cane, in sandy areas and also in areas where rocks are a particular problem as the reverse rotation nature of the rotor means that rocks up to 300 mm diameter tend to be chipped into small pieces, thus protecting the mills.

• Long fibres: Because the shredder is processing cane that is not pre-knifed, the resulting cane fibres it produces are usually slightly longer, which tends to reduce mill slippage as the cane mat binds together better. Long fibres can also be advantageous to boiler operation.

• Increased extraction: Cane with a greater breakage of cells (i.e. more highly prepared) generally results in increased mill extraction, lower pol % bagasse figures and lower final bagasse humidity. Several suggestions have been made as to the increase in extraction possible. Moor (1974) suggests 0.045 units of extraction per 1% increase in preparation index; Edwards (1995) suggested a 0.1% increase in extraction per 1% increase in preparation index. Independent tests carried out at Tongaat Hulett in South Africa some years ago indicated an increase of 0.83% extraction for each 1% increase in preparation index within the range of 87% to 94%.

• The shredder rotor (and carrier width) can be increased later for higher capacities or phased expansions.

• Example case: At the Benito Juarez factory, cane preparation of preparation index approximately 80% was achieved using two cane knives and a light duty shredder. Factory results for this installation over a crop period showed a reduced extraction of 94.9% with an average imbibition rate of 26.6% on cane. After the shredder installation and with no other significant changes to the extraction plant, the reduced extraction increased to 95.85% with an imbibition rate of 21.4% on cane. These results would suggest an increase in extraction of approximately 0.1% per 1% increase in preparation index. Similarly, pol % bagasse reduced from 2.3% to 1.9%. However, these improved figures should be taken as an indication only as to what might be possible rather than an expectation of results.

• Energy savings: For the examples shown earlier in the text, the installed cane preparation powers as advised by Group Fives are as follows:

| In-line shredder | = 3180 kW |
| Cane knives + gravity shredder | = in-line shredder + 33% = 4230 kW |
| Cane knife + preparator + gravity shredder | = in-line shredder + 53% = 4860 kW |

The figures show that significant savings can be made regarding energy usage, allowing increased exportation to the grid where possible. For factories where energy savings are preferential to extraction, it is worth noting that a shredder can increase the overall performance by approximately the same amount as an extra mill; therefore, one existing mill could possibly be removed or bypassed, thus further increasing potential energy exportation.

Note: The figures above are a general indication of installed power only. In some areas, it is possible to install slightly lower installed power than in others. The relative percentage savings of the in-line shredder, both in terms of installed and absorbed power usually, however, remain.

• Reduced maintenance and downtime: To completely change the in-line shredder hammers takes approximately two hours and normally there is no more work required during the crop other than general adjustments. Hammer changes usually
take place at either one week or two week intervals during scheduled maintenance stops. Some factories that do not have scheduled stops change only half the hammers at any one time thus allowing them to complete the task very quickly (1 to 1.5 hours). This operation is completed during unscheduled stops (general breakdowns, process house full etc), so hammer changes do not require any specific down-time. Also, fewer hammers and knives (no cane knives and fewer hammers than a gravity shredder, 144 instead of 180 on an 2135 mm, eight-row shredder) means fewer weld repair materials, reduced man hours in terms of both repair and replacement, and reduced stock levels of equipment

- Milling operation: The addition of a carding drum and an in-line shredder will give a very consistent rate of cane feed, which improves the consistency of the whole milling operation, generally resulting in higher average milling performances.

- Mill protection: No magnet is required before the shredder, but a magnet is always recommended between the shredder and 1st mill to remove any ferrous materials and thus protect the mill. Therefore, No.1 mill is protected from both ferrous materials and rocks, reducing tooth breakage.

Disadvantages
- Individual installed drive power for the shredder rotor is generally higher than for a gravity shredder.
- A slat carrier is normally recommended for this type of shredder.

Conclusion

Fives Group manufactures and supplies almost all different types of cane preparation equipment; cane knives, cane preparators and both main types of heavy duty shredder, (the Fives Cail in-line design and the Fives Fletcher/Tongaat Hulett gravity design). Therefore, the company has no particular bias to any one type of equipment over another and so a balanced overview can be assured. For either new installations or for upgrading purposes, calculating the operational and financial advantages as well as the payback period is of utmost importance and so some or all of the following arguments might be considered:

- Increased co-generation potential
- Lower overall installed power
- Reduced routine and end-of-crop maintenance
- Reduction in off-crop oil consumption due to increased bagasse stocks
- Reduced civils and installation costs
- Reduced down-time (due to simplified installation)
- Reduction in man-hours and materials for refurbishing hammers and knives

It can be seen from the preceding arguments that for the majority of new installations and upgrades, there are genuine advantages to be gained from installing an in-line shredder, in terms of energy savings, installation and civil costs, maintenance savings and particularly co-generation benefits that will allow factories to operate at a higher level of efficiency than might previously have been possible.

MOTS-CLEFS: Shredder, en Ligne, Préparation, Cannes

Résumé

Fives Cail a développé et amélioré sa technologie de préparation de canne à sucre pour répondre aux demandes des sucreries et usines d'éthanol qui veulent moderniser ou construire de nouvelles usines. Les principales préoccupations sont l'investissement, les performances, l’énergie et les opérations. Fives Cail a installé plus de 30 shredders en ligne, en Afrique, Asie et dans les Amériques. On a continuellement amélioré et développé la conception afin d'élargir la gamme jusqu'à une capacité de 825 tonnes canne heure, tout en simplifiant les conceptions d'alimentation, du tambour, du rotor, des marteaux et de l’enclume, tout en augmentant la capacité pour une largeur de transporteur donnée. La technologie shredder en ligne se compose de deux éléments principaux: une égalisation du niveau des cannes et l'assemblage du shredder, qui permet une installation très simple qui peut être soit intégrée dans un système existant ou installée dans une sucrerie neuve. Sa construction est modulaire avec un faible encombrement. Le shredder en ligne peut traiter la canne entière, des tronçons ou n'importe quelle combinaison des deux; il traite aussi la canne lavée et des cannes contenant une grande quantité de sable ou de roches. Tous les résultats présentés ont été obtenus directement des usines, soit par des canaux officiels, soit à partir des visites par le personnel du groupe Fives. Les résultats recueillis en dehors du laboratoire sont toujours moins certains ; toutefois, ils tendent à montrer des chiffres assez cohérents. Il peut donc être conclu qu'après plusieurs années de développements et d'améliorations, la recherche et les résultats montrent plusieurs avantages, directs et indirectes, avec l’installation du shredder en ligne dans une usine. Ces avantages comprennent des frais d'installation et des coûts de maintenance réduits et moins d’énergie, compare aux équipements de préparation plus conventionnels.
PREPARACIÓN DE CAÑA—TECNOLÓGIA OPTIMIZADA

Por

S.T. INSKIP

Fives Fletcher Limited, Derby, England
steve.inskip@fivesgroup.com

PALABRAS CLAVE: Desfibradora, en línea, Preparación, Caña.

Resumen

FIVES CAIL ha desarrollado y mejorado su tecnología de preparación de caña para satisfacer los requerimientos de fábricas modernas de azúcar y etanol que buscan mejorar las fábricas o construir nuevas, siendo las mayores preocupaciones la inversión, desempeño, energía y operación. Fives Cail tiene a la fecha más de 30 desfibradoras en línea instaladas en África, Asia y las Américas, y ha mejorado y desarrollado continuamente el diseño para extender el rango de operación hasta una capacidad de 825 toneladas de caña por hora simplificando al mismo tiempo los diseños originales del tambor alimentador, rotor, martillos y yunque e incrementando la capacidad para un ancho de conductor determinado. La tecnología de la desfibradora en línea consiste de dos piezas principales de equipo: un nivelador de caña (o tambor peinador) y el conjunto de la desfibradora lo que permite una instalación simple y descomplicada que puede ser incorporada a un conductor existente o instalada sobre uno nuevo. Su construcción es modular con pocos requerimientos de espacio. La desfibradora en línea procesa caña entera o caña trozada o cualquier combinación de las dos, y puede operar en todas las condiciones posibles incluyendo la preparación de caña lavada o que contenga cantidades importantes de arena o piedras. Todos los resultados presentados han sido obtenidos directamente de las fábricas, bien a través de canales oficiales o a partir de visitas de personal de Fives Group. Como sucede con todos los datos obtenidos bajo condiciones fabriles y no de laboratorio deben suponerse algunas aproximaciones; sin embargo tienden a mostrar cifras bastante consistentes. Por lo tanto se puede concluir que después de varios años de continuo mejoramiento y desarrollo, la investigación y los resultados muestran que hay varios beneficios genuinos, tanto directos como indirectos, que pueden ser obtenidos incorporando la tecnología de desfibrado en línea en una fábrica para mejorar la preparación de caña. Los beneficios respecto a equipo más convencional se observan en términos de costos reducidos de instalación, menores costos de mantenimiento y menores consumos de potencia.
SUGAR-MILL COUPLING DEVELOPMENTS
SINCE 1987

By

C.T. TOSIO
Eurogear (Pty) Ltd, Johannesburg, South Africa
eurogear@global.co.za

KEYWORDS: Coupling, Mill, Rope.

Abstract

Since the installation of the first Eurogear patented ‘rope’ coupling at the Umfolozi (South Africa) factory in 1987, the design has undergone numerous developments with respect to the materials of construction and the method of fixing to shafts. The material of construction of the main coupling components has been changed from cast steel grade A3 to fabricated steel grade 300WA and cast steel grade A4 to reduce its cost. Because of fatigue problems caused by excessive misalignment, steel wire ropes have been replaced by two new types of flexible members: polyester slings and the link plates with spherical plain bearings. The coupling hub to be connected to the shaft square has been significantly redesigned to simplify installation and to ensure a more even distribution of stress, even on damaged shafts. Shear pins have been introduced to provide a mechanical torque limitation system to protect the coupling, shaft and gearbox components. With all the developments over the last 24 years, the rope coupling is now a mature product and can provide enormous benefits to consumers.

Introduction

Since the installation of the first Eurogear patented ‘rope’ coupling at the Umfolozi (South Africa) factory in 1987 (Tosio, 1992), the design has undergone numerous developments with respect to the materials of construction and the method of fixing to shafts.

The paper discusses these developments and the reasons behind them, and also outlines new design options.

Background

Under misaligned conditions (which is nearly all the time), traditional ‘tail-bar’ couplings have the following detractions:

- They generate thrust between the mill and final-drive gearbox, resulting in wear to mill components, and gearbox bearing failures.
- In the event of a transverse mill shaft break, the gearbox can be severely damaged by the resulting thrust generated.
- They apply bending moments to the gear shaft that misalign the gear teeth because of bearing clearances, resulting in premature deterioration and failure.
- They are inefficient, and the power loss can affect mill performance if the available power is marginal.
- They require regular lubrication during operations, significant repair costs to shaft squares in the off-crop, and sometimes even cause shaft breakages.

Rope couplings

The ‘rope’ coupling, as it became known, was designed in 1986 to eliminate all of the undesirable effects of tail-bar couplings.

The SWR (Steel-Wire-Rope) coupling is shown in Figure 1.
Fig. 1—The SWR coupling.

The ropes connect the driving and driven yokes in a plane normal to the shaft axes via a floating strut that bends the ropes into two parallel pairs of flexible members roughly at right angles to one another.

Considered in static mode, the pair of near-horizontal ropes can absorb vertical misalignment, while the near-vertical pair of ropes can absorb horizontal misalignment. In addition, any axial movement can be absorbed by all the ropes flexing sideways.

The coupling can absorb any misalignment that may be required in driving a sugar mill, without causing any ill-effects to the mill or gearing.

**Coupling developments**

**Introductory remarks**

Over the years, numerous changes have been made to the design, all in the interests of improving the product.

**Materials of construction**

The yokes of the first 1987 coupling were made of cast steel, grade A3. This material proved to be very good, but expensive, and so other materials of construction were investigated.

Local foundries strongly advocated the use of SG iron, also known as ductile iron. The grade selected, for strength reasons, was SG60. This material worked well for about seven years, but costly failures occurred.

The first failure was caused by a severely out-of-square shaft that caused contact on only two points in the bore that resulted in extreme stresses in the material. The second failure was a casting failure caused by casting the yoke with the hub up. This process led to very slow cooling of the hub section that resulted in carbide separation and very brittle properties.

The material failures led to a re-think and, since then, all couplings have either been fabricated in mild steel grade 300WA of 280 MPa minimum yield strength, or cast steel grade A4, with minimum yield strength of 320 MPa.

**Flexible elements**

The flexible elements that provide the misalignment capability of the coupling have seen a much more radical change. The steel wire ropes proved perfectly suitable for driving mills that are
well aligned to the final drive gearing and well operated (as they should be). In these circumstances, the normal maximum misalignment is less than 20 mm.

In 1997, one installation in South Africa and numerous installations in Brazil suffered premature rope failure. Although lift-indicators showed that misalignment was minimal, this assessment was incorrect. Subsequent irrefutable tests proved that the actual misalignment was, in all of these cases, in excess of 35 mm. As a result, the steel wire ropes had to flex back and forth more than 70 mm every revolution. This movement proved far too much for the steel-wire ropes, especially in Brazil where milling speeds are typically 7 r/min, and alternative designs had to be sought to cope with this type of problem.

Two other flexible members have subsequently replaced the steel wire ropes, namely polyester slings (Figure 2) and link plates fitted with maintenance-free spherical plain bearings (Figure 3).

Fig. 2—Rope coupling with polyester slings.

Fig. 3—Rope coupling with link plates fitted with spherical plain bearings.
The polyester slings (Figure 4) are proving very reliable, although attention has to be paid to the following to ensure they work as designed:

- It is essential that the slings are all the same length so they share the load equally.
- The slings have to be manufactured very uniformly in cross-section so that all the strands share the load equally.
- Frequent destructive tests should be carried out on slings to be sure design service factors are maintained, and that fabricators are not cutting corners.

![Polyester Sling Undergoing Destructive Test](image)

Spherical plain bearings have not achieved the life predicted by the suppliers, but there are numerous reasons for this, the main causes being abuse during operations and poor storage practices during the off-crop.

**Fixing hubs to shafts**

The biggest challenge in the first 10 years of making couplings was to design a good system of fitting yoke-hubs onto shaft-squares that were never, in fact, square. From very early days, all engineers have been advised (in our data sheet that they complete) to restore shafts to original dimensions, and make sure they are square. A typical, non-square, shaft square is shown in Figure 5.

![An Un-Repaired Shaft Square](image)

The first (1987) coupling was fitted to the shaft square with keys. This design required excessive fitting time because of poor machining, so a better system was needed.
Subsequently, cast SG iron couplings were profile cast and machined to slide onto the squares and were fixed in position using reversing screws. This method worked reasonably well until a seriously out-of-square shaft caused failure due to uneven loading and high stress-generation. The practice was subsequently discontinued.

Hubs were then fitted onto shafts using heavy-duty shrink-discs (Figure 6). This method works very well if squares are accurately machined and square, so is good for new installations such as at the Komati factory in South Africa in 1994. This method also requires excessive fitting time and was not deemed suitable for retro-fit installations. Lighter shrink-discs (quicker to fit) were tried but also required close shaft-tolerances. Old shaft-squares are never properly repaired or restored to original dimensions, so this system was also discontinued.

Fig. 6—Shrink-discs used to fit couplings to shafts.

The final solution to fitting problems was introduced in 1996 when a new profile bore design was introduced (Figure 7), and it has been so successful there is no intention to change it.

Fig. 7—Hub fitting on shaft.
This strange-looking slide-on design has a cast or profile-cut bore with very large corner radii, which minimises stresses. In taking load, the bore makes contact close to, but not quite on, all four corners of the square. Note each bore-profile has to be specially designed to fit in the optimum position. Initially the arc-to-flat contact is only line contact, but this line crushes immediately load is applied until the flattened area is so large that the stress falls below the yield point of the hub material, which is always softer than the shaft.

This design caters to small shaft-square dimensional inaccuracies, and always ensures four-corner load-sharing. It also optimises the hub thickness and therefore minimises the cost of manufacture. It can distort slightly should this be necessary, thereby ensuring that all corners are equally loaded. The hubs are retained on the outside ends of the squares by sets of ‘Sandwich’ plates (Figure 8).

![Figure 8 — Hub fitting on shaft.](image)

**Torque limitation**

For the past five years, all designs have had a torque limitation option in the form of shear pins to protect the mill and (more importantly) gearbox from damage should a pinion break or a large object enter the mill and cause a stall. For design purposes, a break torque of 150% of estimated normal driving torque has been used.

The shear-pins, shown in Figure 9, are always fitted to a pair of flanges integral with the gear-side hub or tube-to-yoke connection. The flanges are fitted with hardened bushes to support the shear pins without themselves being damaged.

In the event of the shear pins failing, the coupling stops turning, providing a very visible indication of a problem. The cause of the failure can then be investigated and the shear pins can be replaced. Shear pin replacement takes only a few minutes.

**New Designs**

The following new designs are available:

1. Eurogear’s MKI ‘Link’ coupling, which is of similar construction to the polyester-sling coupling, but which utilises link-plates containing spherical plain bearings to impart the flexibility required.
2. Eurogear’s MK VI ‘multi-link’ coupling, that utilises spherical plain bearings to give it misalignment properties. This coupling is similar to a universal coupling, but has the added advantage of end collapsibility. It was designed for customers who did not like the large swing of the other designs.
Conclusions

Since its introduction in 1987, the rope coupling has undergone significant further development.

The material of construction of the main coupling components has been changed from cast steel grade A3 to fabricated steel grade 300WA or cast steel grade A4 to reduce its cost.

Because of fatigue problems caused by excessive misalignment, steel wire ropes have been replaced by two new types of flexible members: polyester slings and the link plates with spherical plain bearings.

The coupling hub to be connected to the shaft square has been significantly redesigned to simplify installation and to ensure a more even distribution of stress, even on damaged shafts.

Shear pins have been introduced to provide a mechanical torque limitation system to protect the coupling, shaft and gearbox components.

With all the developments over the last 24 years, the rope coupling is now a mature product and can provide enormous benefits to consumers.

DEVELOPMENTS DES MANCHONS
POUR LES MOULINS DEPUIS 1987

Par

C.T. TOSIO
Eurogear (Pty) Ltd, Johannesburg, South Africa
eurogear@global.co.za

MOTS CLEFS: Manchons, Moulin, Corde.

Résumé
Depuis l'installation de la première 'corde' brevetée Eurogear comme manchons à l'usine de Umfolozi (Afrique du Sud) en 1987, les matériaux de construction et la méthode de fixation d'arbres ont subi de nombreux développements. Le matériau de construction des composants principaux est maintenant l’acier 300WA et l’acier grade A4, au lieu de la fonte A3, pour réduire les frais. En raison de problèmes de fatigue, causés par un mauvais alignement, les câbles d'acier ont été remplacés par deux nouveaux types de membres flexibles: écharpes polyesters et les plaques de lien par des rotules. On a simplifié l'installation du manchon pour assurer une répartition plus uniforme du stress, même sur les arbres endommagés. Des mesures ont été introduites pour limiter le couple mécanique afin de protéger le manchon, l’arbre et la boîte de vitesse. Avec tous les développements au cours des 24 dernières années, le manchon a corde est maintenant un produit bien établi et peut fournir des avantages sérieux pour les consommateurs.

DESARROLLOS DE ACOPELES PARA MOLINOS DE CAÑA DESDE 1987

Por

C.T. TOSIO
Eurogear (Pty) Ltd, Johannesburg, South Africa
eurogear@global.co.za

PALABRAS CLAVE: Acople, Molino, Cable.

Resumen
Desde la instalación del primer acople 'de cable' patentado de Eurogear en el ingenio Umfolozi (Sudáfrica) en 1987, el diseño ha tenido numerosos desarrollos respecto a los materiales de construcción y el método de fijación a los ejes. El material de construcción de los componentes principales del acople ha sido cambiado del acero fundido grado A3 a acero laminado grado 300WA y acero fundido grado A4 para reducir su costo. Debido a problemas de fatiga causados por excesivos desalineamientos, los cables de acero han sido reemplazados por dos nuevos tipos de elementos flexibles: eslingas de poliéster y platinas de conexión con cojinetes planos tipo rótula. El cubo de acople que se conecta al cuadrante del eje ha sido significativamente rediseñado para simplificar la instalación y asegurar una distribución más pareja de esfuerzos aún en ejes deteriorados. Se han introducido pasadores de corte para proveer un sistema mecánico de limitación de torque para proteger el acople, el eje y componentes del reductor. Con todos los desarrollos durante los últimos 24 años, el acople de ‘cable’ es ahora un producto maduro y puede dar enormes beneficios a los usuarios.
THE EFFECT OF ADDED WATER TEMPERATURE ON MILLING TRAIN OPERATION AND PERFORMANCE

By

G.A. KENT

Queensland University of Technology, Brisbane, Australia
g.kent@qut.edu.au

KEYWORDS: Added Water, Imbibition, Maceration, Milling, Extraction.

Abstract

Four recent factory experiments have been conducted to provide information to determine an optimal added water temperature. The results were not completely conclusive but did provide some further insight into the effect of added water temperature. The effect of added water temperature on extraction has proven particularly difficult to measure. There is little doubt that bagasse is more compressible at higher temperature. Two experiments have shown that bagasse moisture content is lower at higher temperature. These effects are most likely related. Two experiments produced indirect evidence of an increase in extraction with higher added water temperature. With bagasse being more compressible, mill capacity is increased at higher temperature. The use of a heat exchanger to cool added water with mixed juice reduces heat loss and consequently reduces steam usage for primary heating of juice. Some of the lost heat may serve a useful purpose in increasing boiler efficiency, resulting in more efficient use of bagasse. Hotter added water does not appear to be a complete solution for mill hygiene since even the hottest added water investigated only provides sufficient benefit for the last one or two mills. There remains considerably more work to identify the optimal added water temperature. The main outstanding issues are the effect of added water temperature on extraction, the effect of hotter bagasse on boiler efficiency through moisture content or temperature and the impact of bagasse temperature on hygiene.

Introduction

According to Maxwell (1932), the optimal temperature for milling train added water has been debated since the nineteenth century (von Czernicky, 1899). Chen (1993) provided a comprehensive list of the arguments with benefits of high temperature being fuel economies, rupture of cells, evaporation from bagasse in transit, use of return condensate from evaporators and a gain in extraction, and disadvantages of high temperature being extraction of gums and impurities, poorer mill feeding and the facilitation of growth of micro-organisms that produce dextran.

Much of the data on which today’s understanding of the impact of added water temperature dates back many years. Maxwell (1932) questioned the validity of the results of von Czernicky (1899) since milling technology had changed in the intervening 30 years. Milling technology has continued to evolve, with innovations such as roll roughening, closed feed chutes and automatic control systems. There is a need to reassess conventional wisdom on the subject.

This paper reviews past work, presents recent work and presents a theory to explain the measured impacts.

Definitions

Throughout this paper, added water refers to water that is added to the milling train to aid the extraction process. Added water is usually applied before the final mill.
Most past work on the subject uses the terms *maceration* or *imbibition*. Clayton (1971) defines imbibition as *the process in which water or juice is applied to a bagasse to enhance the extraction of juice at the next mill*. This definition includes the above definition of added water but also includes juice added to mills before the final mill. Clayton (1971) indicates that the term maceration is used *loosely as an alternative to the term imbibition*.

**Review of past work**

**Fuel economy**

Fuel economy results from a boiler efficiency increase that can be achieved through burning bagasse of lower moisture content. Khainovsky (1929) reported reductions in bagasse moisture content from cold maceration (20°C to 30°C) to hot maceration (80°C to 90°C) processes.

**Rupture of cells**

Khainovsky (1929) reported that living cells were not ruptured and actively worked to increase their sucrose content. He found that, using cold imbibition, living cells could still be detected in final bagasse. The actual temperature at which living cells were killed was not measured but Khainovsky indicated it was about 60°C.

Ramaiah *et al.* (1979) stated that surface tension effects were responsible for sucrose being trapped in cells. Kumar and Agrawal (2000) stated that hot imbibition reduces surface tension effects, increasing extraction. No supporting evidence was presented.

**Evaporation from bagasse in transit**

Hotter added water results in hotter bagasse. While it is expected that hotter bagasse will result in greater evaporation, and hence lower moisture content, it is not believed that any such measurements have ever been published.

**Use of return condensates from evaporators**

Many factories use hot condensates from the evaporators for added water. Valdes *et al.* (1994) presented a study to maximise energy efficiency at different added water temperatures.

In some factories, maceration heaters are used to increase added water temperature. Doss (1986) recommends the addition of steam to imbibition in a process called steam aided imbibition. Other published reports discuss methods to reduce added water temperature. Nigam *et al.* (1990) discuss mixing hot condensate with cold water. Leal *et al.* (1986) and Castellat and Mendoza (1988), as reported by Valdes *et al.* (1994), along with Bhojaraj (1990) and Nandagopal (1991), indicate that using a heat exchanger with mixed juice as a cooling fluid is a more energy-efficient method to reduce added water temperature. Bhojaraj (1990) indicates this method can save 3% steam on cane.

**Extraction of sucrose**

Khainovsky (1929) reported reductions in bagasse pol content between the use of cold maceration (20°C to 30°C) and hot maceration (80°C to 90°C) processes. Khainovsky noted that hot bagasse was more compressible and indicated that this property was responsible for the improved performance.

From studying extraction results over several seasons, Gonzalez (1953) found no change in extraction after changing added water temperature from 77°C to 55°C.

Sugar Research Institute (1955) found an increase in total pol extraction by increasing added water temperature from 38°C to 77°C. The hot added water tests also involved the addition of steam into the mill boots, resulting in hotter bagasse at the intermediate mills and increased added water rate because of the condensed steam.

Haines and Hughes (1962) found an increase in pol extraction by increasing added water temperature from 26°C to 77°C.

Hugot (1986) reported that, of his four factories, one factory found an improvement in extraction with hot imbibition but the remaining three factories did not.
Ramasamy (1988) conducted factory and laboratory experiments to compare different imbibition temperatures and steam aided imbibition. He found that bagasse pol content was lower with higher temperature imbibition and attributed that lower pol content to sucrose inversion. He presented no evidence that sucrose inversion was the cause of the lower pol content (as opposed to, for example, the compressibility mechanism proposed by Khainovsky (1929).

**Extraction of impurities**

Honig (1953) carried out a factory experiment to investigate extraction of waxy matter. He carried out 10 pairs of tests with added water temperatures of 28°C and 85°C and concluded that there was no definite proof that added water temperature affected extraction of waxy matter.

Gonzalez (1953) found that sugar filterability was much poorer with an added water temperature of 77°C than with an added water temperature of 55°C. He concluded that poor filterability came from the rind of the cane and hypothesised that it was extraction of waxes that caused the problem.

Garcia and Saska (1992) conducted a laboratory study on the effect of imbibition temperature on the extraction of polysaccharides and lignins. No results were presented.

**Mill feeding**

Khainovsky (1929) reported that, for a milling train set for cold maceration, mill capacity (feeding) initially drops when hot maceration is first used. When optimal mill settings for hot maceration are determined, capacity returns to the cold maceration level.

Sugar Research Institute (1955) found that increasing the imbibition temperature by about 30°C to 77°C resulted in an increase in mill speed.

Haines and Hughes (1962) found that mill feeding became noticeably more difficult at imbibition temperatures above 82°C.

**Growth of micro-organisms**

Moroz (1963), referencing the work of Hucker and Pederson (1930), reported on the presence of micro-organisms in juice, most notably *Leuconostoc mesenteroides*, that are known to cause dextran. He indicated that the temperatures for optimal growth of these micro-organisms was 21°C to 25°C but that the micro-organisms can grow within the wider temperature range from 5°C to 45°C. Moroz recommended temperatures over 65°C for good hygiene.

**Factory experiments**

**Design**

This section summarises the results of four factory experiments undertaken by the author into the effect of added water that have been conducted recently (Table 1).

At Isis and Ledesma, the cooler temperature was achieved through the use of a mixed juice heater, similar to those described by Leal *et al.* (1986), Castellat and Mendoza (1988), Bhojaraj (1990) and Nandagopal (1991).

At Plane Creek and Macknade, the cooler temperature was achieved by mixing the hot condensate with cool injection water, similar to the process described by Nigam *et al.* (1990).
Results

Expressed juice temperature

Figure 1 presents the average expressed juice temperatures for the three factories where measurements were made. Even though the added water temperature at each factory differed by over 30°C, the temperature of the mill 5 expressed juice differed by no more than 22°C, and the temperature of the mill 2 expressed juice differed by no more than 6°C.

![Graph showing expressed juice temperatures](image)

A horizontal line has been drawn across the graph at 65°C, the temperature recommended by Moroz (1963) for good hygiene. The measurements show that, to achieve a juice temperature over 65°C on the final mill, the added water temperature needs to be above 75°C. A juice temperature over 65°C on the second last mill was only achieved with an added water temperature above 92°C. If a temperature above 65°C is to be achieved along the milling train, additional heating is required in the intermediate mills.

Delivery nip compaction

Figure 2 presents the average increase in delivery nip compaction from the tests with the coldest added water temperature to the tests with the hottest added water temperature. Analyses of variance showed that the delivery nip compaction difference for mill 4 and mill 5 at Isis and all mills at Macknade was statistically significant.

![Graph showing increase in delivery nip compaction](image)
The difference in delivery nip compaction has an increasing trend from mill 1 to the final mill in all cases, although the mill 4 result from Plane Creek is quite different. Figure 3 plots the increase in delivery nip compaction against the increase in juice temperature for the Macknade results and shows an almost linear trend. These results support the conclusion of Khainovsky (1929) that bagasse is more compressible at higher temperature.

![Graph showing the relationship between delivery nip compaction difference and juice temperature difference](image)

**Fig. 3—Increase in delivery nip compaction as a function of the increase in juice temperature for the Macknade tests.**

**Total pol extraction and final bagasse moisture content**

Table 2 presents the average increase in total pol extraction and average decrease in final bagasse moisture content from the tests with the coldest added water temperature to the tests with the hottest added water temperature. Analyses of variance revealed that the extraction difference at Plane Creek and the moisture content differences at Isis and Macknade were statistically significant.

**Table 2—Summary of average increase in total pol extraction and final bagasse moisture content from coldest to hottest added water.**

<table>

<tr>
<td>Plane Creek</td>
<td>−0.8</td>
</tr>
<tr>
<td>Macknade</td>
<td>−0.1</td>
</tr>
</tbody>
</table>

The Isis and Macknade bagasse moisture content results were both statistically significant and showed a reduction in bagasse moisture content with an increase in added water temperature, in line with the results of Khainovsky (1929). The Ledesma and Plane Creek results showed the opposite trend but were not statistically significant. Consequently, the Isis and Macknade results are considered a more reliable indicator of the true trend. These results support the delivery nip compaction results, since higher delivery nip compaction is expected to result in lower bagasse moisture content.

The delivery nip compaction and bagasse moisture content results support the argument that an increase in added water temperature will cause an increase in extraction. The Isis and Macknade
results, where statistically significant bagasse moisture results were obtained, do not show this trend. The Plane Creek extraction results, which were statistically significant, show the opposite trend.

At Isis Mill, the cooler added water temperature caused a large increase in torque, beyond the ability of the control system to compensate. To limit the torque, the average added water rate was increased during the cool added water tests from 307 % fibre to 362 % fibre, a statistically significant difference. The increase in added water rate can be expected to increase extraction. Since no increase in extraction was observed during the cool added water tests, it can be concluded that the increase in extraction due to the higher added water rate was counteracted by a decrease in extraction due to the cooler added water temperature.

At Macknade Mill, although the order of tests was randomised, the ratio of pol to fibre in cane was higher during the cool added water tests (1.06 compared to 1.02), a statistically significant difference. Extraction can be expected to be higher when the pol to fibre ratio in cane is higher. Since no increase in extraction was observed during the cool added water tests, it can be concluded that the increase in extraction due to the higher pol to fibre ratio was counteracted by a decrease in extraction due to the cooler added water temperature.

While there is no direct evidence to show that an increase in added water temperature causes an increase in extraction, there is some indirect evidence that such a trend exists. These results support those of Khainovsky (1929), Sugar Research Institute (1955), Haines and Hughes (1962), Hugot (1986) and Ramasamy (1988). There is also, unfortunately, some contradictory evidence such as the Plane Creek Mill results. Weighing the evidence, the author believes that a small increase in extraction with an increase in added water temperature does occur but that it is difficult to measure. This increase is believed to be about 0.2 units of extraction, for an increase in added water temperature from 60°C to above 90°C. An analysis of the Macknade Mill results indicated a standard error in the extraction measurement of 0.6 units of extraction, at least partly explaining why an extraction difference is hard to detect.

**Feed chute exit compaction**

Figure 4 presents the average increase in feed chute exit compaction from the tests with the coldest added water temperature to the tests with the hottest added water temperature. Analyses of variance revealed that the feed chute exit compaction difference for mill 4 at Isis and mill 1, mill 3, mill 4 and mill 5 at Macknade were statistically significant.
The Macknade results do show an increasing trend of feed chute exit compaction with added water temperature, like the delivery nip compaction trend. There is also some evidence of a trend in the Isis and Plane Creek results, although there is some contradictory data. Figure 5 plots the increase in feed chute exit compaction against the increase in juice temperature for the Macknade results and shows, as for the delivery nip compaction results, an almost linear trend. These results provide further evidence that bagasse is more compressible at higher added water temperature.

![Figure 5](image_url)

**Fig. 5—Increase in feed chute exit compaction as a function of the increase in juice temperature for the Macknade tests.**

The feed chute exit compaction is a strong indicator of mill feeding and mill capacity and, unlike mill speed, is independent of fibre rate and mill settings. Higher feed chute exit compaction indicates better mill feeding and correlates with lower mill speed. The feed chute exit compaction at the final mill at Macknade increased 7% by increasing the added water temperature from 61°C to 92°C.

**Energy efficiency**

As part of the experiment at Isis, where a mixed juice heater was used to cool the added water, the heating effect on mixed juice was also examined. By cooling the added water from 98°C to 60°C, the mixed juice temperature increased from 42°C to 54°C. As a result, the steam flow to the primary heaters reduced from 12.5 % cane to 10.8 % cane.

The fact that less steam was required for the cool added water case indicates that it is a more energy efficient option. In the cool added water case, some heat is transferred from the added water directly into mixed juice. In the hot added water case, heat is transferred from the added water to the bagasse and from the bagasse into mixed juice, with some heat lost either in vapour along the milling train and in bagasse. The hotter bagasse may also translate into an energy saving due to improved boiler efficiency, either by greater evaporation to reduce bagasse moisture content or by feeding hotter bagasse into the boiler. The size of this benefit has not been measured or estimated but may at least partly offset the higher juice heating requirement.

**Conclusions**

The effect of added water temperature on extraction has proven difficult to measure. There is little doubt that bagasse is more compressible at higher temperature. Two experiments have shown that bagasse moisture content is lower at higher temperature (1 to 2 units as added water
temperature increased from 60°C to 90°C). These effects are most likely related. Two experiments produced indirect evidence of an increase in extraction with higher added water temperature (predicted to be about 0.2 units). One experiment provided direct evidence of a decrease in extraction with increasing added water temperature. This result is inconsistent with the remaining evidence but cannot be discounted. More research is required to better understand this extraction effect.

With bagasse being more compressible, mill capacity is increased at higher temperature (7% for the final mill at one factory, where bagasse temperature increased from 53°C to 75°C).

The use of a heat exchanger to cool added water with mixed juice reduces heat loss and consequently reduces steam usage for primary heating of juice.

Some of the lost heat may serve a useful purpose in increasing boiler efficiency resulting in more efficient use of bagasse, but this effect has not been measured.

Hotter added water does not appear to be a complete solution for mill hygiene. If bagasse needs to be heated above 65°C, even the hottest added water temperatures only provide sufficient benefit for the last one or two mills.

There remains considerably more work to identify the optimal added water temperature. The main outstanding issues are the effect of added water temperature on extraction, the effect of hotter bagasse on boiler efficiency through moisture content or temperature and the impact of bagasse temperature on hygiene.

Acknowledgements

The financial support of the Sugar Research and Development Corporation, Ledesma s.a.a.i. and CSR Ltd is acknowledged. Isis, Ledesma, Plane Creek and Macknade staff, in particular Mr David Pike, Mr Claudio Zapatero, Mr Paul Benecke and Mr Mick Conroy, provided considerable assistance in conducting the experiments. Mr Neil McKenzie and Dr Floren Plaza of QUT assisted in the conduct and analysis of experimental results.

Résumé

QUATRE expériences récentes, faites en usines, ont été menées pour déterminer une température optimale de l'eau ajoutée. Les résultats n'ont pas été totalement concluantes mais ont fourni des détails supplémentaires sur l'effet de la température d'eau ajoutée. L'effet de la température d'eau ajoutée sur l'extraction s'est avéré particulièrement difficile à mesurer. Il y a peu de doute que la bagasse est plus compressible aux températures plus élevées. Deux expériences ont montré que l'humidité de la bagasse est inférieure à la température plus élevée. Ces effets sont probablement
liées. Deux expériences montrent indirectement une augmentation de l'extraction par la température d'eau ajoutée plus élevée. La bagasse plus compressible augmente la capacité. L'utilisation d'un échangeur de chaleur pour refroidir l'eau ajoutée réduit les pertes de chaleur et par conséquent, réduit l'utilisation de la vapeur pour le chauffage principal du jus. Cela peut augmenter l'efficacité des chaudières, ce qui se traduit par une utilisation plus efficace de la bagasse. L'eau chaude ne semble pas être une solution complète pour l'hygiène du train de moulins étant donné que même l'eau la plus chaude a avantagée seulement le dernier ou les deux derniers moulin. Il faut beaucoup plus de travail pour identifier la température optimale d'eau ajoutée. Les principales questions restées sans réponses sont l'effet de la température d'eau ajoutée sur l'extraction, l'effet d’une bagasse plus chaude sur le rendement des chaudières à travers la teneur en humidité ou la température, et l'impact de la température de la bagasse sur l'hygiène.

EL EFECTO DE LA TEMPERATURA DEL AGUA ADICIONADA EN LA OPERACIÓN Y DESEMPEÑO DE UN TREN DE MOLIENDA

PALABRAS CLAVE: Agua Adicionada, Imbibición, Maceración, Molienda, Extracción.

Resumen

Se efectuaron recientemente cuatro experimentos en fábrica para suministrar información en la búsqueda de la temperatura óptima del agua adicionada. Los resultados no fueron completamente concluyentes pero entregaron una visión adicional sobre el efecto de la temperatura del agua adicionada. Históricamente, este efecto ha sido particularmente difícil de medir. Hay pocas dudas en cuanto a que el bagazo sea más compresible a altas temperaturas. Dos experimentos mostraron que la humedad del bagazo es menor a temperaturas altas. Estos efectos están probablemente bien relacionados. Dos experimentos produjeron evidencia indirecta de un incremento en la extracción con la mayor temperatura del agua adicionada. Siendo el bagazo más compresible la capacidad de molienda se incrementa a altas temperaturas. El uso de un intercambiador de calor para enfriar el agua adicionada con jugo diluido reduce las pérdidas de calor y consecuentemente reduce el consumo de vapor para el calentamiento primario del jugo. Algo del calor perdido puede ser útil para incrementar la eficiencia de calderas resultando en un uso más eficiente del bagazo. El agua adicionada más caliente no parece ser una solución completa para la higiene del tándem dado que solo representa un beneficio, en el mejor de los casos, para el último o los dos últimos molinos. Todavía se requiere considerable trabajo para identificar la temperatura óptima para el agua adicionada. Los aspectos más sobresalientes son el efecto de la temperatura del agua en la extracción, el efecto de un bagazo más caliente en la eficiencia de caldera, a través del contenido de humedad o la temperatura y el impacto de la temperatura del bagazo en la higiene del tándem.
IMPROVEMENTS TO A SUGARCANE ROAD TRANSPORTATION SYSTEM

By

Colombian Sugarcane Research Center, CENICAÑA, Colombia
algomez@cenicana.org

KEYWORDS: Cane transport, Fuel Consumption, FEA Modelling.

Abstract
AMONG the costs of the whole cane sugar and ethanol production system, the activities covered by harvesting (manual and mechanical), road transportation and cane unloading are the most expensive category of operations. A comprehensive study of the cane transport system, that covers topics from system logistics to cane bin design, is being undertaken for the Colombian sugar industry. Models for predicting fuel consumption have been developed and tested using techniques like GPS, pull load and direct fuel flow measurements for the complete operational cycles. Sensitivity trials have also been performed to analyse the influence of bin weight on fuel consumption in the complete cycle and FEA modelling has been applied to the design and construction of new equipment. Results show that reductions of 5% of fuel costs are achieved with the 10% structural weight reduction achieved.

Introduction
Cane supply management represents a real challenge for achieving overall efficiencies in the production processes to obtain sugar, ethanol and exportable electricity.

The huge variety of resources and activities involved simultaneously in field, harvesting (batch processes) and factory (mostly continuous processes) requires modern techniques and tools with a systems approach to assess and influence the processes continuously.

The risk of losing competitiveness because of high production costs, low prices of final products and devaluation of the national currency are threats for Colombia’s sugar industry and it is necessary to look for new and better production systems, especially in the harvesting, transport and delivery of the cane.

These operations constitute, on average, one third of the sugar production costs of which transport is 37% of this figure (Ramirez, 2006).

Currently 80% of the cane is cut manually but some individual mills are approaching 60% mechanical harvesting.

Cane is transported by road using three different size bins with 12, 20 and 30 tonnes capacity of chopped cane.

The 12 and 20 tonne bins are loaded directly with chopped cane from the harvester or from the loader in the case of manual harvesting.

Figure 1 show a typical train composed of four 20 tonne wagons.

At the mill yard, cane is unloaded by lifting cranes tipping on to feeding tables from where the cane is fed controlled to the main carrier. Severe damage and compaction happens in the fields, particularly in the rainy seasons, so the industry is returning to the use of tipping wagons of 7.5 and 10 tonne nominal capacity.

Cenicaña is currently running a research project on cane supply operations, aiming to reduce production costs by improving the complete cane supply system. The project includes field design,
private road circuits for neighbouring factories, logistics strengthening and equipment design, as well as redesigning together with equipment suppliers.

Logistic analysis

A simulation computer program based on Excel and linked with Crystal Ball® has been developed for the analysis of complete cane supply operations. It covers resources configuration and operational strategies evaluation, applying stochastic simulation. Statistical variation of input variables and equations were defined with real time information taken from a pilot mill and also from historical data. Cycle time, number of cycles, number of hauling units and the different logistic indices are obtained as program output.

A logistics benchmark was established and a first opportunity for improvement was found in the mill yard. Some results on improvement of spent time in the mill yard by transport equipment are presented in Figure 2. As a consequence of this improvement, equipment availability was improved.

![Typical train composed of four 20 ton wagons.](image1)

**Fig. 1**—Typical train composed of four 20 ton wagons.

![Mill yard time before and after applying logistics improvements.](image2)

**Fig. 2**—Mill yard time before and after applying logistics improvements.
So far it has been possible to reduce up to 15% of resources in the pilot mill with better coordination in cane loading, transport and unloading. Quality and opportunity of factory and harvesting personnel communication is a key logistic factor (Amú et al., 2007).

**Transport equipment analysis**

Recently, Santarossa et al. (2007), using finite element analysis, developed a new bin design (10 tonne railroad wagon) and achieved important structural weight savings while keeping good strength performance.

From the inventory of wagons in the Colombian industry, the 12 tonne type is the most extensively used unit, comprising 40.03% of the total industry fleet. It was chosen for structural integrity and maintenance costs analysis.

The most maintenance demanding zones in the chassis and bin were determined and compared with Finite Elements Analysis (FEA) predictions. A close agreement between predicted critical points and reported failure zones was found. Upper corners on the unloading side of the bin and the transition between the chassis central member and the neck were found to be the highest stressed zones. Figure 3 shows FEA outputs for the bin and chassis during cane unloading.

![Stresses during cane unloading a) bin b) chassis](image-url)
In order to calibrate the FEA models for the bin and chassis, experimental stress analysis was performed using strain gauges bonded at critical points in the wagon structure (Figure 4).

Stress levels were determined during field loading, while travelling on paved and unpaved roads and while unloading at the feeding table. A static loaded wagon condition was established as Service Factor = 1 and different factors were determined for other conditions (Table 1).

The critical condition for the loaded wagon chassis occurred when travelling in the field (factor 2.92). For the bin, the worst scenario was the unloading operation (factor 2.41). For off-road travel, a bigger factor was found than the factor of 1.8 reported by Moreno et al. (2000). Table 2 shows a comparison between FEA predicted stresses and experimental measurements.

Using the same equipment for receiving the cane from loaders and harvesters and also to transport the cane to the yard for being unloaded by cranes leads to substantially heavier equipment with high impact on the fuel and maintenance costs. A significant number of mills, therefore, are returning to the practice of using smaller tipping wagons to receive the cane inside the field and deliver it to the specialised bigger road wagons for transport to the factory.

Different approaches and activities have been adopted to develop a new transport wagon design with a better cane load to wagon tare relation, without compromising the equipment reliability:

- Load exerted by cane on the side walls of a wagon bin has been modelled and experimentally confirmed (Cobo et al., 2008).
- Pull loads have been assessed using experimental stress analysis.
- FEA modelling of welded connections of thin walled structural members has been performed together with experimental evaluations (Castro et al., 2009).
- New unloading systems, less demanding of wagon strength, have been documented.
- A prototype of a 12 tonne side dumping wagon was developed and tested, with both mechanically harvested and hand cut cane (Figure 5).

Fuel consumption in cane transport

A theoretical model for a train of cane transport wagons was developed to predict pulling force and power and fuel consumption (Ascuntar, 2008). Figure 6 shows a simplified vehicle forces scheme. The model was confirmed with field experiments. The importance of weight reduction on the wagon structure was determined.

A complete cycle of cane supply operations was considered which consists of four main activities:

1. Empty wagons transported to the field.
2. Cane loading operations.
3. Loaded wagons transported to the factory.
4. Mill yard operations (weighing, sampling, unloading).

Typical fractions of time spent on each activity and average speeds of the main activities are shown in Table 3 for a train of six 12 tonne wagons pulled by a STX 275 tractor.

Field experiments were conducted on very fine Tepic Haplustert soils with 200 mm per year of precipitation and medium to high permeability. A CASE IH 9230 tractor (280 kW) was used together with a pull dynamometer developed by Cenicaña with a modified Holland hitch point (Figure 7, Gómez and Bejarano, 2007), a GPS and a fuel flow meter (Figure 8). Tractor position, speed, pull force and on-line fuel flow were recorded.

Fig. 6—Forces involved in a power consumption model for a towed system.

- Wt: Tractor weight
- Frt: Tractive force
- V: Vehicle speed
- Rd: Reactive force of terrain, tractor’s front axis.
- W: Total weight (tare+cane)
- Rd: Reactive force of terrain, tractor’s rear axis
- α = Road slope
- Rd: Reactive force of terrain, wagon’s front axis
- FI: Inertia force
- Rd: Reactive force of terrain, wagon’s first rear axis
- Fair: Air resistance
- Rt: Reactive force of terrain, wagon’s second rear axis

Fig. 7—Holland hitch modified and fitted with strain gauges for pull force measurements.
Figure 9 compares available fuel energy (measured on-line) to energy dedicated to move the loaded vehicle, as calculated from pull force and train velocity. Results show that 76.8% of the fuel available energy is spent in the thermal and mechanical conversion including mechanical losses and motor vehicle displacement, indicating a very inefficient process.

Figure 10 presents fuel consumption for a tractor pulling five different train configurations over the same terrain, during a 500 s period and Table 4 shows the results of integrating the power vs. time curve to determine the total energy for each configuration. Figure 11 presents fuel consumption vs. towed weight for different towing speeds.
Fig. 10—Fuel consumption for five different load configurations.

Fig. 11—Fuel consumption vs towed weight for different towing speeds.

The model predicted a 5.3% fuel consumption reduction for a 10% decrease in wagon weight. For the same condition, experimental measurements so far show fuel consumption reductions of 5.6% at 10 km/h and 5.2% at 12 km/h (Figure 12).
More experiments are in progress to identify the influence of other variables such as tyre type, inflation pressure, and speed.

![Fig. 12—Weight reduction and fuel consumption.](image)

**Conclusions**

There was good agreement between FEA predicted stresses for wagon structures and experimental measurements. FEA modelling of welded connections of thin walled structural members can be used safely for design purposes.

Logistics analysis is an important tool for cost reduction. It has been possible to reduce up to 15% of resources in a mill with better coordination in cane loading, transport and unloading. Quality and opportunity of factory and harvesting personnel communication is a key logistic factor.

Also a good agreement was achieved between fuel consumption model predictions and experimental measurements. So far a 10% wagon tare reduction indicates around 5% saving of fuel in road transport for the complete cycle.

The developed dynamometer proved to be a useful tool for determining forces affecting wagon structures and energy consumption measurements. It can also be used to assess the impact of other variables such as tyre type and inflation pressure.

AMELIORATIONS POUR LE TRANSPORT ROUTIER DE LA CANNE A SUCRE

Par

Colombian Sugarcane Research Center, CENICAÑA, Colombia
algomez@cenicana.org

MOTS-CLEFS: Transporte de la Canne, Consommation de Carburant, Modelage FEA.

Résumé

Le transport routier, la récolte manuelle ou mécanique et le déchargement de la canne à sucre sont les opérations les plus coûteuses pour l’industrie de la canne a sucre et de l’éthanol. Une étude complète du système de transport de canne, comprenant la logistique et la conception des caissons pour la canne, a été entreprise pour l’industrie sucrière colombienne. Des modèles pour prédire la consommation de carburant ont été développés et testés à l’aide de techniques comme le GPS et les mesures directes de débit de carburant pour les cycles opérationnels complets. L’influence du poids des caissons sur la consommation de carburant a été étudiée pour le cycle complet et on a utilisé le modèle FEA pour la conception et la construction des équipements. Les résultats montrent que des réductions de 5 % de frais de carburant sont obtenues avec une réduction de 10 % du poids structurel.

MEJORAS A UN SISTEMA DE TRANSPORTE DE CAÑA POR CARRETERA

Por

Colombian Sugarcane Research Center, CENICAÑA, Colombia
algomez@cenicana.org

PALABRAS CLAVE: Transporte de Caña, Consumo de Combustible, Elementos Finitos.

Resumen

De los costos del sistema global de producción de azúcar y etanol, los relacionados con las actividades de cosecha (manual y mecanizada), transporte por carretera y descarga de caña son los más significativos. Se desarrolla para la industria azucarera colombiana un estudio integral del aprovisionamiento de caña a las fábricas, que incluye desde la logística del sistema hasta el diseño de vagones. Se han desarrollado y probado modelos para predicción del consumo de combustible, usando técnicas como sistemas de posicionamiento global (GPS), medición de fuerza de tiro y de consumo directo de combustible para el ciclo completo de las operaciones. Se han efectuado análisis de sensibilidad para determinar la influencia del peso de los vagones en el consumo de combustible durante el ciclo completo y se ha usado modelamiento por Elementos finitos para el diseño y construcción de nuevo equipo. Los resultados muestran reducciones del 5% en el costo de combustible cuando se logra disminuir en un 10% el peso estructural de los vagones.
CANE TRASH AS FUEL

By

KEYWORDS: Cane Trash, Energy, Trash Processing, Leaching.

Abstract
SUGARCANE dry trash, a residue in cane fields, has significant potential as a biomass fuel. It contains nearly 28% of the total energy content in the sugarcane crop. However, this potential fuel is wasted by burning it in open fields after sugarcane harvesting producing harmful emissions. In India, if all the cane trash be utilised to full potential, the national energy deficit can be reduced by 50%. Moreover, the sugar industry gets an additional 110% power export in the process. Unfortunately, the collection mechanisms in vogue are uneconomical and not suitable to realise the potential energy benefits. Deccan sugars, sugar mill of Nava Bharat Ventures Ltd has tried a collection mechanism by harvesting dry leaves along with cane and processing it through the milling tandem, thus increasing bagasse generation. Sugarcane trash has high alkali and silica content, which makes it unsuitable as boiler fuel directly. Trash processed with the cane supply is thoroughly washed in the milling process, thereby significantly reducing the alkali and silica content of the resultant bagasse. Harvesting and processing trash along with sugarcane seems to be a good method to make trash a suitable boiler fuel and realise its potential.

Introduction
The Indian Sugar Industry is progressing well in its efforts to expand the implementation of cogeneration. The industry is progressively achieving benchmarks in reduced process energy consumption. A few sugar mills have reduced steam consumption to 340 kg/tonne cane producing direct white consumption sugar by following the double sulfitation process. A few more are aiming to achieve steam consumptions of 300 kg/tonne cane.

In India, sugarcane cultivation is done manually except for the operations of land preparation and cane transportation for which tractors are used. Green cane harvesting is done manually. Green leaves and cane tops are used as fodder. Manual harvesting has become a serious production bottleneck threatening the survival of the sugar industry. Various types of mechanical harvesters are being tried in the recent past.

Sugarcane trash, the dry brown leaves attached to the cane stalk, to some extent forms mulch in the fields 5–6 months into the initial growth or ratooning period. Post harvest burning of trash is common practice, releasing harmful greenhouse gases like N₂O, CH₄ and CO₂ in addition to CO. Very few sugar mills having a cogeneration facility are trying to collect trash from the fields by using balers. Manual collection and transport of loose trash from fields is practised at certain mills.

Biomass has got a lot of potential in varied applications from power generation to plastics. There is a growing interest and need for an efficient biomass collection mechanism. Cane trash is a potential source of biomass with well established benefits as a fuel and manure. Appropriate collection mechanisms and attractive markets for trash will make sugarcane cultivation more profitable.

Deccan sugars have undertaken trials to demonstrate the efficient collection of trash by whole-of-crop harvesting and milling. This was to provide additional fuel to their 9 MW rated
boiler pressure: 43 bar (abs)] and 20 MW [rated boiler pressure: 87 bar (abs)] capacity cogeneration facilities. The associated factory process steam consumption has been reduced to 350 kg/tonne cane.

The mill is situated in coastal districts of Andhra Pradesh, South India in the tropics at 17°02′N latitude and 82°09′E longitude. Average altitude is 15 m above MSL. Cyclonic conditions prevail in the area during the cane growing period. Soil conditions and a cyclonic climate are the cause of severe sugarcane lodging. Land holdings are small averaging 1.1 ha. Many fields are not easily accessible for sugarcane transportation. Harvested sugarcane is shifted manually by laborers to a convenient place for loading.

The mill has the capacity to crush 450 000–585 000 tonnes of sugarcane annually. In the recent past, due to uneconomical margins for sugarcane farming with increased labour costs, the crop production reduced to 240 000 tonnes. As the crush rate reduced, we were able to trial this unique approach to trash collection.

Cane trash handling and utilisation–previous research and experiences

Sugarcane produces huge quantities of foliage; up to 40% of total biomass. On an average, 15–20 tonnes of cane trash are produced per hectare. However, the quantity varies with varieties and crop growth. Cane trash contains considerable amounts of plant nutrients. These nutrients can be conserved if recycled into the soil. However, the entire amount of trash obtained from cane fields cannot be utilised for mulching, as an excessively thick blanket of mulched trash can inhibit germination, harbors reptiles and results in poor cane growth.

Results obtained at the Regional Agriculture Research Station, Anakapalle, India led to the recommendation of 3 t/ha of trash mulching to conserve soil moisture and nutrients (Ramalingaswamy 1998). However, mulching is more effective in upland and light soil conditions. The 12 to 17 t/ha of surplus trash has to be economically utilised by proper collection.

Post-harvest trash burning causes loss of nutrients (Krishna, 2002). Cane stubbles get damaged due to the heat and cause delayed germination resulting in poor yield during ratooning. Burning trash generates intense heat ranging from 600°C to 800°C which kills beneficial soil microorganisms and earth worms. The global warming potential of gases such as N₂O and CH₄ in addition to CO₂ that are released during burning is of greater concern. N₂O is the most worrying emission because of its high global warming potential (300 times more damaging than CO₂).

Sugarcane has significant potential as a source of biomass fuel. Sucrose in the stalk only represents approximately 30% of the total energy of the above ground biomass of sugarcane. C₄ species like sugarcane will outperform C₃ species in their ability to accumulate biomass. The maximum above ground biomass growth can be as high as 550 kg/ha/day. When grown under rainfed conditions, sugarcane has one of the highest water use efficiencies of all crops in terms of water used per unit mass of biomass produced (Botha, 2009).

Energy potential in cane trash

Sugarcane is an energy crop produces the energy equivalent per hectare per cropping cycle of 95–114 barrels of crude oil (Botha, 2009; Ripoli, 2000; Rein, 2007; Krishna, 2002). 60% of the energy is transported to the mill as clean cane, 12% is utilised as fodder (young internodes and green leaves) and the rest 28% (trash) is predominantly burnt in the open (Ripoli, 2000; Rein, 2007; Krishna, 2002).

Cane trash is a potential fuel with a calorific value ranging from 3845–4375 kcal/kg on dry basis (Kurt woytuiik, 2006) having moisture in the range of 20–30%.

With an average yield of clean cane of 75–80 t/ha, each hectare of sugarcane cultivation has 12–17 tonnes of excess cane trash available. This is equivalent to a primary energy value of up to 50 000 kWh per hectare of sugarcane-cultivated land. However, associated activities in the process of generating energy from trash such as transportation, processing and energy extraction influence the actual electrical energy benefits reaped from cane trash.
Cane trash as fuel for power generation—the challenges

Field level challenges

Pricing mechanism—Farmer confidence
For a long time now, farmers have been accustomed to send fresh clean cane to the mill. Payment is made to farmers on a weight basis. Average recovery from the previous campaign is also considered in the payment system.

A suitable pricing mechanism for the whole-of-crop harvested cane has to be developed to provide sufficient confidence in farmers.

Collection and transport

Low bulk density
Low bulk density accounts for higher transportation and handling costs. Trash has a very low bulk density, which invariably increases the collection and transportation cost. Experiments at the mill have shown that the density of loose trash is in the range of 50–65 kg/m³. Cane stalk bundled with dry leaves is found to have a bulk density in the range of 220–230 kg/m³.

Baling is one alternative for reducing trash collection and transportation costs. Trash can be compacted to 242–306 kg/m³ using large rectangular balers (Hassuani et al., 2005). However, baling is energy intensive compared to trash collection along with cane.

Collection efficiency
It is observed that 56–84% of trash can be collected by raking and baling trash (Hassuani et al., 2005). We can achieve more than 95% trash recovery by harvesting trash along with cane.

Soil % in trash
The collection mechanism must also ensure that soil is not entrained with the trash during collection. Baling without a prior raking operation is found to have a soil content in the range of 5-6%. With the raking operation, the sand content in the bales is in the range of 1.5–2.0%. (Hassuani et al., 2005).

The soil cannot be easily separated and hence results in excessive erosion in boilers whereas, in the case of harvesting trash along with lodged cane, there is a possibility to provide a sand separation mechanism before processing it in the mill.

Factory level challenges

Fuel usage challenges

Total alkali, sulfates, chlorine and silica concentrations in trash
Alkali metals in conjunction with other inorganic components such as silica, sulfur and chlorine are primarily responsible for slagging and fouling, which reduce the boiler efficiency. These components are common in herbaceous crops. They play an important role in the plant metabolism (Kurt woytuik, 2006).

Volatile alkali metals at high temperatures form inorganic gases which react with other fuel components to exacerbate ash deposition problems by two primary mechanisms. The first mechanism is by reduction of the ash fusion temperature due to the formation of alkali silicates. The second mechanism is by condensation of alkali vapours on boiler tube surfaces, which react with sulfur to form alkali sulfates reducing the boiler effectiveness (Baxter and Jenkins, 1995). Chlorine assists in effective transport of alkali vapours to the boiler tube surfaces (Miles, 1995).

The tendency to form deposits or slag increases significantly at ash levels of between 0.17 kg/GJ to 0.34 kg/GJ. Fouling and possible slagging occurs above those total alkali concentration levels (Miles, 1995).

The total alkali concentration of the fuel can be reduced by blending with a processed fuel-like bagasse. However, composite data (calculated from analysis reports of raw cane trash and bagasse) presented in Figure 1 show that the total alkali, Cl and SO₃ concentration per unit energy is
still above the threshold level (0.17 kg/GJ) for fuel mixtures having trash contents greater than 20%. Boiler manufactures are recommending trash to bagasse ratio of 10:90 for the latest high pressure boilers.

![Graph showing alkali content in trash–bagasse fuel mixture per unit energy content at different mixture concentrations.](image)

Pilot scale experiments on a Cuba mill in Hawaii have shown that leaching by milling is very effective in reducing the total alkali, sulfur and chlorine content of trash. It is also observed that considerable improvement in leaching was achieved by decreasing the particle size (Kurt woytuik, 2006).

All herbaceous crops have higher concentrations of the alkali metals, chlorine, silica and sulfates. Leaching is already proven to improve fuel characteristics in the case of bagasse. Bagasse generated by milling trash along with cane is having the total alkali index well below the threshold 0.17 kg/GJ level because of the efficient leaching in milling.

**Trash processing challenges**

**Crushing rate**

The cane crushing rate is found to reduce by 2.3% for 1% increase in trash % cane processed in milling tandems, primarily due to increased fibre content. It is found that the fibre rate is not affected by processing additional trash along with cane (Kent, 2007).

**Energy consumption**

Electrical energy consumption at the milling station will theoretically increase due to the additional fibre content in trash. However, the lignin content, which generally provides the rigidity or hardness in fibre, is comparatively less in fibre of trash. Hence, the power consumption per tonne of fibre in trash will be less than that of fibre in cane stalk. There will also be an increase in steam consumption due to increased mixed juice % cane.

**Juice quality and sugar extraction**

It is observed that increase in trash processed along with cane during milling results in reduction in purity of juice, increased extraction of reducing sugars and loss of pol carried through extra fibre in trash. A 0.1 unit decrease in extraction and 0.3 units decrease in mixed juice purity was observed for 1% increase in trash % cane. (Kent, 2007)
In the current study, it is assumed that the effect of the above challenges for processing trash in a milling tandem can be managed within limits through minor changes to milling and sugar processing plants.

Methodology

Three trials of 440 minutes duration were undertaken by the mill to evaluate the potential and actual effects on the entire mill of using cane trash as fuel in the existing infrastructure. During the three trials, 89 tonnes of trash were processed along with 417 tonnes of clean cane. The cane received along with trash at the mill was fed to the cane carriers using grab unloaders and processed through three sets of knives, a cane shredder and a 4 milling tandem of 30 × 60’ size with underfeed rollers. The last mill is equipped with a grooved roller pressure feeding device.

The increased bagasse due to extra fibre content in trash is used as fuel for the cogeneration system. The cogeneration system constitutes a 64 t/h travelling grate boiler generating superheated steam at 43 bar (abs) and 415°C. In the campaign, 3000 tonnes of trash were processed intermittently but at regular intervals with cane in the mill.

Results and discussion

Harvesting and transport of trash along with cane

The work required for detrashing during harvesting has reduced but head load to be carried to the truck per hectare has increased. The cost of transportation has also increased due to reduced bulk density of trash along with cane in comparison with clean cane. During the trials, cane trash levels of around 21.4% of the total clean cane received at the sugar mill were recorded. The cane trash levels recorded during the trials are given in Figure 2.

Processing trash along with cane through mills

An effective analysis system is essential to arrive at an accurate price for sugarcane which is consistent with the existing cane payment framework. It is essential for the analysis system to provide sufficient confidence for farmers to participate in the harvesting of trash with cane. Unfortunately, core samplers and NIR analysers are not currently used as the basis for determining the sugarcane price. We had to adopt a random sampling and weight-based analysis system. We have demonstrated its working to the farmers for encouraging harvesting trash along with cane.

The fibre rate through the milling plant has decreased by 14.28% because of inadequate feeding facilities suitable for milling trash along with cane.

Imbibition

To maintain effective sucrose extraction, imbibition was increased to compensate for the increase in fibre content. Pol % bagasse remained at 1.8% for increase in imbibition % cane in the
range of 1.7–1.25 units for 1% increase in trash % cane. The pol in bagasse increased rapidly by further decreasing the increment in imbibition % cane (Table 1).

**Table 1**—Percentage increase in Imbibition % cane for 1% increase in trash % cane.

*derived from data in Table 2

Table 3 shows the effect on sucrose extraction of processing trash along with cane. As it is observed, there is a 0.21–0.36 kg per tonne cane decrease in sucrose extraction for 1% increase in trash % cane. Because of the relatively short nature of the trials, it was not possible to directly measure the effect of trash on sugar quality and recovery. However, the decrease in sucrose content mixed juice (Table 2) is a clear indicator of the effect on sugar recovery.

*Colour removal*

</tr>
<tr>
<td>19 146</td>
<td>17 783</td>
</tr>
</tbody>
</table>
From Table 4 above, there is considerable increase in mixed juice colour observed by processing trash along with cane during the trials. Starch content in the leaves is believed to be primarily responsible for the increased juice colour. There is an increase of between 550–1400 IU colour units in mixed juice for a 1% increase in trash % cane. However, as per Table 5, considerable removal of juice colour was observed in the juice clarification process. The residual colour in clear juice is easily removed in syrup clarification and crystallisation processes. Hence, trash was deemed to have no significant impact on the sugar colour of the product (Figure 3).

**Boiler performance**

Leaching of trash during milling ensured a clean fuel for the boiler. The analysis of the fuel showed concentration of alkali in ash well below the threshold level responsible for slagging. Figure 4 shows a comparison of measurements of concentrations of alkali Cl\(^-\) and SO\(_3^+\) ions in bagasse from clean cane, from trash processed along with cane, and with that of trash in its naturally occurring state.

The results have clearly shown that leaching effectively removes alkali content from trash. There was no noticeable change in the performance of the boiler vis-à-vis flue gas temperature profile as shown in Figure 5.
Increased sand content in bed ash is observed, indicating excess silica being entrained with the trash during trials. Installation of sand separators at the mill feeding point would reduce the excess sand content in cane with trash.

There was an increase in the oxygen content in flue gas during the trials (Figure 6) which may presumably be due to increased moisture content to 52% or the changed fuel properties.

Cost of trash

To understand the economics of collection and harvesting trash as a fuel, a value for trash has been derived by assigning costs to various activities and effects involved (Table 6).

Table 6—Incremental cost of trash as fuel by processing it along with cane in the milling tandem.

</tr>
</tbody>
</table>
Hence, a valuable fuel is available to the mill at $28.6 / tonne or $1.66 / GJ. Hence, processed trash is far more attractive than crude oil [$8.7 / GJ] or coal with carbon capture [$4.8/GJ] (Botha, 2009).

Conclusion

In a country like India, a farmer is used to delivering clean cane to the mill and receiving payment on the basis of weight and previous campaign mill average recovery. The impact for an Indian scenario of collecting and milling trash along with cane has been undertaken. Apprehensions associated with factors such as deterioration in sugar quality, clinker formation and fouling in boiler and resistance from farming community for such change in harvesting and transportation can be overcome to some extent by these successful trials.

These preliminary trials have yielded interesting results such as:

1. The dried leaves, non-cane portion for milling worked out to be approximately 20% of clean cane on weight basis.
2. Raw cane trash (i.e. prior to milling) has a higher calorific value in the range of 3845–4375 kcal/kg on dry basis.
3. Leaching trash in mills effectively reduced fuel alkali concentration delivering a processed fuel to the boiler with minimal risk of slagging.
4. Though transport of cane along with trash from cane fields to sugar mill involved greater transportation costs, trash contributed considerably to the increase in quantity of fuel increasing the net power export from the cogeneration plant.
5. There is a significant reduction in crushing capacity which can be moderately increased by uniform feeding.
6. The colour content of the mixed juice increased due to compounds extracted from the trash by the milling process. However, the increased colour content of mixed juice did not ultimately affect the quality of product sugar as the colour was removed in the juice clarification, syrup clarification and crystallisation processes.

Through the experience gained in this study, it has been established that the following criteria for selecting fields suitable for harvesting trash along with cane make the activity more attractive

- Trash collection should be from fields within 15 km distance from mill
- Erect (non lodging) cane varieties should be selected
- High biomass yielding cane varieties should be selected

Effective separation of sand, uniform feeding of raw material to milling tandem, evolution of right payment mechanism for dry trash based on either core sampler or NIR technique are essential in future to continue this activity.

Summarising, crushing of cane along with trash appears to be of extreme use for increased cogeneration of power. Crushing of cane along with trash reduces atmospheric pollution and helps in reducing global warming. However, the reduction in crushing capacity can adversely affect the mill operations when there is sufficient cane available to be crushed. Suitable additional milling capacity to process trash along with cane is inevitable.

These remarkable advantages of crushing cane along with trash warrant further detailed studies to help alleviate power shortages in India and reduce global warming.

Acknowledgements

The authors would like to thank Mr P. Trivikrama Prasad, Managing Director for his constant support to pursue these trials. The authors also thank sugar mill Agriculture Department for their efforts and the farming community for their cooperation in supplying trash along with cane to make these trials successful.

Résumé

LA PAILLE de canne, un résidu dans les champs de canne à sucre, a un potentiel important comme un carburant de la biomasse. Elle contient près de 28% de la teneur totale d'énergie dans la culture de la canne. Toutefois, ce combustible potentiel est gaspillé par le feu en plein champ après la récolte, produisant des émissions nocives. En Inde, si toute la paille de canne est utilisée, le déficit énergétique national peut être réduit de 50%; en outre, l'industrie sucrière obtient une exportation d’énergie de 110%. Malheureusement, les mécanismes pour récolter la paille ne sont pas

économiques et on n’obtient pas les avantages possibles. La sucrière de Navoï Bharat Ventures Ltd (Deccan) a essayé de récolter la paille avec la canne et de traiter le tout aux moulin, augmentant ainsi la génération de bagasse. La paille contient beaucoup d’alcalins et de silice, ce qui ne convient pas aux chaudières. La paille a été soigneusement lavée aux moulin, réduisant ainsi les alcalins et la silice dans la bagasse. La récolte et le traitement de la paille avec la canne semblent être une bonne méthode pour transformer la paille en un combustible de chaudière approprié, ce qui réalise son potentiel.

PALABRAS CLAVE: Residuos, Energía, Procesamiento de Residuos.

Resumen

El residuo de cosecha de caña seco dejado en el campo tiene un potencial significativo como biomasa combustible. Contiene cerca del 28% del total de la energía de la caña. Sin embargo este potencial es desperdiciado por las quemas abiertas en campo después de la cosecha produciendo emisiones nocivas. En India, si todos los residuos se utilizan en todo su potencial, el déficit nacional de energía puede reducirse en un 50%. Adicionalmente la industria azucarera obtiene una exportación adicional de energía eléctrica del 110%. Desafortunadamente los mecanismos de recolección disponibles no son económicos y no permiten el logro de los beneficios potenciales. Deccan Sugars, ingenio de Nava Bharat Ventures Ltd ha ensayado diferentes alternativas para la recolección de hojas secas para molerlas en el tándem, incrementando la producción de bagazo. Los residuos tienen altos contenidos de álcalis y silice lo que los hace no aptos para uso directo en las calderas. Al procesarlos con la caña son totalmente lavados en el proceso de molienda reduciendo los contenidos de álcalis y silice del bagazo resultante. Cosechar y procesar los residuos con la caña parece ser un buen método para convertir los residuos en un combustible adecuado para las calderas y aprovechar su potencial.
COGENERATION – A NEW SOURCE OF INCOME FOR SUGAR AND ETHANOL MILLS
or BIOELECTRICITY—A NEW BUSINESS

KEYWORDS: Cogeneration, Bioelectricity,

Abstract
COGENERATION, energy efficiency and surplus power production are old topics in Brazilian sugarcane mills. However, until 2003, they lacked institutional and regulatory support, when the Brazilian government decided to encourage and regulate alternative electricity production. Today, bioelectricity production in sugarcane mills and sale of the surplus power to the grid is a consistently fast-growing new business. Installed bioelectricity capacity in the Brazilian sugar industry reached 1800 MW in 2007/08. In a public auction on August 8th, 2008, the Brazilian Energy Agency (Agência Nacional de Energia Elétrica – Aneel) determined the bidding rules, including the maximum price to be paid for bioelectricity as reserve energy for the next 15 years, resulting in a total installed capacity of the auction winners of 2385 MW. Projections for 2020/21 foresee that the supply to the grid will be equivalent to 14 400 MW average, and that the revenue generated with this new business will be similar to Brazilian sugar production. This scenario opens opportunities for new energy optimisation technologies. This paper is focused on the use of sugarcane from an energy point of view, and how to (a) maximise the use of energy contained in sugarcane; (b) minimise energy consumption by the sugar and ethanol mills; (c) integrate the electricity production process into the sugar and ethanol process; (d) maximise surplus electricity production. New technologies are integrated to the mill to improve the energy balance: electrical/mechanical drives via planetary gearbox and frequency inverters or electro-hydraulic drives to milling units; fermentation at higher ethanol content using absorption chillers to permit lower temperatures; combined pressurised and vacuum distillation; membrane utilisation for dewatering and dehydration; biogas-from-vinasse production and its subsequent use as fuel; use of sugarcane straw (sugarcane crop residues, i.e. tops, leaves and straw) for fuel; multifuel boilers with high pressure, high temperature and high efficiency (120 bar(g), 530ºC, 89% – LHV); condensation/extraction turbogenerator. Three hierarchical stages of technology are presented: sugarcane mills of first generation, second generation and third generation. The ‘Bioelectricity State-of-the-Art Mill’ is presented, and innovations are considered in the design of the complete sugarcane mill.

Introduction
Sugar and ethanol plants in Brazil have operated cogeneration systems for a long time. Until 2003, almost all cycles used by the mills operated with back-pressure turbo-alternators. Although the Brazilian industries have technology for high-pressure cogeneration systems, they have not been
used by the mills (Olivério and Ordine, 1987; Olivério et al., 1989). Demand specifically for power from biomass and, particularly, the lack of a well developed market for sale of the surplus energy did not attract investment in more efficient generation systems. The lack of transmission lines connected to the mills has also contributed negatively to the implementation of cogeneration systems to produce surplus energy for export to the grid. Investment in transmission lines was discouraged by the absence of regulations in the sector.

Therefore, the mills energy balances did not consider surplus power generation. Only low-efficiency cogeneration projects were contracted, consisting of low-pressure and low-heat efficiency boilers and turbogenerators, with use of low-efficiency steam drives. Processes were designed for high steam consumption because there was more than enough power produced in the mills and, as a result, optimisation was not needed.

With the increase in electricity demand in recent years, and the imminent risk of blackouts as a result of insufficient capacity, the Brazilian government decided to support and regulate power generation and distribution.

The government quickly diversified the national electric power program to explore the potentials of every power generation sector. In 2002, Proinfa was launched, with the objective of guaranteeing the price of the energy produced from alternative sources and to stimulate investment in cogeneration and electricity export to the grid (Olivério and Ribeiro, 2006). Besides Proinfa, the government also organised four auctions to sell the surplus power produced from biomass.

Along with the new rules, new concepts of cogeneration were designed for the mills, and more modern and efficient technologies began to be used in the cogeneration systems and production processes. Such technologies were grouped into the following categories:

- **First Generation:** the optimised technologies commercially available to the sugar and ethanol mills; the state-of-the-art solution.
- **Second Generation:** this includes the anaerobic digestion of the vinasse for biogas production to be used as a fuel in high-pressure boilers. It also includes the use of sugarcane residues (referred to as straw, which are tops, green and dry leaves) in the boilers.
- **Third Generation:** this is the development of economically feasible technologies for bagasse and straw gasification to be used in combined cycles for surplus power production in the mills.

**Energy valuation of sugarcane—surplus bioelectricity production process in sugar and ethanol mills**

The energy contained in sugarcane was largely underexploited prior to 2003. The Brazilian mills focused only on the extraction of energy contained in the sugarcane juice, ignoring, in other words, wasting the energy contained in the bagasse and straw (sugarcane crop residues, that means: tops, leaves and straw). By making use of the juice exclusively we can say that only 1/3 of the energy contained in sugarcane is used efficiently.

The remaining energy in sugarcane (2/3) is present in bagasse and straw, an energy that was underutilised because the energy efficiency of the mills’ cogeneration systems was very low. Regarding the energy contained in straw, this is completely lost because it is burnt in the field before harvesting. The loss of the energy present in straw is very high, representing 1/3 of the total energy contained in sugarcane (Olivério, 2003).

If we sum up the three components of energy contained in one tonne of sugarcane, we will see that such energy corresponds to approximately 1.2 barrels of crude oil, as shown in Table 1. Table 1 also shows the possible transformations of each component of energy as well as its equivalence in barrels of crude oil. By summing up the energy available in total sugarcane to be produced in the Brazilian 2010 season, we will have $1.17 \times 10^{15}$ kcal available. Current and 2010 projected figures are almost the same.
Table 1—Sugarcane energy potential (Olivério, 2003; Olivério and Ribeiro, 2006).

Compared to UK, which consumes energy from crude oil, the total energy available in sugarcane produced in Brazil is 124% of the energy from oil (9.41 x 10¹⁴ kcal) consumed in UK. The energy available in Brazil from sugarcane is 80% of the energy from oil consumed in Germany and 42% of the energy consumed in Japan.

The amount of energy present in sugarcane is huge and is being wasted; for this reason, a production increase of surplus power in the mills to make better use of this energy should be pursued. By means of the equation below, we can see how to increase surplus power generation:

Maximum surplus power in the mill (\(=\)) Maximum use of the energy available in sugarcane (\(\rightarrow\)) Minimum consumption in the mill processes

The maximum surplus energy equation (Olivério, 2008; 2009) is very simple, but it helps to understand all necessary changes in the mill for maximum surplus generation.

First, let’s analyse the part of the equation that aims at the maximum use of the energy available. Here we should include the use of surplus cane bagasse as a fuel. By using bagasse, the mill will produce more steam than the process requires. It can also replace the back-pressure turbines by condensing turbines with controlled extraction. Another item to be added in the equation is the use of high-pressure, high-temperature boilers with high energy efficiency. Similar to the above, more steam will be produced for condensation besides a higher enthalpy drop in the turbine.

Let us analyse now the part of the equation for minimum energy consumption in the plant. It is necessary to reduce steam consumption in the sugar and ethanol processes to have more surplus steam for condensation and, as a consequence, higher surplus generation. It is also possible to replace the inefficient steam drives by more efficient electrical, electromechanical or electro-hydraulic drives. Therefore, there will be more energy produced with a positive balance in the replacement of the steam drives.

Technologies to maximise surplus bioelectricity production

According to the technological hierarchy presented earlier, let’s now detail the technologies used to maximise the surplus power generation by means of a case study. We will present the technological innovations of first and second generation, which are available in commercial scale. The third generation technologies will be presented in the next section, as part of the prospects for bioelectricity production. For our case study, a typical sugar and ethanol mill configuration will be used as a base case with specifications shown in Table 2. We emphasise that, as far as energy is concerned, the specifications of the chosen base case are typically prevalent in Brazil, with more than 70% of the mills with this energy profile.

First generation technologies

Table 2 contains data for preparation of the energy balance of the sugar and ethanol mills. Figure 1 is a flowchart of a typical mill that does not produce surplus power and represents the energy balance of the base case represented in Table 2. Observing and understanding the flowchart are important to understand the technological innovations that will be described.

In the flowchart can be seen the hourly crushing capacity (500 tonnes of cane) and the respective bagasse generation. In the sequence we can see the strategic reserve, 5% (6.5 t/h) of the total bagasse produced, for the plant start-up, re-starts and heating, once at this moment sugarcane is not being processed and generating bagasse to be used in the boiler. We can also see the surplus bagasse, which represents 8.11% (11.4 t/h) of the total.

If we analyse the other end of the flowchart we can find the process steam requirements for production (492 tonnes of steam/tonne of processed cane). By linking the bagasse to the process, we have the boilers, turbogenerators and pressure-reducing valves which will be the goal of the technological innovations, besides the reduction of steam consumption in the production process so that we can draw the maximum energy contained in sugarcane.
In this mill configuration we can see the use of pressure-reducing valves to satisfy the varying process steam demands.

Starting from the configuration of Figure 1 (Olivério, 2008; 2009) and using the equation of maximum energy generation, as presented earlier, a step-by-step overview of the technological innovations and their corresponding surplus power generation is given, until we reach the configuration called ‘State-of-the-Art Mill’.

To facilitate the understanding of the technological innovations that will be presented step by step, Table 3 summarises the operational conditions of the elected plant for our case study.

This same table will be presented at the end of each innovation, showing the changes in process and facilitating the understanding of the changes.

**Generation of 4.9 MW of surplus power**

A simple strategy to produce 4.9 MW of surplus power is proposed. This strategy consists of replacing the pressure-reducing valve by a back-pressure turbogenerator. When the turbogenerator is used to reduce the pressure of the 59.9 t/h of make-up steam, 4.9 MW of electricity is produced for export to the grid (see Table 4).

**Production of 8.7 MW of surplus power**

A total of 8.7 MW of surplus power can be generated with the utilisation of higher levels of surplus bagasse. In addition to the 5% reserve for plant re-starts, there is a bagasse surplus of 8.1% (11.4 t/h).

The strategy proposed here is to increase the boiler capacity by making changes in the furnace, so that the surplus bagasse can be burnt. By burning the surplus bagasse, steam output will be 278.6 t/h.

The additional 20.7 t/h of steam to be produced in the boilers will be used to replace the pressure-reducing valve by a condensing/extracting turbogenerator. The flow of steam (surplus to process heating requirements) passing to the condensing turbine increases production to 8.7 MW of surplus power (see Table 5).

Production of 34.8 MW of surplus power

In the previous steps, there was no need for major technical innovation to meet 8.7 MW of surplus power. The focus of the next strategy will be the boilers, which will be replaced by equipment with high thermal efficiency, high pressure and high temperature (65 bar(g) / 485ºC). The efficiency of the condensing/extracting turbogenerator is also assumed to be increased. In this scenario, the equipment is assumed to be upgraded to include features such as:

- De-super heating system for better outlet steam temperature control.
- Fully automated systems for ash removal.
- Single-pass evaporators eliminating maintenance of the stream-gases baffles.
- Cooled grates allowing high temperature of the combustion air.
- Heat exchangers designed for greater heat recovery.
- Turbines with high isentropic efficiency.
By adding these features, steam production will be 293.8 t/h, which will be directed to a condensing extracting turbo-generator. Extraction at 21 bar(g) for the process equipment drives is assumed; the equipment drives operate at 1.5 bar(g) of back-pressure, because extraction of the same goes to the process. The other extraction is 1.5 bar(g) to meet the remainder of the process steam demand. The remaining 38.6 t/h of steam will pass through the condensing turbine stage. With this configuration, 34.8 MW of steam will be produced (see Table 6).

### Production of 40.7 MW of surplus power

The focus in this scenario is on the minimum consumption of power by the plant: reduction of the process steam consumption and replacement of steam drives by electromechanical or electro-hydraulic drives. Reduction of process steam consumption from 492 kg steam/tonne of cane to 400 kg/tc is possible with the technological innovations described below.

It is possible to bring down the process steam consumption to 400 kg/tc approximately, by designing the fermentation unit to receive more concentrated juice and then produce wine with higher alcohol content (11.0ºGL or higher), which permits that the distillation unit operates with a specific steam consumption of 2.6 kg/litre of anhydrous ethanol. This requires that the fermentation unit be automated and a CIP (cleaning-in-place) system implemented to keep the process heat transfer surfaces in good condition. Production of anhydrous ethanol utilises molecular sieve technology with low steam consumption. In addition, it is important to use indirect vapours from first effect for the distillery heating by using falling-film evaporators, which operate with very low load loss. The results of this scenario are summarised in Table 7.

### Production of 50.7 MW of surplus power. The State-of-the-Art Mill

To obtain 50.7 MW of surplus power and introduce the state-of-the-art mill, again we refer to the maximum surplus energy equation. By observing the part of the equation relating to maximum use of the available energy, we will replace the 65 bar(g)/485ºC boilers by 100 bar(g)/530ºC boilers, which have the following technological advances:

- Single drum boilers.
- A suspension fired combustion system. This system ensures stable combustion operation and rapid response to changes in steam demand during operation. With systems of this type, an increase of the steam generation capacity can be expected,
with the greater vertical dimension of the boiler permitting adequate dimensioning of the furnaces.

- Reaction turbogenerators. These are more efficient equipment.
- Automation. Appropriate automation systems for boilers, turbogenerators and total process consumption of 2.0 kg steam/litre of anhydrous ethanol.

</tbody>
</table>

To reduce process steam consumption to nearly 300 kg steam/tc, it is necessary to:

- Maximise the heat recovery of the condensate and make use of the flush vapours heat.
- Increase the alcohol content in fermentation to the range of 13.0ºC with the use of a fermentation chiller-type cooling system to permit operation in lower temperatures (e.g. 28.0ºC), steam consumption in distillation will be lower. To reduce the use of Power, a lithium – bromide (LiBr) absorption chiller should be used (using the hot stillage as a heating source), instead of traditional chillers (mechanical compression type: reciprocating, centrifugal, screw) that need more energy.
- Use split-feed distillation which can reduce specific steam consumption to levels below 1.8 kg of steam/litre of ethanol.
- Use membranes for ethanol dehydration, which also contributes to reduce steam consumption as compared with molecular sieves. Total steam required will be 2.0 kg/litre of anhydrous ethanol. This scenario is summarised in Table 8.

Second-generation technologies

The state-of-the-art mill makes use of the maximum energy embodied in juice and bagasse. However, the energy contained in vinasse and crop residues can also be utilised. Taking advantage of both sources is part of the second-generation technologies.

To make use of vinasse, an aerobic biodigestion system is required. Besides treatment of the mill effluents, it also generates biogas.

This technology is already available at a commercial sugar industry scale. The biogas generated must be pressurised and sent to burners installed in the biomass boiler.

This additional energy in the boiler will generate more steam, which will be used in the condensing turbine. By this means, surplus power will increase from 50.7 MW to 55.7 MW.

Let us consider now the use of 50% of the straw (harvest residue) as feedstock. Similar to biogas, this feedstock will be burnt in the boiler, generating more steam for the condensing turbine and, therefore, more surplus electricity.

Technologies and operational changes associated with the recovery of straw are currently still under development and are expected to be ready for commercial application in the near term. Multi-fuel boilers capable of burning bagasse, biogas and straw are already commercially available.

With the introduction of biogas and 50% of the crop residues, surplus power generation can reach 83.9 MW. Figure 3 is a schematic representation of second generation technology bioelectricity production (Olivério, 2008; 2009).
Technological trends in bioelectricity production

Third-generation technologies under development include bagasse and straw gasification for the production of synthesis gas to power advanced cycle bioelectricity plants. With the application of this technology, it will be possible to operate an integrated gas turbine combined cycle (IGCC) in the mills. In this cycle, the biogas produced from vinasse and the syngas from bagasse and straw will be used in the gas turbine, which drives the generator and produces surplus power. The gases that leave the gas turbine are directed to a heat recovery steam generator (HRSG). Steam generated in the HRSG goes to a steam turbogenerator configured similarly to the processes described earlier. After the development and availability of this technology in commercial scale, surplus power production can be as high as 110 MW. In this case, gasification of bagasse and 50% of crop residues are assumed; if 100% of the crop residues could be transported from the field to the mill to produce syngas, surplus power generation would be as high as 150 MW (Olivério, 2008; 2009).

A diagram of the third generation technology is shown in Figure 4 (Olivério2008; 2009), forecast for long term implementation.
Bioelectricity—a new business in sugarcane sector

With the new rules introduced by the Brazilian government and with the use of the technologies presented in this paper, large scale production of surplus power represents a new business for the sugar and ethanol mills.

With the technologies currently available, there is great flexibility for retrofits of the existing plants.

In new projects (Greenfield), the implementation of new technologies is much easier, because the mill is designed according to the concept of maximum use of the energy contained in sugarcane.

It is also important to emphasise that the payback for a retrofit in the existing plants is 4–5 years, depending on the technological solution chosen (Olivério, 2008; 2009).

A good way to evaluate the success of the bioelectricity program is the growing interest of the industry in the biomass energy auctions that have been promoted in Brazil. The amount of installed power generation capacity as a result of the Brazilian programs for production of energy from biomass is increasing, as can be seen in Table 9 (Olivério, 2008; 2009)

Résumé

LA COGENERATION, l'efficacité énergétique et la production d'électricité excédentaire sont des anciennes rubriques dans les usines de canne du Brésil. Toutefois, jusqu'en 2003, le soutien institutionnel et réglementaire n’existait pas, le gouvernement brésilien a alors décidé d'encourager et de réglementer la production d'électricité. Aujourd'hui, la production de bioelectricity dans les usines de canne et la vente d’électricité au réseau sont de plus en plus importantes. Le potentiel de bioelectricity dans l'industrie du sucre brésilienne atteint 1800 MW en 2007–2008. Pendant une vente aux enchères le 8 août 2008, l'agence brésilienne de l'énergie (Agence Nacional de Energia Elétrica – Aneel) a déterminé les règles d'appel d'offres, y compris le prix maximal à payer pour la bioelectricity comme énergie de réserve pour les 15 prochaines années, ce qui se traduit par une capacité installée totale de 2385 MW. Les projections pour 2020–21 prévoient que l'alimentation de la grille sera équivalente à 14 400 MW, et que les revenus générés par cette nouvelle entreprise seront comparables à la production de sucre brésilien. Ce scénario ouvre des opportunités pour les nouvelles technologies d'optimisation énergétique. Ce document est axé sur l'utilisation de la canne d'un point de vue énergétique pour (a) optimiser l'utilisation de l'énergie contenue dans la plante (b) pour réduire au minimum la consommation d'énergie par les usines de sucre et d'éthanol (c) pour intégrer la production d'électricité dans le production du sucre et de l'éthanol (d) pour maximiser la production d'électricité excédentaire. Des technologies nouvelles sont intégrées à l'usine pour améliorer le bilan énergétique: approche mécanique/électrique ou électro-hydraulique pour la conduite des moulins; fermentation a des concentrations d'éthanol plus fortes à l'aide de refroidisseurs pour permettre des températures plus basses; distillation combinée sous vide et pressurisée; utilisation de membrane pour la déshydratation; production de biogaz a partir de la vinaise et sont utilisation comme carburant; utilisation de la paille comme carburant; chaudières capables d’utiliser plusieurs carburants, à haute pression, température et d'efficacité élevée (120 bar(g), 530°C, 89% – LHV); turbogénérateur de condensation/extraction. Trois étapes hiérarchiques de la technologie sont présentées: usines de canne a sucre première génération, deuxième génération et troisième génération. L’usine Bioelectricity « dernier cri » est présentée et des innovations sont considérés pour la conception de l'usine de canne complète.

PALABRAS CLAVE: Cogeneración, Bioelectricidad, Optimización Energética.

Resumen

COGENERACIÓN, eficiencia energética y producción de energía para la venta son temas antiguos en los ingenios brasileños. Sin embargo, no contaron con soporte institucional y regulatorio hasta 2003, cuando el gobierno brasileño decidió impulsar y regular la producción alternativa de producción de electricidad. A la fecha la producción de bioelectricidad en los ingenios y la venta de energía a la red son un nuevo negocio de rápido y sostenido crecimiento. La capacidad instalada de bioelectricidad en la industria azucarera brasileña alcanzó 1800 MW en 2007/08. En una licitación pública en Agosto 8, 2008 la Agencia Nacional de Energía Eléctrica determinó las reglas de comercialización, incluyendo el precio máximo a ser pagado por bioelectricidad como una reserva de energía por los próximos 15 años, lo que resultó en una capacidad total instalada de los ganadores de la licitación, de 2385 MW. Las proyecciones para 2020/21 anticipan que el suministro a la red será equivalente a un promedio de 14 400 MW, y que los ingresos netos generados con este nuevo negocio serán similares a los de la producción de azúcar de Brasil. Este escenario abre oportunidades para nuevas tecnologías de optimización energética. Este trabajo se enfoca sobre el uso de la caña desde un punto de vista energético y como (a) maximizar el uso de energía contenida en la caña (b) minimizar el consumo de energía de las plantas de azúcar y etanol; (c) integrar el proceso de producción de electricidad con el proceso de producción de azúcar y etanol; (d) maximizar la producción de energía exportable. Nuevas tecnologías se incorporan a las plantas para mejorar el balance energético: accionamientos electromecánicos con engranajes planetarios e inversores de frecuencia o accionamientos electrohidráulicos para a las unidades de molienda; fermentación a contenidos más altos de etanol usando chillers de absorción para permitir temperaturas más bajas; combinación de destilación presurizada y en vacío; uso de membranas para deshidratación; biogás a partir de vinaza y su uso como combustible; uso de los residuos de cosecha como combustible; calderas multicomestible con altas temperaturas, presiones y eficiencias (120 bar$\text{(g)}$, 530ºC, 89% – PCI); turbogeneradores de extracción condensación. Se presentan tres etapas jerárquicas de tecnología: ingenios de primera, segunda y tercera generación. Se presenta el ingenio ‘estado del arte’ en bioelectricidad y las innovaciones son consideradas en el diseño del ingenio completo.
ETHANOL DEHYDRATION SYSTEM BY SIFTEK™ POLYMERIC MEMBRANE

KEYWORDS: Ethanol Dehydration, Polymeric Membrane, Vapour Permeation, Pervapouration.

Abstract
ETHANOL is very important renewable energy to Brazil and several companies are improving their technologies by developing processes to increase the benefits of ethanol compared to fossil sources. The Siftek™ polymeric membrane is a technology that can save between 35 and 70% of energy when compared with conventional processes. The first pilot plant (Tiverton, Canada) operated dehydrating grain-based ethanol from 80–90 wt% ethanol to 99.2 wt%, showing the good performance of the membrane system. With the goal of testing the system in a commercial capacity, a second plant (Chatham, Canada) was built and operated with success, drying grain-based ethanol from 40–60 wt% ethanol to 99.5 wt%. To demonstrate this technology to Brazilian ethanol producers, a third demonstration unit was built and operated in ethanol plants from sugarcane. The results confirmed the excellent selectivity of the membrane system to water, dehydrating ethanol from 85–93 wt% to higher then 99.5 wt%, with lower energy consumption and preserving product quality.

Introduction
Ethanol is becoming every day a more popular and important bio-energy source for liquid fuels. In Brazil, its production from sugarcane has reached 22 billion litres in 2007/08, with anhydrous ethanol corresponding to 35% of the total (Unica, 2009).

This result has been achieved by the popularity of the flexible fuel cars and the mixture of ethanol with gasoline that currently represents 25% of the Brazilian ethanol market.

However, it is even more important to have an alternative energy source that has a positive energy balance and the membrane technology can contribute very well to reach this goal.

Recently, polymeric membranes have received much attention because of their excellent performance in gas and vapour separation, especially in separation of water from organic vapour mixtures in industrial processes, which include water-ethanol systems (Huang et al., 2003a).

Considering that there are several kinds of polymeric membranes in existence, the one to be used in the industrial process should be solvent resistant and have high permeability (Huang et al., 2003b).

The Siftek™ polymeric membrane has these properties and was designed specifically for ethanol-water separation with a higher selectivity for water over ethanol.

Distillation and dehydration are responsible for the largest fraction of energy use in ethanol production.

The technology discussed in this paper has the potential to reduce this energy consumption between 35 and 70% when compared with conventional technology, like molecular sieve or extractive dehydration with cyclohexane (Côté et al., 2007).
**Siftek™ membrane and system**

Siftek™ is a hydrophilic polymer membrane that can be used to dehydrate ethanol in the vapour phase in a continuous process illustrated in Figure 1. The ethanol-water vapour mixture is fed in one side of the module containing thousands of fine polymeric hollow fibre membranes.

The mixture travels in the parallel channels and the water vapour is drawn through the dense polymer membrane (while the ethanol is rejected) under a driving force established by a vacuum on the shell side of the module. The hollow fibre membranes are assembled into a shell to form a module. These modules are arranged in series-parallel in a system (Côté *et al.*, 2007).

![Fig. 1—Conceptual operation of membrane.](image1)

The membrane is used under rigorous conditions and has exceptional thermal, mechanical and solvent resistance properties. It is a proprietary polymer formulation based on polyimide that provides a high flux and water/ethanol selectivity.

The main components of the system are shown in Figure 2. The dehydration system is an integrated solution of the membrane with conventional technology. The pre-treatment heats the ethanol-water vapour mixture about 5°C above the dew point. Typically, the operating temperature and pressure is between 100–110°C and 125–170 kPa absolute.

![Fig. 2—Components of the Siftek™ membrane system.](image2)

In both stages a vacuum is applied on the permeate side of the membrane to create a driving force for water permeation. A lower vacuum is required in Stage 2 because of the lower water concentration after Stage 1 (less than 5%). Typical values for vacuum are 10–30 kPa for Stage 1 and 2–10 kPa for Stage 2. A vacuum pump is normally used to reach a lower vacuum and to evacuate non-condensable gases.

The membrane system is fully integrated with the ethanol plant from a mass and energy point of view. There are many installation options available to maximise the benefits of a membrane.

**Tiverton Field pilot unit**

The first polymeric membrane technology demonstration was done at the Greenfield Ethanol plant in Tiverton, Ontario, Canada from August 2006. The goal of the field pilot unit was to
test the membrane under field conditions. The pilot unit was equipped with a single module (the first generation of commercial modules).

The pilot plant was fed with an ethanol-water mixture from a rectification column with concentration varying between 80 and 90 wt% ethanol. The unit, with capacity of 1.0 m$^3$/day, operated at an absolute pressure of 120–140 kPa and temperature of 105 to 115°C producing fuel-grade ethanol. Figure 3 shows the results of a continuous operation over 200 days producing ethanol to an average of 99.2 wt%.
