Abstract

Globalisation is driving unprecedented, radical internal and external reforms in sugar industries across the world. In addition to this, five major emerging or intensifying forces with extraordinary implications will shape sugarcane farming and the sugar industry in future—demographic, economical, socio-political, environmental and technological. This paper first addresses the growth and status of the sugar industry and impact of these emerging forces in shaping future Indian sugarcane farming. Emerging complexities and diversities in farming structure and process demand a new and more complex model of research and technology transfer. Consolidation of the best technologies for maximum exploitation, identification of technology diffusion and adoption gaps, and introduction of new technologies and innovative practices throughout the farming chain will continue to play a vital role in sugarcane productivity improvements. Demographic changes, socioeconomic status of farmers and prices for competing crops will demand sugar companies provide, in addition to competitive cane price, targeted delivery of diverse services to farmers to ensure a sustainable cane supply. Introduction of new sustainability standards and the need for certification from consumers will drive sugar companies to integrate the entire value chain from farmer to consumer through various forms of cooperation, relationship and partnership. These emerging realities will open up untapped potentials and utilise opportunities throughout the value chain to create a new research and technology transfer architecture and competitive landscape for the sugar industry in India.

Introduction

Sugarcane, sugar beet and sugar are politically regulated agricultural crops and a commodity. However, during the past two decades, liberalisation and globalisation has been driving internal and external reforms in the sugar industry.

Sugar production has more than doubled since the 1960s and the production share from cane has increased to 78%. Regional composition of production, consumption and exports/imports has shifted considerably. Brazil, India, the European Union and China are the largest sugar producers with roughly 55% of world production. These are followed by USA, Thailand, Pakistan and Australia with 15% of production during 2007–2008. Eight of these countries are also among the top sugar consumers, representing 55% of global consumption. Historically, sugarcane research has also been concentrated in these countries.

Factors that determine the fundamentals of success and failure in sugarcane research, farming and sugar businesses have also changed. New innovative players, especially Brazil, have
demonstrated their ability to adopt these changes quickly and have dominated the world market. However, multiple utilities of sugarcane as a feedstock for production of sugar, electricity, alcohol, biofuels, bio-polymers and bio-pharmaceuticals are creating a new competitive landscape. These result in increased complexities and diversities in farming structure and process, and demand a new and more complex model of research and technology transfer. Further demographic, economical, socio-political, environmental and technological changes demand consolidation, innovation, and integration across the entire value chain.

Changing landscape

Demographic shift

Along with continued population growth, the world population is experiencing unprecedented demographic changes. People are living longer and increasing numbers are moving from villages to cities in search of a better life. United Nation’s revised estimates on population growth indicate the world population will reach 7.5 billion in 2020 (UN, 2001). All of this growth will occur in Africa, Asia and Latin America, the major cane growing areas of the world. In contrast, in the developed world, the area of major beet growers (Europe, Japan and North America), populations will either decline or remain the same. This means that the demand-supply situation of sugar will move towards the Asian, South East Asian and African countries. Presently, India is the largest consumer of sugar representing 15% of world consumption, even with its lower per capita consumption than the world average (18 kg/22 kg). A projected population of 1.3 billion in 2020 with its large working population (60% in the age group 15–64 years) and emerging young generation (36% younger than 15 years) with wide choices and life styles will push per capita sugar consumption beyond world averages.

Economic growth

Globalisation and the information technology revolution are creating dramatic changes in the economic growth pattern of the developing countries. The World Bank Global Economic Prospects (2009) forecast that the average annual growth rate over the next decade will be highest in China followed by India, Brazil and South East Asia and African countries. This will generate demand for diverse foods. These demands are expected to have a significant impact on the type of sugar consumption among the new generation elites. As a consequence, Brazil, India and China are becoming new centres of forces shaping world sugar production, consumption and trade. A nationwide survey conducted in 2007 also confirmed that there was a shift in consumption pattern of sugar from domestic to industrial use (beverages, confectionery, preserved food, etc.). Of the total sugar sold in the free market, 61% accounted for industrial and the balance of 39% for household use (KPMG, 2007).

Socio-political situation

Sugar is produced in more than 100 countries. However, sugar trade is limited to 30% of the production with long-term agreements. Various socio-political policies continue to influence sugar prices and increase volatility. WTO agreements are expected to liberate the sugar trade from some of these distortions. The major beneficiaries of these sugar reforms will be least-cost-of-production countries with potential to expand production. However, countries such as Brazil, Thailand, India, Pakistan and South Africa, where the domestic market prices are lower than the average world traded price, will face pressure from domestic consumers and political lobbies will continue to constrain price.

There is a need for production to keep pace with sugar consumption. Only Brazil has the capacity to expand the area under sugarcane; another 9 million hectares without affecting their food crops (UNICA, 2008). The Brazilian industry is expanding to capitalise on these opportunities along with its pro-alcohol flex-fuel program. Countries such as Brazil, Australia and South Africa
are more advantaged than others, because of the size of their farms, the structure of operations, and their integrated value chains.

India, with 17.5% of global population but only 2.4% of the world’s arable land, cannot further increase its area under sugarcane without replacing other food crops. Between 1960 and 2003, the number of agricultural holdings doubled (51–101 million), while the area operated declined from 133 to 108 million hectares. This has led to a sharp decline in the average size of holding (2.63 ha to 1.06 ha) leading to an increase in the number of marginal farmers (22.6 to 39.1%; marginal means <1 ha (GOI, 2007; NSSO, 2005). Increasing marginalisation leads to insecurity, increasing costs, inadequate returns, and difficulties in accessing credit. The consequence is exploitative informal credit and resulting pervasive indebtedness (Assadi 1998; Posani 2009).

Hence, India’s farming costs continue to lag behind over the present low-cost producers. There is a growing view that most smallholders do not have a viable future, and agricultural development should focus on larger, commercially oriented farms that can be successfully integrated with technological breakthroughs and linked with emerging markets. The scale of operation is a significant factor in reducing costs as shown in Australian sugarcane farming system studies (Hanlon, 1996; Wegener, 2000). Further, greater integration of harvesting and transport operations would remove inefficiencies and better utilisation of capital leading to substantial gains for global competition. However, India provides a different picture of inverse relationships or lack of relationship in farm size and productivity (Sen, 1964; Dipak, 1965; Ashok, 1985; Mahesh, 2000).

Despite different farm size and technologies, in India small farm holdings have advantages that enable them to dominate. Small farms have lower labour-related transaction costs and more family workers per hectare, each motivated to work and supervise hired workers. Hence, small farms have an advantage in early stages of developing countries through low capital for unskilled workers. These advantages are slowly disappearing in India because of economic growth and labour scarcity through migration of workers to towns and non-farm jobs. Labour cost of cane cultivation has been increasing over the last few years.

Sugarcane being a highly labour-intensive crop, farmers divert to less labour-intensive crops, evident from the recent decrease in the area growing sugarcane. The only available alternative is to mechanise the farming operations. With millions of small and marginal land holdings, large-scale mechanisation poses many challenges compared to countries such as Brazil, Australia, Africa and Latin America where farm sizes are large. Large farms have lower capital and land-related transaction costs, allowing owners to more readily finance equipment that they can use over many hectares. Further efficiency, adaptability and manoeuvrability of these large machines in small farmer holdings are still under question.

With increasing wealth and the IT revolution in India, many farmers are sending their children for education in cities—then take up jobs in cities or abroad. The wealthy, salaried middle class with decreasing loyalties to agriculture and the village still owns a large part of the rural land (Lindberg, 1995; Gupta, 2005). In rural societies, the identities of villager and farmer and how they relate to village are changing. Managing, sustaining and improving productivity of these absentee landlords offers new opportunities and challenges for innovation. This requires a new pragmatic approach with deep insight to customer’s minds to reduce the drudgery associated with farming and offer benefits to customers.

**Environmental issues**

Sugarcane cropping systems that use intensive land, water and other inputs continue to raise concerns about environmental issues and sustainability of farming (WWF, 2003). Globally, irrigated agriculture accounts for almost 70% of water withdrawn for human use. Ground water withdrawals exceeding natural recharge rates of aquifers are leading to the lowering of water tables,
salinisation and land subsidence in many parts of the world. There is not enough additional water resources that can be diverted for increased sugarcane production. In countries such as India, the current water development and management system is not sustainable. India has a highly seasonal pattern of rainfall with 50% of precipitation falling in just 15 days and over 90% of river flows acquired in just 4 months. India’s dams can store only 200 cubic metres of water per person constituting 30 days of rainfall compared to 900 days in the major river basins (World Bank, 2005; IPCC, 2008).

Over the last two decades, 84% of the total addition to net irrigated area came from exploitation of ground water and only 16% come from canals. By 2020, India will need about 29% more water for agriculture, whereas water availability for agriculture is likely to be reduced by 12%.

In 2007, the Intergovernmental Panel on Climate Change (IPCC, 2007) confirmed that climate change is accelerating and, if the present trend continues, average global temperature will rise by 6°C in the long term. A compounding fact is that there is likely to be rapid de-glaciations in the Himalayas, resulting in a substantial impact on the river flows in India. Further, an Indian model of climate change suggests a decrease in the number of rainy days and an increase in extreme precipitation.

This means that the water requirements of sugarcane need to be minimised through finding ways to improve productivity of the crop per drop of water. Irrigation technologies such as furrow, border and flood irrigation need to be replaced by sprinkler and drip irrigation to increase water use efficiency.

**Technological changes**

Sugarcane is among the plant kingdom’s most efficient converter of sunlight into chemical energy that is stored in sugars, fibre and straw. These three products can yield 7192.92 MJ from one tonne of cane–equivalent to 1.2 barrels of oil (Oliverio and Riberio, 2006). Over the last 30 years, Brazil has developed a successful ethanol industry.

Presently, 37 countries mandate for blending ethanol as a fuel component, either directly or blending with gasoline or fuel. Another important aspect of the sugarcane biomass source is the significant generation of electricity using bagasse, which reduces carbon dioxide emissions.

With integration of biotechnological and bioprocess engineering, the sugarcane biomass has been tailored to produce a wide range of products similar to petroleum refiners, the so-called ‘Carbohydrate Economy’ (Allen et al., 1997; Rogers et al., 2001; Edye et al., 2007; Gravitis, 2007).

At the farm level, improved productivity per unit area is critical. In response to concerns about the sustainability of ‘Green Revolution’ technologies and their ability to manage the environmental interface, many are advocating agro-ecological and sustainable agriculture approaches, based on ecological principles of farming (REAP, 2003; Suttivan, 2003). By contrast, advocates of biotechnology argue that biotechnology can help to overcome limitations and offer major yield benefits.

Although these two approaches represent themselves in opposition to one another, both approaches have been integrated successfully in small farms in India with respect to Bt-cotton. These ecological methods include technologies for land preparation, water conservation, soil health and balanced nutrition, farm management, integrated pest and disease management in a sustainable way.

Conventional sugarcane breeding continues to be the major source of varieties. Complexities of breeding, a narrow source of germplasm and diverse requirements of industry resulted in recent biotechnological interventions in the sugarcane genome (Fitzgerald and Bonnett, 2007). However, their commercial applications have so far been limited to field trials. Advances in biotechnological
manipulations, integrated with ecological principles, will play a significant role in future sugarcane productivity improvements.

**Sugar: Indian scenario**

The sugar industry in India is the second largest agro-industry with more than 516 sugar mills operating in 18 states, and it plays a significant role in socio-economic development in rural areas (KPMG, 2007 and MoCFA, 2007). About 249 factories are in the co-operative sector and the balance is in the private or public sector. About 50 million sugarcane farmers and a large number of agricultural labourers are involved in sugarcane cultivation and ancillary activities, constituting 12% of the rural population. In addition, the industry provides employment to about 2 million skilled/semi-skilled workers mostly from rural areas.

Sugarcane growing areas of India may be broadly classified into three regions based on agro-climatic conditions, yield of cane and sugar content (Table 1).

Table 1—Classification of sugarcane regions of India.

Source: Sugar data from Cooperative Sugar Journal, published by Indian Sugar Mills Association
Temperature data from [www.indiawaterportal.org](http://www.indiawaterportal.org)
Values are average of 2001–02 to 2006–07

Sugarcane supply to mill is dependent on the cane production from a large number of small farmers within a 15–20 km radius (average holding less than one hectare). Crop cycle (plant and ratoon) is limited to two or three years because of extreme climatic conditions, compared to six to seven year cycles in other countries. The value chain of the sugar industry has significant regional variations in its profitability to farmers and millers (KPMG, 2007; ISMA, 2009). In India, the sugar industry is beginning to diversify to an integrated complex with co-generation of power and alcohol for industrial and fuel uses.

Sugar is a controlled commodity in India under the Essential Commodities Act of 1955 and is regulated across the value chain. The heavy regulations in the sector artificially impact on demand-supply forces, resulting in market imbalance. Due to a realisation of these problems, since 1993 the regulations have been progressively eased out. However, central and state governments still have control over the sugar value chain, through mandatory and state advisory cane price (SMP and SAP), mill capacity expansion, geographical area of operation, by-product utilisation and movements, levy and sugar release mechanisms and exports and various forms of taxes at central and state level.

**Cyclical sugarcane and sugar production**

Since independence, the land area under cane cultivation, cane production, productivity and sugar production has increased dramatically (Figures 1 and 2).
Fig. 1—Cane area and sugarcane production, India.

Fig. 2—Sugar production and consumption—growing trends.
Irrespective of increased growth in area and productivity, production of sugarcane and sugar fluctuate considerably from year to year in India (Figure 1). This volatility is influenced by natural and man-made factors (KPMG, 2007; Gopinathan and Sudakaran, 2009).

Natural factors include distribution of rainfall, climatic conditions of flood and droughts, pests and diseases. Man-made factors are primarily government policies regarding sugarcane price, release mechanism, taxes and export and import controls.

In the past, these cycles arose every 4 to 5 years (Figure 3). In recent years, these deficit/surplus gaps are becoming wider irrespective of stock positions and various control regimes. India started its biofuel initiative in 2003.

This initiative differs from the rest of the world in its choice of raw material for biofuel production: molasses for bio-ethanol (Gopinathan and Sudakaran, 2009). Cyclicality of sugar, molasses and ethanol production and restrictive policies, availability of molasses, and fluctuating price hampered the fuel ethanol program.

**Strategic options**

Various authors have projected the demand supply requirements of sugar for the next decade (Table 2). Most projected a wide gap between demand and supply. It is evident from the factors that increased production can be brought only through productivity improvements per unit area.

**Table 2**—Projected demand supply—sugar based—food, fuel and power.

</tbody>
</table>
The vision 2025 document of the Sugarcane Breeding Institute (ICAR, 2007) envisages at least the average yield of the sugarcane to be increased (105 tonnes per hectare from the present 67.5) to meet the sugarcane production of 450 million tonnes from 4.3 million hectares in 2020 (Table 2). This is going to be a challenging task.

Yield levels in cane and sugar has plateaued for the last 10 years (Figures 4 and 5) and shows wide variability between three agro-climatic regions and cyclicality year after year (Figure 6).

![Fig. 4—Cane area shift and yield gaps year after year.](image)

![Fig. 5—Cane yield and recovery, Plateau Trend.](image)
Even within the 15–20 km radius of a supply area representing 20 000 farmers, yield levels can range from 1–10 to 100 tonnes per hectare (Figure 7). Such wide variations within the farm and among farms and year after year has been attributed to complex agro-ecological conditions, access and adoption of technologies, cash and credit availability, timing of application of inputs, management of biotic and abiotic stresses, availability of power and labour, and willingness to manage risks. Heavy investments in inputs, infrastructure, and technology added with credit and weather risks and declining profitability can lead to pervasive indebtedness of small farmers. Technologies themselves are not sufficient to bring sustainability and profitability to farming in these situations.
There is an urgent need to evolve strategies and feasible alternatives for creating a viable future for the small farmers. Scientists need to re-orient and adapt to understand the management issues of farming, considering the bio-physical and socio-economic components. There is a need to consider the farmer beyond the passive receiver of technologies and information to a ‘partner’ in the entire value-chain.

Various interlocking arrangements, such as contract, network and leased farming, can create highly integrated backward and forward linkages converting small farmers as entrepreneurs in their own backyards. There is a need for a concerted effort by governments, millers, research institutions and non-governmental organisations to create a more equitable, economic environment for these small farmers to compete in a global context.

This includes targeted customer-oriented agricultural research and extension at local, state and national level, tenure security, efficient land management, assured market-linked competitive price, micro-credit facilities, risk management policies and technology/knowledge access with hassle-free farming.

In addition to this, government needs to continue investment with increased allocations in basic infrastructure such as roads, irrigation, communication, health, and strategic research and extension with long-term objectives.

**Parry way: a strategic initiative**

This calls for a different approach to the dissemination of agricultural research technology for sugarcane production in India by the millers. The conventional pipeline approach to agricultural research and extension has its serious limitations to meet the broad-based sustainable agriculture with complex demands of environmental, economic and diverse aspirational level of farmers.

An innovative integrated approach practised by Parry (*Parry way*) from cane registration to delivering payment on-line to the farmer at his doorstep using research, information technology, extension, development of Farm Process, out-sourcing (FPO) at village level in co-operation with financial institutions, and net working with National and State Research Institutions and Government establishments is depicted as a conceptual framework in Figure 8.

---

**Fig. 8—Farmer relationship: conceptual framework—Parry Way.**
The approach emphasises that innovation is a systemic process and can emerge from any source, complex interactions and the knowledge sources throughout the value chain—farmer to consumer. The conceptual framework envisages a millers’ partnership with farmers in an interdependent way to ensure their aspirations are met through mutual dialogue and service rendered to facilitate hassle-free farming.

On registration of his land for cane, the grower is offered by the miller credit or advance and infrastructure loan either directly or through banks to facilitate easy cash flow.

Extension/Operation staff provide crop advice, farming calendars, soil analysis reports, fertiliser recommendations and suitable varieties. Farm Process Outsource (FPO) centres were developed within the village by selecting entrepreneur farmers and providing technical and financial support.

These FPO centres at village level deliver services at farmers’ door-steps by a mobile call or a request from land preparation to harvesting including the supply of inputs. On successful completion of each activity, millers make the payments to FPO and deduct the same from the farmer’s cane proceeds, enabling cash flow of the FPO.

Agricultural extension staff reduce the risk of farming operations through insurance, survey, monitoring and controlling crops from pests and diseases. Operation staff organise harvesting, transport of cane to factory and payments on time (within 14 days). In-house research staff continue to develop Parry varieties and technologies and also out-source suitable varieties and technologies from National or State institutions.

Traditional on-farm demonstrations, print media, and TV, combined with modern on-line kiosks, are used for communication and information sharing. Traditional class rooms, on farm training and feedback sessions, are an integral part of farmer training offered throughout the year. Information and communication technologies, integrated with geographic information, financial and cane management systems offer reliable and crop-specific information and knowledge flow on-line, accessible through kiosks, internet or mobile phones (Figure 9).
Such information flow throughout the value chain enables traceability of agriculture even to small farms and also facilitates sustainability certification standards.

Open communications and access to information continue to build trust and relationships among the partners and create new avenues of opportunities for extracting value throughout the chain on a sustainable and profitable way for all stakeholders.

Beyond the convenience of farming, working together through an integrated professional culture, the farmer and FPO develop a sense of pride and ownership within himself and in his village.

Such relationships and respect can play a reversal role in rural-to-urban migration in the long term by attracting and retaining youth in farming and thus making farming intellectually stimulating, financially rewarding and a respectable profession.

MOTS-CLÉS: Canne à Sucre, Recherche, Innovation,
Transfert de Technologie, Vision de Parry.

Résumé
LA GLOBALISATION est en train de conduire à des réformes radicales externes et internes sans précédent dans les industries sucrières à travers le monde. Ajouté à cela, 5 forces émergentes, qui montent en puissance, vont redessiner la production de canne à sucre et l’industrie sucrière dans le futur, avec des implications extraordinaires sur le plan démographique, économique, sociopolitique, environnemental et technologique. Cet article dresse tout d’abord un tableau de la croissance et du statut de l’industrie sucrière et l’impact des forces émergentes sur le remodelage des systèmes de production agricoles. La complexité et la diversité émergente des exploitations agricoles requièrent la mise en place d’un modèle de recherche et de transfert de technologie nouveau et plus complexe. La consolidation des meilleurs systèmes pour l’exploitation, l’identification de la diffusion optimale des technologies et des problèmes d’adoption, ainsi que l’introduction de nouvelles technologies et pratiques innovantes dans la chaîne agricole va continuer de jouer un rôle primordial dans l’amélioration de la productivité. Les changements démographiques, le statut socioéconomique des planteurs et les prix relatifs à la compétitivité des cultures vont demander aux compagnies sucrières de fournir, en plus d’un prix compétitif de la canne, la livraison de divers services aux planteurs pour assurer un approvisionnement durable des cannes aux usines. L’introduction de nouveaux standards pour la durabilité et le besoin de certification pour les consommateurs conduira les compagnies sucrières à intégrer l’ensemble de la chaîne de valeur du planteur au consommateur au travers de divers formes de coopération, de relations et de partenariats. Ces réalités émergentes vont débloquer des potentiels inexploités et opportunités inutilisées à travers la chaîne de valeur pour créer une nouvelle architecture de recherche et de transfert de technologie et un paysage compétitif pour l’industrie sucrière en Inde.
ESTRATEGIAS PARA LA TRANSFERENCIA DE INVESTIGACIÓN Y TECNOLOGÍA PARA LA PRÓXIMA DÉCADA–UN EJEMPLO DE LA INDIA

Resumen
LA GLOBALIZACIÓN está impulsando reformas internas y externas radicales y sin precedentes en las industrias de azúcar alrededor del mundo. Además de esto, cinco fuerzas principales emergentes o intensas, con grandes implicaciones extraordinarias - demográficas, económicas, sociopolíticas, ambientales y tecnológicas- moldearán el cultivo de caña de azúcar y la industria azucarera en el futuro. En primer lugar, este documento aborda el crecimiento y el estado de la industria azucarera y el impacto de estas fuerzas emergentes en el moldeamiento del futuro agrícola de la caña de azúcar. Complejidades y diversidades emergentes en la estructura y el proceso de explotación agrícola exigen un modelo nuevo y más complejo de investigación y transferencia de tecnología. La consolidación de las mejores tecnologías para la explotación máxima, la identificación de las lagunas de difusión y adopción de tecnología, y la introducción de nuevas tecnologías y prácticas innovadoras a lo largo de toda la cadena de agricultura van a seguir desempeñando un papel fundamental en la mejora de productividad de la caña de azúcar. Los cambios demográficos, el estado socioeconómico de los agricultores, y los precios de los cultivos competidores exigirán a las empresas de azúcar ofrecer, además de precios competitivos de caña, entrega específica de diversos servicios a los agricultores para asegurar un suministro sostenible de la caña. Introducción de nuevos estándares de sostenibilidad y la necesidad de certificación por parte de los consumidores conducirá a las empresas de azúcar a integrar la cadena de todo valor desde el agricultor hasta el consumidor, mediante diversas formas de cooperación, relación y asociación. Estas realidades emergentes abrirán potenciales sin explotar y oportunidades sin utilizar a lo largo de la cadena de valor para crear una nueva arquitectura de transferencia de investigación y tecnología y un panorama competitivo para la industria del azúcar en la India.
SUGARCANE RESEARCH AND TECHNOLOGY TRANSFER—STRATEGIES FOR THE NEXT DECADE

By

ALVARO AMAYA

KEYWORDS: Research Challenges, Multidisciplinary Research, Sustainability.

Abstract

AGRONOMIC challenges required for the decades ahead will focus on (1) research and technology transfer based on multidisciplinary approaches; (2) a transition from production-oriented models to consumer-driven systems; and (3) developments that promote sustainability and concerns for environmental issues. A multidisciplinary approach ensures that scientists, growers and factory engineers are aware of the contributions of other disciplines, rather than isolated, individual efforts. This requires not a narrowly focused ‘specialist’, but rather someone with a ‘special’ interest in various disciplines, whose wide vision could make integrated contributions to developing a true Renaissance in sugar industries. The transition to a consumer-driven model requires the identification of new priorities. Technologies for sugar production will remain a priority, but greater emphasis must be directed towards technologies for using sugarcane for energy production and for value-added products. In the case of energy production, the use of sugarcane has been possible because of the availability of proven technologies, interest from investors, government regulation and consumer demand. For value-added products, the challenge for scientists lies not just in concrete research outputs, as has been the case for sugar production. Their skills for knowledge management and the vision to transfer their achievements, open new markets and generate interest in funding new research must be strengthened. Sustainability and environmental protection will continue playing a role in future research, both in the field and in factory processes. Climate change is on the agenda of challenges that agronomists and their allied specialists must address in the design and management of future production systems. The prospective use of sugarcane as a source of bioenergy to reduce carbon dioxide emissions to the atmosphere offers an opportunity for scientists, investors and consumers to work together on sustainability and environmental protection. Research achievements and projections in the sugar industry worldwide, reported in the literature as well as by the Colombian sugar industry, are used to illustrate these strategies.

Introduction

Technology development and the strategies for responding to the consumers of sugarcane by-products in the next decade will depend on the clear identification of their consumption requirements and trends.

History shows that countries or sectors that invest greater resources in Research and Development (R&D) achieve greater socioeconomic development while responding to their consumers (OECD, 2008).

The technological advances of the last century have generated benefits for mankind, which have also been incorporated in the technology developments of our sugar agro-industries and can be linked to what is called the innovation revolution (Hockfield, 2009).
This revolution is based on the convergence of several areas of knowledge that we should maintain and strengthen. The first of these, which took man to the moon, developed communications, improved agricultural production and sustained economic development during the decade of the 1950s that was based on the convergence of engineering and the physical sciences. The second took place in the 1980s with the information explosion generated by genomics and proteomics, which accelerated innovation in the life sciences. These two supported the third, which integrates life sciences, engineering and physical sciences. Accelerating these innovations will require changes in education, sources of financing and interaction among those who have the knowledge and between them and the users of the resulting technological products.

The technological challenges depend not only on the resources and infrastructure that are available. The new technological advances that will benefit our agro-industries will depend ever more on (a) R&D and innovation based on multidisciplinary teams, teamwork and alliances with other institutions; (b) the transition from production-oriented to consumer-defined work models; and (c) developments that promote sustainability and greater relevance of environmental issues.

**Multidisciplinarity, teamwork and alliances**

Research based on multidisciplinarity, teamwork and alliances highlights the importance of agro-industrial researchers and professionals being aware of the contribution of other disciplines and of the knowledge from their settings in a globalised world. This contrasts with continuing to face the challenges and solutions required in an isolated fashion.

In the former case, a broader vision of the environmental settings identifies the reality of technological requirements and the opportunities for new developments. There are three principal products that are derived from sugarcane that are in demand by consumers and on which today’s R&D is centred: sugar, ethanol and co-generation of electricity. Of the 1.4 billion tonnes of sugarcane produced today, approximately 75% is destined for sucrose and 25% for ethanol. The co-generation of electricity and the use of products with added value are minimal but have great potential (ISO, 2008a).

A knowledge of consumer demand and interests is decisive for defining future research. If the target is to improve the efficiency of sugar production, technology developments should not be indifferent to population growth and consumption. Income (ISO, 2004) and socio-political factors also influence future consumption. In absolute terms, large populations tend to be associated with high levels of sugar consumption. It is not surprising that the five countries with the greatest growth in consumption in absolute terms are among the ten largest in population.

Future expectations of research funders will be for technological advances that contribute to a greater demand for sugar and its by-products and, consequently, generate greater productivity, income and promote sustainability. Greater income can contribute to a greater demand for sugar and its by-products and, consequently, create challenges for new technology developments. In a global economy in crisis, we are part of the solution; thus knowledge of the environmental setting is fundamental.

Technological advances and their impact on productivity in the sugar industries are evident in the last 30 years. Advances in productivity, a function of technology development (Cox et al., 2005; Edme et al., 2005; Cenicana, 2008; Davis, 2007) highlight the role of R&D for responding to the 2% yearly increase in the consumption of sugar, which today is 160 million tonnes. Despite the progress made in productivity, improvements have not plateaued, so there remain opportunities for improvement via multidisciplinary groups and alliances.

Increased productivity has contributed to reducing the use of the land without affecting food security through expanding the planting of cane in areas occupied by other food crops. This has been the experience of the sugar agro-industry in Colombia, where thanks to the technology developments in the last 30 years, the productivity in sugar has doubled without having to expand the crop to other farming areas (Asocana, 2007).
Sugar industries worldwide use only one-third of the plant’s biomass to produce sugar, so R&D has focused on this aspect. With the potential to use the biomass as a source of energy, either for ethanol or co-generation of electricity (Leal, 2007), demands for new technology offers an opportunity for research. This means the validation and adoption of available technologies, research at the level of cane production in the field and in industrial processes, changes in attitude toward working in multidisciplinary teams, knowledge of the environmental setting, and response to the challenge of using the biomass in a sustainable production system. The updating and acquisition of new knowledge should be permanent, but we should also progress as individuals. Researchers and the organisations need to do their part in order to make full use of the strengths of the human talent and facilitate the improvement of their capacities.

Over the next ten years, the challenges will be greater given the technological advances and impacts reached thus far. This means greater knowledge and integration of other disciplines; and, although there may be a need for greater funding, integration can lead to better rationalisation in the use of the resources and capacities.

What the users of the technology expect will be based not only on the number of products but also on the benefits that they generate (Mervis, 2005). This will be accomplished by integration, teamwork and alliances. Agronomists and professionals linked to cane production will continue to play an important role in facing these challenges, but they will not necessarily be the only actors in the future scenario of agricultural research (Miller, 2008). After the ‘Green Revolution’ era, centred on commodities and research in organisations, the ‘Evergreen Revolution’ has followed, centred on the integrated management of natural resources and participatory research (Swaminathan, 2006). This should be accompanied by a continuous technology transfer and prompt adoption of innovative technologies in order to exploit them at the right moment and not when they are obsolete.

Multidisciplinarity implies interaction. Interaction of researchers with the users of their products should be emphasised in order to provide the scientific foundations for the new technologies and about the concerns that end users may have. The assumption that the user of the technology understands the scientific bases of the developments is not sufficient – the problem is not one of scientific comprehension but of satisfying their needs and concerns (Leshner, 2007).

On the other hand, there is a tendency in the minds of those who need the technology – cane producers, managers and funders – to minimise the range of actions that researchers can have. In some cases, the users feel intimidated by the idea of working with researchers. The best way to change such an attitude is through permanent interaction with them in the environment in which the work is being done (Alberts, 2009).

The culture of teamwork is now beginning to be visible, and it should become stronger in the future. A recent study of publications in the last five decades shows that work teams (reflected in the number of authors) significantly surpasses individual authors in the majority of scientific fields (Wuchty et al., 2007).

The benefits of alliances are also evident in the sugar industry worldwide. One of the best examples is the International Consortium for Sugarcane Biotechnology (ICSB), which integrates 14 countries and 19 institutions in the search for genetic and molecular knowledge of sugarcane and the search for genes of agronomic interest.

All participants contribute to the definition of priorities and finance the research. This has generated knowledge that contributes to improvement and technology development that would not have been possible working in isolation (Moore, 2005).

Internally, at the level of the countries, alliances are being made; and the actors related to R&D are being integrated, such as has occurred in Australia (Maldonado and Troedson, 2009), South Africa (SASRI, 2007), and Colombia (Amaya, 2008), among others. We need to be open to joint developments for generating knowledge, technology and greater welfare in our agro-industries.
The foregoing gives an idea of the profile of the specialist required in the coming decade. This requires not a narrowly focused ‘specialist,’ but rather someone with a ‘special’ interest in several disciplines, whose wide vision could lead scientists to make significant contributions to developing a true Renaissance in our industries.

**From production-oriented models to consumer-driven systems**

The transition from production-oriented work models toward consumer-driven work models requires going beyond the indicators of productivity. Added value, cost reduction, quality raw materials, compliance and interest in the market and consumers’ proposals need to be kept in mind in the new production model.

The production of the sugar already has technological support and experience in R&D. In the future, the refining of the current technology and incorporation of others in the development process are needed.

Cane producers will face an increased demand from the cane processors for cane with higher sucrose content and less extraneous matter. For the sugar producers, greater value can come from supplying the type of product that the consumer wants. This will range from different forms of sugar to nutraceutical products with information on their effect on health and clarity as to their origin with respect to the production system or to whether they were obtained through conventional genetic improvement or genetically modified varieties. A well-informed consumer demands better knowledge of the product.

For more than two centuries, cane has been fundamentally used to produce sugar. In the case of the production of ethanol, the transition has been relatively smooth because the same varieties and the system for producing cane in the field are used, and there were well tested industrial production technologies available in the market. Moreover, the countries that have led the production of ethanol have also had a supporting platform of government regulations, and there has been an ever-growing interest in clean energy on the part of the consumers.

Today, the use of sugarcane to produce value-added products other than ethanol faces a different scene. The challenge for R&D and innovation is even greater given that their impact will depend not only on the technology **per se**, but also on a greater capacity for managing knowledge, a vision for innovation, transfer and marketing of results and technologies, and different forms and sources of financing. The benefits derived from other products with added value are expected to have an economic impact and sustainability that will motivate new R&D and open doors for new financing.

Technology development in the world’s leading sugar industries has been financed to a great extent by the sugar industries themselves, complemented by support from the respective governments. The tendency towards networking, and the complement of external financing have the potential for generating products or patents of greater value in shorter time and with lower costs, incorporating the knowledge of researchers from different organisations.

The availability of information about external funding for the sugar industries is scarce. However, there is a growing trend in this direction, given the global financial crisis. External funding requires a change of paradigms. It is imperative that researchers be aware that, in addition to the economic support from our industries, we also have a ‘capital’ of great value. This is knowledge that we should strengthen and exploit in order to generate greater value, and be supported by an external finance.

In this sense, researchers should be more proactive and eliminate some of their rationalisations that still prevail; e.g. lack of time, ignorance in how to proceed, belief that someone else should do it, believe that is something too big and lacking aid, among others (Wells and Farnham, 2006). Such attitudes must be eliminated in future researchers if they are to attract funding with competitive proposals and based on their merits.
Sustainability and concerns for environmental issues

Developments that promote sustainability have become current concerns, given that, in addition to the investors’ expectations, there is the consumers’ interest of preserving natural resources and conserving the environment. The potential for reducing carbon dioxide emissions to the atmosphere through the use of renewable energy sources such as sugarcane makes this crop an ideal option. A global vision, multidisciplinarity and strategic alliances can generate a better future for the sugar industries that face these challenges.

Sustainability, understood as satisfying the needs of the current generation without compromising the needs of the future generations (IPCC, 2007), refers to the need to take into account the economic, social and environmental benefits in any production system. Unfortunately, political interests have also arisen around this topic; thus, it is imperative that researchers be informed as to what is going on in their settings in order to give an objective response based on research or to incorporate those concerns in future research.

Sugar industries around the world have been incorporating sustainability in their technology developments related to the environmental issues. If we start with the production in the field, the raw material is the genetically improved varieties. In the majority of cases, new varieties have generated greater production with the same level of natural resources (soil and water) and inputs less than those used previously. This also contributes to the social component, freeing-up arable land and improving the efficient use of the water. In the Colombian sugar industry, improvements in technology for water management (Torres et al., 1996, 2004) and planting varieties that require less irrigation (Victoria et al., 2002) have reduced water consumption by approximately 50% without affecting production.

In the case of the cane varieties, the majority of those released are resistant to diseases and pests, which decreases the use of agrochemicals. In the control of some pests, the use of biological control is routine, which decreases the use of insecticides.

Today, field technology is targeted to specific conditions, defining the technologies, varieties and agronomic management practices in accordance with climatic zones and the cane producers (Carbonell et al., 2001; Isaacs et al., 2007). This site-specific agriculture approach has generated up to 30% increases in production in some zones of the Colombian sugarcane industry (Isaacs et al., 2007; Viveros et al., 2009). The management of the crop in the field with specific technologies and the search for environmentally friendly products will be of relevance to the final acceptance by consumers. Therefore, this should be a priority in future research.

Climate change is a reality (IPCC, 2007); and, in order to adapt or mitigate the effects of this change, future actions should consider changes of scale. We have moved from a temporal scale of the climate that affects a crop cycle for short periods of time to consider the impact of the evolution of the climate over hundreds or thousands of years on agriculture and life today on the planet. We’ve also moved on the spatial scale, from metres or hectares to regions and the entire globe (Steiner and Hatfield, 2008). This reality leads us to define different strategies in the management of the inputs required for producing the crop and the industrial processes. That is another reason for working together.

A focus on climate change projects a more integrated vision for future R&D. There are platforms for analysing the impacts of climate change and the measures required for mitigating them in sugarcane (Nayamuth, 2005; Schulze, 2007; Park, 2008). The use of cane for biofuels contributes not only to reducing the dependence on fossil fuels, but also to reducing carbon dioxide emissions into the atmosphere.

The Brazilian experience and their success in the ethanol production system is today a reference point for industries that are moving to the production of biofuels. We should learn from this arduous path and the weaknesses they have to overcome in this development. That will help project the research that fills the information gaps for both science and for society.
Conclusions

R&D challenges facing the sugar industries in the next decade will depend on strategies that involve greater emphasis on changing the way of doing things more than on the development of the technology per se. Technological advances will be fundamental, but changes in our attitudes that promote multidisciplinarity, teamwork and alliances will underpin innovations of impact that will generate greater growth of our industries, consumer satisfaction and sustainability of the ecosystems where sugarcane is produced and processed. The renaissance that we expect to occur in the world’s sugar industries will depend on incorporating in our R&D the vision that prevailed in the era of Renaissance of a ‘Homo universalis’ with an open mentality and interest in the advances of other disciplines that will contribute to realise the potential of today’s capacities to address future challenges.

MOTS-CLÉS: Défis de la Recherche, Recherche Multidisciplinaire, la Durabilité.

Résumé

Les challenges agronomiques nécessaires pour les décades à venir seront centrées sur (1) la recherche et le transfert de technologie basés sur des approches multidisciplinaires; (2) une transition à partir de modèles de production orientés sur des systèmes pilotés par les consommateurs et (3) des développements qui promeut la durabilité et les préoccupations concernant les enjeux de l’environnement. Une approche multidisciplinaire permet aux scientifiques, planteurs et ingénieurs d’usine d’être informés des contributions des autres disciplines, plutôt que sur la base d’efforts individuels isolés. Il ne s’agit donc pas d’avoir un spécialiste à vision étroite, mais plutôt quelqu’un qui a un intérêt particulier dans plusieurs disciplines, et dont la vision permettrait d’intégrer les contributions pour développer une renaissance des industries sucrières. La transition vers un modèle piloté par la demande des consommateurs requiert l’identification de nouvelles priorités. Les technologies de la production de sucre vont rester prioritaires, mais une pression plus importante doit être mise sur les technologies utilisant la canne à sucre pour la production d’énergies et d’autres produits à valeur ajoutée. Dans le cas de la production énergétique, l’utilisation de la canne à sucre a été possible grâce à la disponibilité en technologies éprouvées, l’intérêt des investisseurs, la régulation du gouvernement et la demande du consommateur. Pour les produits à forte valeur ajoutée, le challenge pour les scientifiques, ne se situent pas uniquement au niveau des retombées de recherche comme cela a pu être le cas pour la production de sucre. Leur aptitude à appréhender la connaissance du management et leur vision pour le transferts des résultats, à ouvrir de nouveaux marchés et à générer de l’intérêt pour financer de nouvelles recherches doit être renforcer. La durabilité et la protection de l’environnement va continuer à jouer un rôle dans la recherche future que ce soit au champ et au niveau des processus technologiques dans les usines. Le changement climatique fait partie des challenges que les agronomes et leurs partenaires spécialisés doivent prendre en compte dans la conception et le management des systèmes de production du futur. L’utilisation prospective de la canne à sucre comme source d’énergie pour réduire les émissions de dioxyde de carbone dans l’atmosphère offre une opportunité pour les chercheurs, les investisseurs et les consommateurs de travailler ensemble sur la durabilité et la protection environnementale. Les avancées majeures de la recherche et les projections dans l’industrie sucrière à travers le monde répertoriés dans la littérature et au niveau de l’industrie sucrière colombienne, sont utilisés pour illustrer ces stratégies.
INVESTIGACIÓN Y TRANSFERENCIA DE TECNOLOGÍA DE LA CAÑA DE AZÚCAR- ESTRATEGIAS PARA LA PRÓXIMA DÉCADA

PALABRAS CLAVES: Desafíos de la Investigación, Investigación Multidisciplinaria, Sostenibilidad.

Resumen

Los desafíos agronómicos requeridos para las próximas décadas se centrarán en (1) la investigación y la transferencia de tecnología basada en enfoques multidisciplinarios, (2) una transición de modelos orientados a la producción a sistemas dirigidos por el consumidor, y (3) los desarrollos que promuevan la sostenibilidad y las preocupaciones en cuestiones medioambientales. Un enfoque multidisciplinario garantiza que los científicos, los cultivadores y los ingenieros de fábrica sean conscientes de las contribuciones de otras disciplinas, en lugar de esfuerzos aislados e individuales. Esto requiere no tener un enfoque en el restringido 'especialista', sino más bien a alguien con un interés 'especial' en diversas disciplinas, cuya visión amplia le daría la capacidad de hacer contribuciones integradas para el desarrollo del verdadero renacimiento en las industrias de azúcar. La transición a un modelo orientado al consumidor requiere la identificación de nuevas prioridades. Las tecnologías para la producción de azúcar seguirá siendo una prioridad, pero un mayor énfasis debe ser dirigido hacia las tecnologías para el uso de caña de azúcar en la producción de energía y productos de valor añadido. En el caso de la producción de energía, el uso de la caña de azúcar ha sido posible dado a la disponibilidad de tecnologías probadas, el interés de los inversionistas, regulación del gobierno y demanda del consumidor. Para los productos de valor agregado, el reto para los científicos consiste no sólo en los resultados concretos de investigación, como ha sido el caso para la producción de azúcar. Sus habilidades en gestión del conocimiento y su visión para transferir sus logros, abrir nuevos mercados y generar interés en financiar nuevas investigaciones deben ser fortalecidas. La sostenibilidad y la protección del medio ambiente seguirán desempeñando un papel en el futuro de la investigación, tanto en el campo como en los procesos de fábrica. El cambio climático está en la agenda de los desafíos que deben abordar los agrónomos y sus aliados especialistas en el diseño y administración de futuros sistemas de producción. El uso prospectivo de caña de azúcar como una fuente de bioenergía para reducir las emisiones de dióxido de carbono a la atmósfera ofrece una oportunidad para que los científicos, los inversores y consumidores trabajen juntos para la sostenibilidad y la protección del medio ambiente. Los resultados de investigación y las proyecciones de la industria del azúcar en todo el mundo, reportados en la literatura, así como por la industria del azúcar colombiana, se utilizan para ilustrar estas estrategias.
KEYWORDS: National Programs, Stakeholders, Matrix Management.

Abstract
Research is the cornerstone for maintaining healthy and sustainable agricultural industries. Systems for obtaining funding and managing and dispersing resources are as diverse as are there systems for culturing sugarcane. This paper presents a model of managing agricultural research programs at the Federal agency level. The Agricultural Research Service (ARS) is USDA’s principal in-house agricultural research agency and, as a Federal agency, it is tasked with conducting publicly-funded research for the benefit of the United States. ARS aims to generate relevant, significant, and timely scientific information for use by the Agency’s many stakeholders: agricultural producers, food processing industries, natural resource managers, universities, and non-profit research institutions. To ensure that these objectives can be achieved, ARS implemented the National Program cycle, a cycle of phases embodying a series of recurring activities. Customers and stakeholders are actively engaged in each phase of the process and their contributions are integral to the direction of research and its success. Input, Planning, Implementation, and Assessment — are the four sequential phases through which ARS research progresses, ensuring that it remains of the highest quality. The cycle ties these activities together in a recurring 5-year sequence to ensure an effective and efficient program and project management within ARS. These efforts are aimed at maintaining a sustainable sugarcane industry that is responsive to changing economics, production problems, and opportunities, and will require continued Federal, but also State, private, and international cooperation to be successful. The beneficiaries of a sustainable sugarcane industry will be the citizens of the U.S. who will enjoy abundant and affordable sugar and sugar-based products.

Introduction
The Agricultural Research Service (ARS) is USDA’s principal in-house agricultural research agency and, as a Federal agency of the United States, it is tasked with conducting publicly-funded research for the benefit of the United States. To meet this mission, ARS has developed a system for developing and managing the Agency’s research priorities that actively engage the private and public sectors in research planning and implementation.

ARS aims to generate relevant, significant, and timely scientific information for use by the Agency’s many stakeholders: agricultural producers, food processing industries, natural resource managers, universities, and non-profit research institutions. The larger body of USDA beneficiaries, customers, and stakeholders includes U.S. consumers, other Federal agencies such as the Food and Drug Administration, regulatory agencies such as USDA-Animal Plant Health Inspection Service (APHIS) and the Environmental Protection Agency (EPA), and international markets.

Management of the ARS national research programs is headquartered in Beltsville, Maryland—also home to the largest ARS research facility—which is in close proximity to USDA.
administrative headquarters in Washington, D.C. There are over 100 ARS research locations that serve crops, animals, natural resources, and food safety and quality throughout the United States, Puerto Rico, and the U.S. Virgin Islands, and four laboratories overseas.

Individual laboratories are led by research leaders, who oversee a number of related research projects, and who are responsible for ensuring the quality and performance of each project. Laboratories are grouped into eight geographical areas, each of which is under the direction of an area director. Sugarcane research is located at these primary sites: Canal Point and Miami, Florida; Houma and New Orleans, Louisiana; and Beltsville, Maryland.

The number of facilities in each area varies, as does the research focus, but all ARS scientists are tasked with addressing agricultural issues of regional and national significance. These issues are identified and selected through a national priority-setting process involving scientists, customers, stakeholders, and program officials.

National scientific direction is provided by the Office of National Programs, located in Beltsville. National Program Leaders (NPLs) are assigned to specific programs for leadership, based on their expertise and the research area of need.

Sugar crops, including sugarcane and sugarbeet, are assigned to one NPL as part of their national portfolio of crop responsibilities, and that person works with a team of NPLs to address the diversity of issues facing the national research program.

The annual fiscal budget for ARS is set by the U.S. Congress and is nominally similar each year. In 2009, the total ARS budget was US$1.14 billion. Every spring, the NPLs, area directors, budget staff, and the agency administrator decide on the budget requests to be made for the following fiscal year, including what research should be continued, what new research should be initiated, and what, if any, should be terminated. These decisions are based on administrative priorities, progress obtained from individual annual reports submitted for each project, and research needs identified through ongoing contacts with stakeholders and customers associated with each national program.

To plan, implement, coordinate, and account for its research, ARS uses a matrix management approach. The matrix is composed of vertical (‘line’/local) management organised by geographic Areas, and horizontal (‘programmatic’/national) management organised by research programs (Office of National Programs), functions (budgeting, information technology, technology transfer, security), and business processes (administrative and financial management). The administrator and the executive team of ARS provide leadership to the matrix management system in accordance with the ARS strategic vision and mission, national program action plans, and established operating policies.

**Background: National program organisation**

Senior leaders in ARS moved toward the present concept of national programs in 1993. ARS leaders realised that, to remain on the leading edge of agricultural research, the agency approach to interdisciplinary, nationally collaborative research had to be updated. With better national coordination of ARS’s considerable resources, the agency could more effectively focus on significant problems of high national priorities.

In 1998, Congress decided that ARS establish procedures to enhance its accountability, and mandated that all new proposed research projects be subjected to scientific peer reviews. The ARS Office of Scientific Quality Review (OSQR) was organised as a result of this act, and is described below under Phase II: Planning.

Over the next few years, ARS revamped the way it managed its research portfolio; the 1000-plus research projects were aligned into 21 national programs that encompass all research in the agency. These national programs are grouped into four program areas: (1) Nutrition, Food Safety, and Quality; (2) Animal Production and Protection; (3) Natural Resources and Sustainable
Agricultural Systems; and (4) Crop Production and Protection (where most of the sugarcane research is conducted) (Table 1). Each of the four program areas is managed by a Deputy Administrator.

Each National Program is led by a team of NPLs, selected based on their area of expertise to provide research direction on a national level. Currently, 25 NPLs are responsible for planning and developing research strategies to address critical issues affecting American agriculture.

Implementation of the 5-Year National Program Cycle

The overarching objectives of the National Programs are relevance, quality, and impact, all important elements of accountability for ARS research.

Research must be relevant to the highest priority problems; the goals and outcomes of the research should significantly impact the problems; and the science must meet the highest standards of quality. To ensure that these objectives can be achieved, ARS implemented the National Program cycle; a cycle of phases embodying a series of recurring activities (Figure 1).

Customers and stakeholders are actively engaged in each phase of the process described below, and their contributions are integral to the direction of research and its success.
The descriptors on the inside of Figure 1, input, planning, implementation, and assessment, are the four sequential phases through which ARS research progresses, ensuring that it remains of the highest quality. The cycle ties these activities together in a recurring 5-year sequence to ensure effective and efficient program and project management within ARS.

**Phase I: Input**

Research in ARS derives its strength from its responsive nature to the needs of the U.S. public. At the National Program level, senior program leaders meet with customers, stakeholders, and partners; participate in Federal and USDA working groups and initiatives; and interact with Congress to build a strong understanding of national issues in agriculture and science. At the local level, senior managers also meet with customers, stakeholders, and partners, and participate in working groups to build a strong understanding of issues facing producers and industry. Each type of input is coordinated to produce a responsive program and project. This holds true for sugarcane research as well, as state and national stakeholders and scientists team up with the NPL to develop a regional and national program that addresses the most critical needs in breeding, genomics, germplasm preservation and distribution, pathology and entomology, agronomy, weed science, horticulture, remote sensing and monitoring, physiology, and sugar processing technologies.

Although input from these constituencies is ongoing, formally and informally, throughout the program cycle, the beginning of the cycle marks the consolidation of all input into a National Program Action Plan. The largest formal face-to-face input mechanism, the National Program Customer/Stakeholder workshop, immediately precedes the writing of that Action Plan. These meetings are designed to define specific researchable problems aimed at meeting high-priority needs within the agricultural community.

The workshops also provide an opportunity for ARS research scientists and program managers to interact and develop rapport with customers, stakeholders, partners, non-ARS scientists, and representatives from other agencies. For example, in the Crop Production and Protection Area, leaders from most, if not all, commodities work with our scientists and NPLs to determine the most critical needs of industry. In addition, input is obtained at numerous meetings and workshops during the year that is either commodity- or discipline-based.

Commodity representatives contribute greatly to the success of ARS research by providing in-kind support to relevant programs. For the ARS sugarcane programs in particular, Florida and Louisiana locations both have close collaborations with their respective industry and university researchers, growers, and producers. In 2007, as a response to requests from industry, a national
ARS Sugarcane Workshop was held for the first time in almost 25 years. Results from that 2-day event were captured in an Executive Summary with a vision and mission statement and primary research needs that can be viewed on the ARS Web site:

Phase II: Planning

Planning of ARS research is organised at two levels: National Program and individual project planning. National program planning begins at Headquarters with the development of the Action Plan. This plan is based on the vision and mission of ARS that encompass the broad goals of the Agency and on feedback from the Customer/Stakeholder workshop to define (1) problems to be addressed, (2) actions ARS will take to achieve the mission and goals of the National Program, (3) expected targets or outcomes of the research, and (4) locations that will be responsible for carrying out the work. As such, Action Plans provide guidance for project development, but also for facilitating project review and assessment of the National Programs. Scientists who contribute to the National Program are engaged in the process and often assist in the writing and formulation of the Action Plan.

Subsequently, scientists and line managers participate in planning individual research projects. Using research objectives identified in dialogue between researchers and the National Program team, a Project Plan is developed that addresses — either with basic, applied, or developmental science—the primary research objective(s). A robust Project Plan outlines research approaches, defines interactions among team members, enhances scientist productivity and impact, and creates opportunities for working with collaborators.

Once developed, the 5-year project plan is submitted for external peer review under direction of the ARS Office of Scientific Quality Review (OSQR), which develops a panel of highly regarded university and industry researchers in related fields. The ARS NPLs select the panel chair only, who in turn selects the panel members. The panel is asked to evaluate and rate the scientific quality, methodology, and outcomes in the proposed project plan based on the direction outlined in the Action Plan. As part of the review, the panel can suggest changes in the Project Plan to improve focus or identify other research considerations that also should be addressed. Plans that do not receive passing scores are asked to revise their plans based on the panel’s comments and to resubmit for a second review by the panel. Once plans are passed by the panel, a new 5-year project is implemented.

Phase III: Implementation of the research plan

This phase covers a wide range of processes, all of which are designed to optimise the research environment at all levels in the Agency. During this phase, line management may fill scientist vacancies and abolish positions, obligate and disperse funds, and develop agreements with outside organisations. As the cost of research continues to increase, there is a risk of losing resources to support important projects; thus, there is constant pressure to maximise efficiency, enhance collaborations, and accurately target the most important research.

Several mechanisms are in place to ensure that ARS research meets customer and stakeholder needs and is of high quality and impact. Included in these mechanisms are annual evaluations of individual scientist performance, annual reports of research progress, and yearly National Program reports that compile the best project accomplishments for a broader audience. If midcourse adjustments are necessary to avoid duplication of research and address gaps in research for new and emerging priorities, National Program Leaders have the authority to shift research objectives to meet these priorities, in consultation with project scientists and line management. For example, the finding in 2007 of orange rust (caused by Puccinia kuehnii) in Florida sugarcane, was the first report in the Western hemisphere, and prompted immediate attention to this new and serious disease.
Phase IV: National program retrospective assessment: 5-Year programs

Near the end of the project’s 5-year life, the annual reports from each of the program’s projects is summarised in a comprehensive Assessment Report, which looks at the past 5 years of accomplishments to compare against what was outlined in the Action Plan. This National Program assessment process (Retrospective Review) plays a key role in both retrospective evaluation and future priority setting in ARS. This report is used by an external panel of university and industry experts from relevant scientific disciplines to evaluate success of the National Program’s performance in the prior 5-year cycle.

The panel assesses the National Program’s impact and its delivery of information, knowledge, and technology that meet customer expectations, as determined by actual impact or progress toward anticipated benefits to end-users, scientific communities, and/or broader society as outlined in the Action Plan. After evaluating the compiled accomplishment summaries, the panel assesses the value of the research that has actually been conducted. The panel prepares a written report and makes recommendations for future research priorities. One outcome of the panel’s Assessment Report is that the National Program team has tangible, independent judgment and commentary of the previous 5-year’s research agenda, and a basis upon which to update the vision, direction, focus, and rationale of the research agenda (Action Plan) for the next 5 years.

ARS continually monitors the quality of its work to meet Federal requirements and ensure public accountability. These retrospective assessments reveal how well programmatic goals were met, whether any deviations from plans proved productive, and how future research can be focused on unmet needs.

The nature of high-risk, long-term research is that such endeavours may lead to applications only after many years, and many factors beyond the Agency’s control can affect ultimate use by producers, processors, consumers, or policy makers. Thus, ARS strives to identify ways to assess performance, impact, or value beyond simple metrics of technical inputs and outputs. For example, programs like breeding for cold tolerance for sugarcane, adaptation to marginal soils, and application of genomics for enhancing the breeding program are long-term programs to which ARS is committed for the future sustainability of sugarcane in the United States.

The key building block for any performance assessment is the project annual reports, which describe the project’s research progress and accomplishments each year. This information is used by management at all levels of the Agency, and it also informs the public about ARS progress and accomplishments.

Audiences of the annual reports, which are posted on the ARS Web site, include Congress; the White House Office of Management and Budget; stakeholders, customers, and other scientific agencies and scientists; and the general public.

Conclusions: ARS vision for the future of sugarcane research

ARS sugarcane research at a glance

ARS has a long history of international sugarcane research cooperation, aimed at improving productivity in the United States and abroad, and developing new markets for the various products that can be produced from sugarcane and other agricultural crops grown in the United States. As pressures mount on global agriculture to solve the world’s need for food and fuel in a sustainable fashion, interest in sugarcane has increased.

The success of these programs is due to their specific resources, diverse talents, and to the rich local, national, and international collaborations that are characteristic of these programs.

Primary ARS research programs for breeding, pathology, entomology, agronomy, physiology, and production at Houma and Canal Point have a long and productive history of collaborations with their respective university and industry partners. Although they are both located in a subtropical climate, their growing conditions are so different that surprisingly, in the history of
the breeding programs, only two cultivars (CP 65-357 and CP 89-2143) have been grown successfully in both states. Cultivars have traditionally been released for high sugar yield and adaptability to the local environment, but recently cultivars more suited for use as biofuels have been released. The ARS location in Miami, Florida houses the world sugarcane collection that conserves, protects, and distributes sugarcane and related germplasm to ensure genetic diversity for breeding programs worldwide.

Both Canal Point, FL and Houma, LA breeding programs have contributed significantly to international sugarcane programs through the direct use of commercial cultivars and through use of parental clones for breeding. For example, in Central America, where the climate is more similar to that of Florida, approximately 50% of the acreage in commercial production is with cultivars developed by the CP (Canal Point) USDA-ARS Sugarcane Field Station. There has also been extensive international collaboration, training of scientists and technology transfer with ARS research programs. Likewise, the Commodity Utilisation Laboratory in New Orleans, LA has made important contributions to improved industrial processing of sugarcane, and improved measurement and reduction of sugarcane deterioration.

Current ARS research priorities are listed below:

- Development of high yielding, widely adapted breeding lines and cultivars for sugar and bioenergy that yield well on varied environments to include marginal lands;
- Evaluation of complementary crops that can be grown as feedstocks with sugarcane for the year-round processing of biofuels;
- Association genetics and molecular marker development to advance conventional breeding programs;
- Precision agriculture and remote sensing;
- Mechanical harvesting and use of chemical ripeners;
- Resistance to a constantly changing array of disease, insect, and weed pests;
- Sugar chemistry, physiology, chemical engineering and impact on harvesting, and storage processing;
- Pathology to support the breeding program for disease resistance, detection, and monitoring; and
- Strategies for integrated and sustainable weed and insect management.

Currently, the two most serious threats to the U.S. sugarcane industry are brown and orange rust diseases, caused by the fungal pathogens *Puccinia melanocephala* and *P. kuehnii*, respectively. Orange rust in the United States is restricted to Florida at this time and, when found in 2007, was the first report in the Western Hemisphere.

There is a concerted effort by the research communities to identify useful fungicides as a short-term control measure, and sources of genetic resistance to support and advance the sugarcane breeding program. Fungicide use is not sustainable, however.

Thus, molecular and other efforts to support and advance the breeding programs are critical. A full interdisciplinary approach to this disease is vital to provide a profitable crop for the sugar industry and the new biofuel crops.

Efforts are aimed at maintaining a sustainable sugarcane industry that is responsive to the changing economics, production problems, and opportunities, and will require continued Federal, State, private, and international cooperation to be successful.
LE SERVICE DE LA RECHERCHE AGRICOLE DE L’USDA: UN PARTENAIRE PUBLIC DE LA RECHERCHE ET DU DEVELOPPEMENT POUR LA CANNE A SUCRE

Par

GAIL C. WISLER
USDA-ARS, National Program Leader for Horticulture and Sugar, Beltsville, Maryland, U.S.A.
Gail.Wisler@ars.usda.gov

MOTS-CLÉS: Programmes Nationaux, Acteurs, Gestion Matricielle.

Resumé
La recherche est la pierre angulaire d’un maintien d’une industrie agricole viable et durable. Les systèmes pour obtenir des financements, gérer et distribuer les ressources sont aussi diversifiés que le sont les systèmes pour cultiver la canne à sucre. Cet article présente un modèle de gestion des programmes de recherche agricole au niveau d’une agence fédéral. Le service de la recherche agricole (Agricultural Research Service, ARS) est la principale agence fédérale créée et abritée par l’USDA, avec comme tâche principale de mettre en place et conduire les financements publiques pour la recherche au bénéfice des États-Unis. L’ARS a pour objectifs de générer une information scientifique pertinente, significative et opportune pour une utilisation par les nombreux partenaires et acteurs de l’agence: producteurs agricoles, industries alimentaires, gestionnaires des ressources naturelles, universités et institutions de recherche sans profit. Pour garantir que ces objectifs seront bien finalisés, l’agence agricole ARS a mis en place le cycle de Programme National, un cycle d’étapes comprenant une série d’activités récurrentes. Les clients et partenaires sont activement engagés dans chaque étape/phase du processus et leurs contributions sont partie intégrante de l’orientation donnée à la recherche et son succès. L’apport d’idées, le planning, la mise en place et l’évaluation sont les 4 phases séquentielles à travers desquelles l’ARS progresse, tout en s’assurant que le processus reste de la plus haute qualité. Le cycle d’étapes relie ces activités entre-elles sur une séquence récurrente de 5 années pour garantir, au sein de l’ARS, un programme et un projet de gestion efficace et efficient. Ces efforts ont pour objectif de maintenir une industrie de canne à sucre durable et réactive au changement économique, aux problèmes de production, aux opportunités, et ceci va demander la mise en place, avec succès, d’une coopération fédérale, nationale, privée et internationale. Les bénéficiaires d’une industrie de canne à sucre durable sont les américains eux-mêmes, qui vont profiter d’un sucre et ses produits dérivés abondants et bon marché.
USDA—SERVICIO DE INVESTIGACIÓN PARA LA AGRICULTURA: UN SOCIO PUBLICO PARA LA INVESTIGACIÓN Y EL DESARROLLO DE LA CAÑA DE AZÚCAR

PALABRAS CLAVES: los Programas Nacionales, las Partes Interesadas, la Administración de Matriz.

Resumen

LA INVESTIGACIÓN es base para el mantenimiento de las industrias agrícolas sanas y sostenibles. Los sistemas para la obtención de financiación y para la administración y la dispersión de recursos son tan diversos como hay sistemas para cultivo de caña de azúcar. En este documento se presenta un modelo de gestión de programas de investigación agrícola al nivel de la Agencia Federal. El Servicio de Investigación Agrícola (ARS) es la Agencia principal de investigación agrícola del USDA y, como una Agencia Federal, se encarga de llevar a cabo investigaciones financiadas con recursos públicos para beneficio de los Estados Unidos. ARS pretende generar información científica pertinente, importante y oportuna para el uso de las partes interesadas de la Agencia: los productores agrícolas, las industrias de procesamiento de alimentos, los administradores de recursos naturales, las universidades y las instituciones de investigación sin fines de lucro. Para garantizar que se puedan conseguir estos objetivos, ARS ha implementado el ciclo del Programa Nacional, el cual es un ciclo de fases que incorpora una serie de actividades recurrentes. Los clientes y las partes interesadas participan activamente en cada fase del proceso y sus contribuciones son parte integrante en la dirección y el éxito de la investigación. Datos iniciales (de entrada), planificación, implementación y evaluación son las cuatro fases secuenciales a través de las cuales se desarrolla la investigación de la ARS, asegurando que siga siendo de la más alta calidad. El ciclo une estas actividades en una secuencia recurrente de 5 años para garantizar una gestión de programas y proyectos eficaz y eficiente dentro de la ARS. Estos esfuerzos están encaminados a mantener una industria de la caña de azúcar sostenible, que sea sensible a la evolución de la economía, y a las oportunidades y problemas en la producción, que requerirán apoyo federal continuo, así como también la cooperación internacional, estatal y privada para tener éxito. Los beneficiarios de una industria sostenible de la caña de azúcar serán los ciudadanos de los Estados Unidos que disfrutarán de azúcar y productos a base de azúcar abundantes y asequibles.
THE DSM—DEDINI SUSTAINABLE MILL: A NEW CONCEPT IN DESIGNING COMPLETE SUGARCANE MILLS

By

J.L. OLIVÉRIO, V.B. CARMO and M.A. GURGEL
Dedini S. A. – Indústrias de Base
jose.oliverio@dedini.com.br

KEYWORDS: Ethanol, Sugarcane, Sustainable, Bioelectricity, Biomass.

Abstract
For almost 500 years, sugarcane has been considered almost only as a raw material for sugar production. In the last decades, in Brazil, it has also been used for ethanol production. So, the complete sugarcane mill’s design evolved significantly in that direction, utilising sugarcane juice as a feedstock for sugar and ethanol processes. Recently, for environmental, economical, social, in other words, for sustainability reasons, the world started to search for new and cleaner energy sources. As a consequence, world interest in ethanol grew spectacularly, due to its environmental qualities and because it is produced from renewable biomass. That scenario changed the prospect for sugarcane: it allowed sugarcane to reach a new and higher dimension, and to generate a cycle of new businesses, derived from traditional and new products. This paper has the objective to show how that evolution is modifying and will continue to influence the complete sugarcane mill design, considering technological development and sustainability evolution. The paper describes an integrated sugarcane mill with the most advanced disruptive (breakthrough) innovations, considering the technological hierarchy of first, second and third generations, in bioelectricity, bioethanol, and integrated biodiesel production. Also, sustainability is incorporated into the concept of the mill resulting in an upgraded solution to an optimal design. In summary, the paper has the objective to show the upcoming sugarcane mill, the DSM – Dedini Sustainable Mill, designed for maximum efficiency and sustainability, producing six bioproducts, in an approach named ‘the 6 BIOS revolution’.

Introduction
How to design the industrial plant for bioenergy: the sugarcane mill
For a sugarcane mill design, some primary design parameters (input data) are necessary: sugarcane specifications; desired products; capacity of the mill; crushing period; number of effective crushing days; location and access; local conditions; standards, regulations and laws; local infrastructure; water availability, and so on (Oliverio, 2008a).

The products’ mass balances, steam, water and utilities requirements are also necessary, which must be complemented by a process flow diagram (PFD) for each product, as well as a processes and instrumentation diagram (P&ID).

All equipment to be used must be defined, specified and then quantified, followed by an overall plant layout (utilisation of the area, main facilities, road system). The plant layout will be detailed and then the following will be included: ancillary services and utilities; civil works designs; electrical and hydraulic designs including water, steam and products; instrumentation and control designs; treatment of wastewater and residues, as well as designs to meet the relevant laws and regulations.

Such requirements can be used to design different kinds and concepts of industrial plants, from the traditional to the most advanced (breakthrough) type.
This paper describes how Dedini views the recent evolution of the sugarcane industry from a technological point of view and how the mills evolution can influence and modify the factories, i.e., the concept and designs of the future industrial plants production systems.

The technological development of the sugarcane processing units has evolved towards a better use of sugarcane and new products. Initially, only sugar was produced, a solution that prevailed for almost 500 years: the first cane sugar mill in Brazil was built by Martin Afonso de Souza, in São Vicente, São Paulo, in 1532.

The sugarcane activity in Brazil remained so until the 1970s, when ethanol became another important product of the mill. Ethanol production increased dramatically in recent years. The recent and fast-growing world interest in ethanol is mainly due to its environmental characteristics and for being produced from a renewable feedstock. Furthermore, for economic reasons and taking into account the technological development, the world is seeking new, ‘clean’ (eco-friendly), sources of energy.

In this scenario, sugarcane as a biomass and renewable feedstock for the production of biofuel and bioenergy can be evaluated positively and attains a new dimension from the environmental point of view.

Considering the growing tendency for sustained development, sugarcane will generate a new cycle of new businesses.

**Traditional mill design**

The simplified flowchart in Figure 1 shows the technologies and production processes of a traditional mill for production of sugar, bioethanol and generation of surplus bioelectricity.

---

**Fig. 1**—Traditional technology and production process: sugar, bioethanol and surplus bioelectricity.
As shown in the flowchart, we have the following main processes: sugarcane processing; sugar process; bioethanol process, and bioelectricity process.

**Sugarcane processing**

Sugarcane reception and cleaning – The cane to be processed is unloaded on feed tables where it is washed with water to remove the mineral impurities and then transported to the crushers by metal conveyor belts, passing through the preparation system.

Sugarcane preparation (knives: knives set and shredders) – The preparation system consists of one or two sets of knives, the first being designed to level the cane and the second to chop it with the purpose of levelling the cane bed that comes from the feed table and reduce the size of the feedstock. The shredders are used to open the cane cells to facilitate juice extraction.

Juice extraction: consists of feed, crushing and primary juice treatment. After the cane preparation, the cane feed into crushers is made by a device called a Donnelly chute (a forced-feed vertical chute).

Crushing consists of making the shredded cane pass through crushers comprised of rolls, installed in a series, usually 4 to 6 units, at a given pressure and rotation, to extract the juice contained in the cane and produce the co-product bagasse.

Traditionally, drive units are steam turbines (for crushers, knives and shredders).

The purpose of the juice primary treatment is to remove the impurities by means of cushion device and screens.

**Bioelectricity process**

After juice extraction, bagasse is obtained, which is composed of about 46% fibre, 50% water, and 4% dissolved solids. Conveyor belts transport the bagasse to be burnt in the boilers where high-pressure steam is produced. The steam produced is used to drive the turbines where the thermal energy is transformed into mechanical energy for machinery drives. In the power house, the turbine drives a generator that produces electric power to meet the internal requirements of the mill. Such bioelectricity generation can be optimised with solutions that will generate surplus bioelectricity to be used outside the mill (Olivério, 2008b).

**Sugar process**

The extracted juice is chemically treated to coagulate, flocculate and precipitate the minor remaining impurities after the juice primary treatment. In this stage, the juice treatment takes place in the following phases: sulfitation, liming, heating, settling, filtration and evaporation to obtain the syrup. After leaving the evaporators, the syrup is sent to another stage of concentration where sucrose crystals will be obtained. Next, it is centrifuged to separate the crystals from the end syrup (molasses) and this is sent to ethanol production.

The sugar crystals that are obtained go to the drying system and then will be bagged, weighed and stored.

**Ethanol process**

After the primary treatment, the juice is treated in a similar but not so intensive way as in the sugar process, and then must be pasteurised with heat and immediate cooling to eliminate contaminations and impurities. The treated juice and the molasses are mixed and form a mash that is sent to fermentation.

It is also possible that, in some ethanol processes, the syrup or molasses is individually sent to fermentation.

It is possible, too, that in certain ethanol processes the syrup or molasses is individually sent to fermentation.

Fermentation – mash fermentation is a result of the action of yeast, which first inverts the sucrose into glucose and fructose (monosaccharides) and then converts the monosaccharides into ethanol and carbon dioxide.
**Centrifugation** – After fermentation, the resulting product is centrifuged to separate the yeast from the fermented broth (wine).

**Yeast treatment** – The yeast, after centrifugation, is treated with sulfuric acid and taken to the fermenters to be reused.

**Distillation** – The wine is distilled in a sequence of distillation columns separating the water from the ethanol. This process takes place basically due to the temperature differences of ethanol and water ebulition.

For the production of hydrated ethanol, columns are used to obtain the ethanol concentration of 92.6° to 93.8° w/w. From the first column, stillage is obtained, which is typically used as fertiliser in the sugarcane crops.

**Dehydration** – To produce anhydrous ethanol, two additional columns are used to obtain the ethanol concentration of 99.3 min.° w/w. In the first column, the excess of water can be separated with the help of cycle-hexane or by using molecular sieves.

**New trends in traditional mill design**

The processes are evolving in order to obtain higher efficiencies and yields, i.e., bigger amounts of end products (biosugar, bioethanol, bioelectricity, others) from the same amount of raw material (sugarcane). Such technological evolution can be classified according to the impacts of the technology, promoting incremental or disruptive innovations, and follows a technological hierarchy of first, second and third generation (Olivério, 2008a, 2009a).

Regarding the incremental innovations to optimise the sugar and ethanol production processes, we can cite:

a) In sugarcane processing, the incremental innovations will benefit both the sugar process and the ethanol process in the same way by:
   - Substituting the cane wash process by dry cleaning, thus avoiding the loss of sugars carried by the cleaning water. This innovation avoids losses that can reach 2% of sugars;
   - Applying more efficient crushers associated with imbibitions comprised of hot water, which can raise extraction to 97% of the sugars present in the sugarcane by using a set of 6 crushers, or alternatively
   - Using the latest generation diffusers, capable of extracting 98% of the sugars.

b) In the sugar process:
   - In the conventional process, all unitary operations are performed to obtain the raw sugar. In those unitary operations, there are losses caused by sucrose inversion, caramelisation (Maillard reaction), evaporation and boiling entraining; losses in the rotary filters, and degradation, among others. When granulated refined sugar is produced by the conventional process, after the raw sugar is obtained it must be dissolved again, floated, filtered, evaporated, purified in ion exchange columns, crystallised, centrifuged, dried and stored. In these conditions, there are other losses besides those present in the raw sugar fabrication. By using the DRD process for production of granulated refined sugar, several unit operations are eliminated, as shown in Figure 2. So, there is a significant reduction of process losses that are inherent to those unitary operations.
   - Using the DRD process (Dedini Direct Refined) to produce refined sugar directly from the juice, in one crystallisation stage process, without the need of further processing at the refinery, avoids sugar losses in handling and other processes, which can be as high as 4% of the sugars. Additionally, lower production costs can be obtained with less investment and less energy consumption due to the elimination of the several stages of the traditional process. The DRD process, which produces sugar directly at the sugarcane mill and without a refinery is shown in Figure 2 and compared with the traditional process (Olivério and Boscariol, 2008; Olivério et al., 2010b).
c) In the ethanol process
  - Similar to the sugar process, avoiding sugar losses in evaporators and heat exchangers;
  - Fermentation optimisation by keeping the temperature controlled at the optimal degree for the yeasts activity with the use of absorption chiller (Boscariol, 2008; Yamakawa, 2009; Oliveira et al., 2010a).
  - The same as above, using stainless steel (instead of carbon steel) fermenters, with internal polishing, which facilitates asepsis and the microbiological control of the fermentation environment;
  - Both solutions will enable operations with fermentation yields around 92% (Figure 3).
d) In the bioelectricity process

The incremental innovation to produce maximum surplus energy leads to the introduction of new technologies that allow maximum use of the energy available at the mill and the minimum consumption of energy in the internal processes, as can be seen in Figure 4 (Olivério, 2008b; Olivério and Ribeiro, 2006; Olivério, 2008c; Olivério, 2009b; Olivério and Ferreira, 2010).

To reduce the energy required by the mill’s production processes, we can mention: electrical drive in knives and shredders; use of electrical-hydraulic or electrical-mechanical drives with use of planetary gearboxes in the mills or, alternatively, the use of modular diffusers; regenerative heat exchangers; multi-effect evaporation systems with the use of falling-film evaporators; continuous vacuum pans; use of absorption chiller (the chiller with the lowest energy consumption), which improves fermentation yields and enables a better use of energy because it introduces a chilled water stream into the mill, optimising heat exchanges; use of advanced solutions in distillation/dehydration (Boscariol, 2008; Yamakawa, 2009; Olivério et al., 2010a).

In this case, a new concept of distillery is introduced, with advanced criteria of the petrochemical industry, particularly the split-feed distillation system, which combines vacuum columns with pressurised columns, thus reducing steam consumption.

Also, the use membranes made of polymers, such as Siftek™, can save 35%–70% of energy when compared with the traditional processes, also having excellent selectivity for separation of water and ethanol, thus improving the quality of the ethanol produced. (Figure 5) (Olivério et al., 2010c).
To make the best use of the energy available in the mill, we can cite the use of almost 100% of the bagasse as a fuel (except about 6% to re-start operations); steam generation by boilers with high pressure, high temperature and high energy efficiency and the use of multi-stage condensation turbines with controlled extraction, suitable to the boiler parameters; the use of biogas from stillage as a source of energy. All those innovations permit the customisation of mills according to the investor’s objectives: mill with maximum bioethanol production; mill with maximum sugar production; flexible mill for maximum sugar/bioethanol production; or mill with maximum energy production (Olivério, 2008b; Olivério and Ribeiro, 2006; Olivério, 2008c; Olivério, 2009b).

From the beginning of the Proalcohol Program (1975), when the modernisation of the Brazilian mills began, until now, those incremental innovations brought significant productivity gains and better yields in the sugar, bioethanol and bioenergy production processes, with worldwide competitive products derived from sugarcane, as can be seen in Table 1.

As a reference and to correlate the current performance in the state-of-art with equipment and typical solutions, we include in Table 1 the products and technologies commercially available by the Dedini company, and part of its line of products.

(*) without considering agricultural development, that is, considering the same sugarcane sugar content.

**Designing the breakthrough mill**

When evaluated in its bioenergy aspect, sugarcane has an expressive dimension, which can surprise even the experts.

Figure 6 shows us that if we compare the amount of energy contained in sugarcane, i.e., if we measure the energy contained in the juice sugars, in bagasse and ‘straw’ (cane residues: tops, leaves and others), we will see that coincidentally the values are very similar. This would allow us to assume, in a simplified way, that the energy contained in sugarcane is: 1/3 in juice, 1/3 in bagasse and 1/3 in ‘straw’.
Now, if we compare the energy contained in sugarcane with that contained in crude oil, we have 1 tonne of clean sugarcane – corresponding to 1.2 tonnes of whole sugarcane, which contains $1718 \times 10^3$ kcal – is equal to 1.2 barrels of oil ($1.2 \times 1386 \times 10^3$ kcal).

The conclusion is that sugarcane is pure energy, but the industry has not taken advantage of its potential, mainly those energies contained in the bagasse (partially used and even so with low energy efficiency) and in cane residues (currently this energy is almost completely wasted, being usually burnt before the cane harvest).

Fig. 6—The agri-energy view of sugarcane.

Taking the 2008/2009 milling season as reference for an evaluation of the energy content of the Brazilian cane production, if all energy contained in juice, bagasse and ‘straw’ (or cane residues) were used, we would have a total annual average of energy equivalent to 1 944 000 barrels of oil/day and, in the 2010/11 season, to 2 310 000 barrels/day.

For an international evaluation of this dimension, if we compare the total potential energy contained in sugarcane (2 310 000 barrels/day) with the energy demand in some developed countries, it represents 124% of the energy consumed in oil/derivatives in the United Kingdom, 80% in Germany and 42% in Japan, which shows the relevance of this energy dimension (Figure 7).

Fig. 7—Energy contained in Brazilian sugarcane versus the oil demand in some countries.
As a conclusion of this new vision of the sugarcane potential, technological developments will be focused on the maximised use of sugarcane and the resources available at the mill.

Among all technologies under development, we point out three emerging technologies for their revolutionary impact on the sugarcane industry, which we call the ‘3 BIOs Revolution’: bioelectricity, bioethanol and biodiesel (see Figure 8).

In bioelectricity production, the new technologies seek the maximum use of the sugarcane energy, that is, the complete and optimised use of bagasse, cane residues and stillage (biogas from biodigestion).

In bioethanol production, the new technologies also look for the optimum use of sugarcane, including bagasse and cane residues as a cellulosic feedstock for the production of biofuels, especially ethanol.

And in biodiesel production, the new technologies seek the integration of its production into the sugar and ethanol mill.

Fig. 8—The 3 BIOs revolution.

The First Bio – Bioelectricity

For surplus energy generation, let’s consider three hierarchical technologies, the first generation being the technology available in the state-of-the-art; the second generation with the use of biogas from stillage and ‘straw’ as energy sources; and the third generation with the use of gas / steam combined cycle.

By using technologies of the first generation, with the most advanced technologies commercially available, in a state-of-the-art mill processing 500 tonnes of cane per hour (TCH), the production of surplus electric power is 50.7 MW (Olivério, 2008b; Olivério, 2008c; Olivério and Ferreira, 2010).
The State-Of-The-Art Mill

Figure 9 represents a diagram of the first generation technology for bioelectricity production.

![Diagram of first generation technology for bioelectricity production](image)

Fig. 9—Diagram of the first generation technology for bioelectricity production.

To obtain 50.7 MW of surplus power and introduce the state-of-the-art mill, we refer to the maximum surplus energy equation in Figure 4. By observing the part of the equation relating to the maximum use of the available energy, we will use all bagasse as a fuel (except the bagasse needed to re-start operations) in a 100 bar/530°C boiler, 89% efficiency (low heat value) which has the following technological advances:

- Single drum boilers, with combustion system and burning in suspension;
- Reaction type turbogenerators, condensation/extraction multi-stage turbines
- Automation – proper automation systems for boilers, turbogenerators and total process consumption.

If we observe now the part of minimum power consumption by the plant, it is possible to reduce the steam required by the process according to the following technological innovations:

- Use of electrical drives for knives and shredders, and electro-hydraulic or electro-mechanical drives with planetary gearboxes in crusher drives or, alternatively, use of the modular chainless diffuser, with lower specific power consumption;
- Use of regenerative heat exchangers;
- To maximise the heat recovery of the condensate and make use of the flash vapours heat;
- Use of multi-effects falling-film evaporators in thermal cascade;
• Use of continuous vacuum pans for sugar production;
• By increasing the alcohol content in fermentation to the range of 13.0% with the use of a fermentation containing absorption chiller-type cooling system to permit operation at lower temperatures (e.g. 28.0 to 30°C), steam consumption in distillation will be lower. To reduce the use of power, a lithium-bromide (LiBr) absorption chiller should be used;
• Use of split-feed distillation, which permits specific steam consumption to be reduced to levels as low as of 1.6 kg of steam/litre of hydrated ethanol;
• Use of membranes for ethanol dehydration, which also contribute to reduce steam consumption as compared with molecular sieves. Total steam required will be 2.0 kg/litre of anhydrous ethanol;
• Automation – adequate automation systems with the use of intelligent software to control all operations of the mill for optimum energy generation.

**Second generation technologies**

The state-of-the-art mill makes use of the maximum energy contained in juice and bagasse. However, the energy contained in stillage and crop residues can also be used. Taking advantage of both sources is part of the second generation technologies (Olivério and Ferreira, 2010).

To make use of stillage, an anaerobic biodigestion system is required. Besides treatment of the mill effluents, it also generates biogas. This technology is already available in commercial scale. The biogas generated is sent to the burners of the biomass boiler. This additional energy in the boiler will generate more steam, which will be used in the condensation turbine. Surplus power will then increase from 50.7 MW to 55.7 MW.

Let’s consider now the use of 50% of the ‘straw’ (crop residues) as feedstock. Similar to biogas, this feedstock will be burnt in the boiler generating more steam for condensation and, therefore, more surplus electricity. The complete technology cycle (agricultural and industrial) of ‘straw’ utilisation as an energy source is under development in Brazil and is expected to be ready
for application in the short term. Boilers will be multifuels ready to use bagasse, biogas and crop residues and are already available in the market. (Figure 10).

The same other technologies seen in the first generation will be used. With the introduction of biogas and 50% of the crop residues, surplus power generation can reach 83.9 MW and, using 100% of the ‘straw’, reaches 112.1 MW, as shown in Figure 11.
Third generation technologies

Third-generation technologies represent trends in the production of bioelectricity that are under development worldwide. These technologies consist of bagasse and cane residues gasification producing synthesis gas (CO + H₂), and operating a combined cycle in the mills. In this cycle, the biogas produced from stillage and the syngas from bagasse and cane residues will be used in the gas turbine, which drives the generator and produces surplus power. The gases that leave the gas turbine are directed to a heat recovery boiler; steam generated in the recovery boiler goes to a steam condensation/extraction turbogenerator. After the development and availability of this technology in commercial scale, surplus power production can be as high as 112.1 MW. In this case, gasification of bagasse and 50% of cane residues are assumed; if 100% of the cane residues could be transported from the field to the mill to produce syngas, surplus power generation would be as high as 150 MW.

A diagram of the third generation technology is shown in Figure 12, expected to be implemented in the long term.

![Flowchart of third generation technology for bioelectricity production.](image)

The second Bio – Biofuels (mainly ethanol)

The second Bio of the ‘3 Bios Revolution’ is the production of biofuels, and let’s starts with the first generation, the optimisation of a traditional mill to a state-of-the-art mill.

Let us assume an agricultural productivity of 80 tonnes of cane/hectare, and a mill that optimises the use of juice for ethanol production, reaching 89.8 litres of ethanol/tonne of cane, totalling then 7 184 litres of ethanol/hectare of cane, as shown in Figure 13.

The first generation technologies for the optimum production of ethanol from cane juice representing the state-of-the-art were described previously in ‘New trends in traditional mill design’.

Fig. 12– Flowchart of third generation technology for bioelectricity production.
The second generation of bioethanol production will use the lignocellulosic materials, the bagasse and crop residues as additional feedstock to the cane juice (Olivério and Hilst, 2005).

The conversion processes include chemical and biological conversions by means of hydrolysis and hydrolysed liquor fermentation, which will almost permit doubling the productivity in the biofuels production for the same amount of crop land, attaining 12,824 litres of ethanol/hectare of cane, as can be seen in Figure 14.
We believe this technology will be competitive and will be implemented in a medium to long term. In Figure 15, the DHR – Dedini rapid hydrolysis semi-industrial plant is presented.

The third generation of biofuels use the thermochemical technological route to process the lignocellulosic material, bagasse and crop residues for generation of syngas and, next, the production of liquid biofuels. This technology is also called BTL – biomass to liquid, which gasifies biomass and converts the syngas via Fischer-Tropsch type reaction into liquid fuel (hydrocarbons) bioproducts such as: naphtha, gasoline, kerosene and diesel, besides other chemical products. This technology enables productivity higher than 12 834 litres of liquid biofuel per hectare of cane, as can seen in Figure 16.

It is a prospective technology in the long term with great interest and investments currently being performed in various countries around the world.
The Third BIO – Biodiesel

Biodiesel production integrated to the sugar, bioethanol and bioelectricity producing mill is also a technology with significant prospective impacts (Olivério et al., 2007).

The production of oleaginous grains (soybean or sunflower) is made in rotation to sugarcane crops during sugarcane renovation, providing the farming integration of the two crops. And the industrial integration is made with the use of bioethanol as the second feedstock for biodiesel, the use of the energy from bagasse in the biodiesel plant and the surplus bioethanol dehydration in the same installations of the ethanol mill, and sharing of utilities (Olivério et al., 2007).

Such integration permits the use of the biodiesel by the same farming sector, and can generate surplus biodiesel for sale. It happens in three stages: the first is the partial integration of the industry; the second is the agricultural and industrial integration; and the third is the processes integration of the production chains of grains and sugarcane, as shown in Figure 17.
For stages 1 and 2, the technology is already available, and the third is in the initial stage of development and will have a significant future impact on additional reduction of biodiesel and bioethanol costs. To cite possible examples of the third stage, bioethanol can be the solvent in the extraction processes of oil from grains, replacing hexane, increasing oil production and at the same time producing value-added meal with higher protein content. Additionally, some sugars present in soybean may be added to the juice, thus increasing ethanol production by the mill.

At this point it is important to emphasise that the technology for the continuous process of biodiesel production has been available by the methyl route only, particularly developed in Europe. For the biodiesel-bioethanol integration, it was necessary to develop the ethyl route in a continuous process.

The conclusion of such development was presented in July 13, 2004, during the II SIMTEC – International Symposium and Technology Exhibit of the Sugar and Ethanol Industry – held in Piracicaba, when Dedini and DeSmet Ballestra launched the pioneer process of continuous production of biodiesel by the ethyl route.

For this kind of application, Dedini sold the first biodiesel mill with this format, the Barralcool Mill in Barra do Bugres, MT, Brazil in 2005, which started operation in November 2006, Figure 18.

It should be emphasised that the Barralcool Mill is the first mill in the world that produces the 4 BIOs: biosugar, bioethanol, bioelectricity and biodiesel.

Fig. 18—Barralcool Mill – Operational flow.

The picture in Figure 19 gives an overview of the biodiesel plant integrated to the Barralcool Mill.
Fig. 19—Integrated mill with the 4 BIOs: biosugar, bioethanol, bioelectricity and biodiesel – Barralcool Mill.

**DSM – Dedini Sustainable Mill: the 6 BIOs revolution**

To meet the new world demands for sustained solutions in the economic, environmental and social issues, Dedini has developed the DSM – Dedini sustainable mill. It is a product in continuous development and was commercially available in 2008 in its first commercial stage (Olivério, 2009c).

The innovative feature of DSM is that it is a physical system, consisting, for example, of machines, tubes, tanks, and the sustainability is more evident in operational management. The question then is: How can a set of physical items contribute to sustainability?

This question is analysed in the following text, and is represented in Figure 20.

In the economic aspect, the DSM is competitive in the free market, without any kind of subsidies.

Regarding the environmental aspect, the solutions include minimal, or zero, water and energy demands, non-generation of polluting wastes, including the reduction of greenhouse gases (GHG) emissions, minimised use of feedstocks and inputs from non-renewable and polluting sources – it is a zero-wastewater, zero-residues, zero-odours and minimum emissions mill.

These solutions should meet the environmental standards and regulations so as to contribute to mitigate or eliminate the impacts on the environment and provide sustained farming.

The Dedini sustainable mill allows an easier implementation and management of ISO 14000 system.

Regarding the social aspect, the equipment, processes, materials and facilities are arranged in such a way to facilitate operations, materials handling and compliance with standards and regulations, providing comfort, safety, hygiene and good health conditions to the workers.

The operators can work with minimal physical effort, as far as ergonometric concepts are concerned, providing the correct man/machine interaction. Also, the use of automation is
considered by means of intelligent and integrated softwares, at MES – Manufacturing Execution System level, which links shop floor operations to management. The Dedini sustainable mill also includes the integration to the management systems (ERP) to facilitate the implementation and management of the SA 8000 system.

This work will focus on environmental issues, highlighting the contribution of DSM to mitigate the greenhouse gases released in the atmosphere, particularly in the direct reduction of CO₂ emissions, its capture and avoidance, contributing to reduce the factors that are promoting climate change.

With the introduction of DSM’s new technologies, this kind of mill will generate an ethanol with significant reduction of carbon emissions when compared with the ethanol produced in a traditional mill.

To illustrate the cycle of emissions of greenhouse gases (GHG), we demonstrate in the next infographic, as can be seen in Figure 21, the ethanol complete life cycle of production, corresponding to equivalent 1000 litres of ethanol, showing the absorbed, generated and avoided direct emissions in a traditional mill, from the sugarcane plantation to harvest (generated emission), passing through the sugarcane growth (absorbed or captured emission), the sugarcane processing to transform it into ethanol (generated emission), bioelectricity generation (avoided emission), ethanol transportation from the mill to the distributor (generated emission), and finally the use of ethanol in vehicles (generated emission), in a blend of 25% with gasoline (Brazilian blending standard).

This infographic shows that, in the complete cycle, the difference between the generated emissions and the absorbed/avoided emissions is 260 kg of CO₂/m³ of ethanol. However, when ethanol is used in vehicles as a substitute for gasoline, the emissions that would be released by gasoline in its complete cycle would be avoided, corresponding to 2280 kg CO₂/m³ of equivalent
ethanol. So, in the final balance, we have 2.28 kg of avoided CO$_2$/litre, when ethanol replaces gasoline as an automotive fuel, less 0.26 kg CO$_2$/litre, corresponding to a direct reduction of 2.02 kg of CO$_2$/litre of ethanol.

![Image of diagram](image1.png)

**Fig. 21**—GHG emissions captured/avoided considering ethanol complete life cycle when produced in a traditional mill. Source: UNICA website, Accessed 28/07/2009.

To conclude, the use of the ethanol produced in the Brazilian reference mill (traditional) avoids emissions of 2.02 kg of CO$_2$/L of equivalent anhydrous ethanol, with mitigation of 89% of direct emissions when compared with gasoline (traditional mill), as shown in Figure 22 (Unica, 2009).

![Image of diagram](image2.png)

**Fig. 22**—Emissions balance flowchart in the anhydrous ethanol life cycle when produced in a traditional mill. Source: Unica, 2009.
The big question that arises is: How can the mills contribute to further mitigation of direct emissions of GHG in the agricultural and industrial sectors?

The answers to this question are as seen in Figure 23.

First, taking the traditional mill as reference, technological innovations are introduced to optimise energy efficiency with the purpose of maximising surplus MW generation (Chapter 4 – bioelectricity: first generation); increase the overall yields to maximise productivity (litres of ethanol/tonne of cane – Chapter 4 – bioethanol: first generation); provide CO₂ direct reduction by using internal processes in the mill with minimal CO₂ emissions; increase avoidable emissions by using the CO₂ produced by the mill (for example, the CO₂ from ethanol fermentation) to replace fossil CO₂, to be used in the production of other products such as sodium bicarbonate; contribute to the reduction of emissions in farming by avoiding the use of products that release CO₂, like fertilisers and diesel; reduction of CO₂ emissions by eliminating the cane burning before harvest.

Another reference is the bioethanol – biodiesel integration in a 3 BIOs mill, where the contribution to CO₂ mitigation may occur in several links of the production chain, particularly considering the agricultural and industrial integration of the two processes, as seen in Figure 24.

In this integration, mitigations occur as a function of the following factors: maximisation of surplus bioelectricity production (MW) (bioelectricity: first generation); maximisation of yields (litres of ethanol/tonne of cane – bioethanol: first generation); substitution of the diesel oil used in farming for biodiesel from renewable origin (biodiesel integrated to the sugar and ethanol mill); double use of land by producing grains (mainly soybean) in rotation with sugarcane crop; utilisation of the bioenergy from bagasse in the biodiesel plant replacing the energy from fossil origin that prevails in the traditional biodiesel plants (biodiesel integrated to the sugar and ethanol mill); use of
the renewable ethyl route instead of the methyl route, because the methanol traditionally used is from fossil source (bioethanol integrated to the sugar and ethanol mill); reprocessing of the surplus bioethanol plus water in the dehydration process of the mill by using the energy from bagasse instead of the fossil energy that is predominant in the traditional dehydration plants (bioethanol integrated to the sugar and ethanol mill). (Olivério et al., 2007).

As seen, the introduction of the new technologies described herein, particularly the 3 BIOs revolution, contribute to the reduction of the greenhouse gases and to the mitigation of the causes of global warming and other climate changes.

Other important aspects for the improvement of sustainability are also incorporated in the mill designs.

It is a fact that sustainability will have an increasing influence on the concept and design of new mills; in this context, the DSM in the state-of-the-art stage is a solution in line with this tendency. New sustainability indicators are being considered for evaluation of the processes efficiencies, to identify the levels of energy and water demand to evaluate different kinds of input materials or consumables, besides wastes and residues. The DSM is part of this context for using new technologies that increase sustainability, and producing other BIO-products as will be seen next. As a preliminary reference configuration, the 4 BIOs mill will be adopted – biosugar, bioethanol, bioelectricity and biodiesel – to which another BIO will be incorporated, the first being the fifth BIO: Biowater.

The Fifth BIO – Biowater

An important step towards sustainability was the introduction of the water self-sufficient mills in 2008 and a more advanced solution, the water-producing mills.

These concepts are a breakthrough in the world market: the water self-sufficient mills do not demand water-supply systems, i.e., water is not supplied by rivers, lakes, springs or wells. Only the
water contained in sugarcane is sufficient to meet the needs of the mill processes (Olivério, 2009c; Olivério et al., 2010d).

An evolution of this concept is the technology optimisation which allows the mill to recover more water from the sugarcane than it will use internally and so it can export the surplus water for other uses. On the average, there are 700 kg of water in one tonne of sugarcane. A typical Brazilian mill (Unica, 2005) demands 1830 kg of intake water to process one tonne of cane, and by adding the water contained in the sugarcane, a total of 2530 kg of water is used per tonne of cane. This amount meets the usual losses in the sugar and ethanol production processes, i.e., 1919.57 kg (evaporation, cane wash and others) and the water that is incorporated in the mill’s products and by-products (stillage and others) totalling 610.43 kg (Figure 25).

Assuming as reference the production of 80 litres of ethanol/tonne of cane, the intake water specific consumption from supply sources will be 22.9 litres of water/litre of ethanol.

![Fig. 25—Water consumed by the traditional mill.](image)

When we look for possible savings in water-consuming processes, we have three natures of processes and demands:

a) Processes that demand water and can be substituted for other non-demanding processes, e.g., sugarcane dry cleaning instead of cane water cleaning.

b) Processes where there is loss of water that can be recovered, such as in evaporation; with the use of efficient condensers and cooling towers, water can be recovered and reused.

c) Traditional diluted processes that can operate with higher concentration or concentrated stream processes, such as in fermentation with higher alcohol contents.

With this concept in mind, other water-saving solutions are incorporated in the mill’s design: indirect heating in distillation; cooling towers; condensate monitoring and entrainer separator, etc. As a result, we have a new mill design: the Hydro Mill, the water self-sufficient mill,
as can be seen in Figure 26. The second revolution stage of this Hydro Mill, and the BIOwater production will be seen together with the sixth BIO product.

The Sixth BIO – Biofertiliser

The sixth BIO is BIOFOM®, an organomineral fertiliser.

Based on the self-sufficient mill, we can move forward to the water exporter mill by incorporating the sixth BIO in the mill design.

In this case, stillage concentration to about 65° Brix is introduced into the mill to recover and reuse water. A fertiliser blending and pelletising plant is incorporated to the mill which will produce BIOFOM and recover the remaining water for further use (Olivério, 2009c; Olivério et al., 2010e).

BIOFOM results from the mixture of the mill process residues that have fertilising properties like concentrated stillage, filter cake, boiler ashes and soot.

As a result, we have a more advanced design, the Hydro Mill Plus, the water producing mill that exports water for other purposes.

By producing biowater, the mill condition is reversed: from a big water waster in the traditional mill – 22.9 litres of water/litre of ethanol, to water exporter in DSM – 3.6 litres of exported water/litre of ethanol (Figure 27).
Fig. 27—The hydro mill plus, the water exporting mill.

The concern with non-renewable natural resources, like fossil fuels, mainly crude oil, has forced many companies to seek a solution to replace these resources in the production processes. In this scenario, the DSM incorporates BIOFOM\textsuperscript{TM} (organomineral biofertiliser), a fertiliser produced from the residues of the sugarcane processing and a solution to replace the mineral fertilisers used in sugarcane crops.

The product resulting from the mixture of these residues, with the addition of chemical nutrients, is processed into an organomineral fertiliser containing the elements that can be dosed according to the specific needs of the soil for sugarcane culture, besides improving the physical, chemical and biological conditions of the soil due to the organic matter, as can be seen in Figure 28 and 29.

Fig. 28—BIOFOM: organomineral biofertiliser.
In addition, because it is a granular fertiliser, BIOFOM permits an easier application if compared to the distribution of stillage in the cane crop, thus reducing investments and costs.

To evaluate the performance of BIOFOM, experimental tests were conducted at ESALQ, Escola Superior de Agricultura Luiz de Queiroz – USP (São Paulo University), which showed the best growth and productivity was afforded by the use of BIOFOM. (Figure 29) (Olivério, 2009c; Olivério et al., 2010e).

This can be explained by the aggregation of soil particles, providing nutrients for the culture, favouring the development of microorganisms (fungi and bacteria) and greater retention of water – taking part in the water requirements of plants during the dry season.

**DSM benefits regarding GHG emissions**

In the current context, the world is releasing a huge amount of greenhouse gases (GHG), resulting in global warming, mainly because of the use of fossil fuels.

Any solution focused on GHG reduction should be prioritised for meeting social and environmental sustainability, besides its economic feasibility.

New technologies already available for sugarcane processing in the mills can contribute to the reduction of GHG emissions. In line with this demand, Dedini has developed new technologies to mitigate GHG emissions.

These new designs contribute to sustainability for introducing bioproducts, in a methodology that the company calls ‘The 6 BIOs revolution’ (biosugar, bioethanol, bioelectricity, biodiesel, biofertiliser and biowater), integrating them so as to optimise the social, environmental and economic feasibility (Figure 30).

In the Dedini Sustainable Mill concept, the pursuit of sustainability requires the continued development of increasingly upgraded solutions.
Fig. 30—The 6 BIOs – DSM – Dedini Sustainable Mill in continuous development.

The complete integration of farming and industry to the integrated production and utilisation of the 6 BIOs permits an effective and significant contribution to the mitigation of the GHG, as can be seen in Figure 31.

Fig. 31—The DSM impact to mitigations of GHG.
The technological evolution can be evaluated by analysing the life cycle of ethanol production/utilisation, considering the equivalents of direct emission of CO₂ in the diverse phases of the cycle: sugarcane production, comprising the activities of planting, cultivation and harvest; sugarcane processing in the mill; distribution of ethanol from the mill to the refuelling stations; and use of ethanol as an automotive fuel.

The absorption, reduction or avoidance of emissions is also contemplated: absorption occurs in the sugarcane sprouting, growth and maturation; avoidance, in the sale of surplus bioelectricity to the grid, avoiding the use of fossil fuel for the production of the same electricity.

With these data, it is possible to calculate the complete balance of direct emissions in the life cycle from the production to the use of ethanol in the DSM.

As a result, three stages of evolution are presented, according to the introduction of new technologies, some already developed and available in the market, some in development to be introduced in the medium term and others to be developed in the long term.

In each stage, the benefits for the mitigation of GHG are presented, measured by the net emissions avoided in relation to the emissions released by gasoline.

**Results and impacts of GHG emissions**

The DSM in the state-of-the-art stage will reduce CO₂ emissions using technologies commercially available, i.e., those that: raise productivity from 86.3 litres of ethanol/tonne of cane (in the traditional mill) to 89.9 L/tonne (bioethanol: first generation); increase surplus power generation from 9.2 MW to 50.7 MW (bioelectricity: first generation); produce biodiesel integrated to the mill to replace 5% of the diesel oil consumed by trucks and 30% of that consumed by tractors, according to Figure 17 and 18 (biodiesel production integrated to the sugar and ethanol mill – first stage); introduce Biofom – organomineral biofertiliser, replacing most of the mineral fertilisers; make use of the water contained in the cane (producing biowater), with these technologies implemented by the mill, **2.56 kg of CO₂/L of equivalent ethanol** are avoided, which mitigate **112%** of emissions (DSM state-of-the-art) (Figure 32).

The upcoming DSM (near future) considers the use of oil and 50% of the sugarcane crop residues as energy with additional technologies, other than those of the DSM state-of-the-art, and will avoid **3.02 kg of CO₂/L of equivalent anhydrous ethanol**, with mitigation of **132%** of emissions (DSM Plus).

In this case, bioelectricity production rises to 83.9 MW, corresponding to the second generation, according to Figure 11 (bioelectricity of second generation), and also as can be seen in Figure 33.
Another technology that may have a significant mitigation impact is the use of the CO$_2$ generated in the fermentation process, together with boiler gases after purification as, for example, industrial gas, as already used in: food freezing/cooling, beverage carbonation, polyurethane foam expansion, textiles neutralisation, modified/controlled atmosphere, metallurgical furnaces, water hardness increase, pulp wash in the pulp and paper industry, pH control in paper, leather de-liming, video laparoscopy, high power laser, supercritical fluid chromatography, soap acidulation, carbon fertilisation, dry ice, sand moulding, among others.

Another example of application is the production of sodium bicarbonate, as demonstrated in an industrial plant supplied by Dedini (Figure 34).
All these applications are possible, but not always competitive. Another aspect is that these solutions have limited application, because the market for each of them and even as a whole is small to absorb all the CO2 that is generated in the production of Brazilian ethanol.

Therefore, it is necessary to develop new competitive applications so that one can consider that this CO2 avoids the use of the CO2 from fossil fuels.

For these reasons, we will include this contribution in the ‘Potential DSM’, the next stage of the DSM, viable in the long term if we succeed in making use of the carbon dioxide from fermentation, therefore contributing to the mitigation of GHG for every litre of ethanol produced and consumed.

The Potential DSM, with the introduction of new technologies, the use of 100% of crop residues as energy to produce 112.1 MW (Bioelectricity: second generation), the use of the CO2 generated by fermentation (as mentioned earlier) and replacement of 100% of the diesel oil by biodiesel that will occur after adaptation of truck and tractor engines, will have an avoided emission of 5.0 kg of CO2/L of equivalent anhydrous ethanol, mitigating 219% of the emissions released by gasoline (Potential DSM-1) (Figure 35).

Fig. 35—Mitigation effect of the DSM in a long term future – Potential DSM – 1.

Assuming the previous potential DSM – 1 and the foreseen technologies for the third generation of bioelectricity, we will have 150 MW of surplus and, considering the additional CO2 produced (by gasifying all bagasse and cane residues and burning this syngas at the gas turbogenerator), replacing fossil generated CO2, we will have a mitigation of 5.47 kg of CO2/L of equivalent anhydrous ethanol and mitigation of 240% of the emissions released by gasoline (Potential DSM–2) (Figure 36).

Fig. 36—Mitigation effect of the DSM in a long term future – Potential DSM – 2.

**Conclusion**

This work showed the evolution of the mill design from bio-initial stage as a traditional sugar factory, passing through the introduction of new technologies to enhance bioethanol and bioelectricity production up to the state-of-the-art mills.
Then, it was shown how disruptive innovations (breakthroughs) have been applied in the 3 BIOs route, which will revolutionise the industry and improve even more the yields and productivity, in accordance with such trends. Also, it was shown how all those developments permit a significant reduction of emissions, even much higher than ethanol already does in the traditional mill, and that the new trends are aligned with GHG mitigation.

Finally, Table 3 presents a summary of the impacts on the mitigation of GHG as a result of the technologies that have been introduced into the Dedini Sustainable Mill, from the state-of-the-art to a potential and promising outlook that can be expected with the technological trends in development.

MOTS-CLÉS: Ethanol, Canne à Sucre, Durabilité, Bioélectricité, Biomasse.

Résumé
PENDANT Presque 500 ans, la canne à sucre a été considérée presque exclusivement comme de la matière brute destinée à la production de sucre. Dans les dernières décennies au Brésil, elle a aussi été utilisée pour la production d’éthanol. Dans ce contexte, la configuration de l’usine de canne a évolué de manière significative pour s’adapter à de nouvelles utilisations du jus de canne, non seulement pour le sucre mais pour le processus de fabrication de l’éthanol. Récemment, pour des considérations environnementales, sociales et économiques, en d’autres mots de durabilité, le monde a commencé à rechercher des énergies nouvelles et plus propres. De ce fait, l’intérêt mondial pour l’éthanol s’est accru de façon spectaculaire, dû à ses qualités environnementales et aussi parce qu’il est produit à partir de biomasse renouvelable. Ce scénario a changé la perspective de la canne à sucre : il a permis à cette culture d’atteindre une nouvelle et plus large dimension, et de générer des opportunités commerciales à partir des produits traditionnels et nouveaux. Cet article a pour objectif de montrer comment cette évolution modifie et va continuer à influencer la configuration complète de l’usine sucrière, considérant le développement technologique et une évolution vers plus de durabilité. L’article décrit une usine de canne à sucre intégrée avec des innovations très en pointes voire révolutionnaires, considérant la hiérarchie technologique de la première, la deuxième et la troisième génération en bioélectricité, bioéthanol et la production intégrée de biodiésel. La durabilité est aussi incorporée dans ce concept de l’usine apportant une solution adaptée pour une configuration optimale de l’usine. En résumé, l’article a l’objectif de présenter l’usine de canne à sucre à venir, la DSM – Dedini Sustainable Mill (l’usine durable de Dedini), configurée pour un maximum d’efficacité et de durabilité, réalisant six bioproduits, dans une approche appelée «la révolution des 6 BIOS »).
EL DSM—DEDINI FABRICA SOSTENIBLE: UN NUEVO CONCEPTO
EN EL DISEÑO COMPLETO DE FABRICAS DE AZUCAR

Por

J.L. OLIVÉRIO, V.B. CARMO y A.M. GURGEL
Dedini S.A. – Industrias base
jose.oliverio@dedini.com.br

PALABRAS CLAVE: Etanol, Caña de Azúcar,
Sostenible, Bioelectricidad, Biomasa.

Resumen
Durante casi 500 años, la caña de azúcar ha sido considerada en su mayoría sólo como materia prima para la producción de azúcar. En las últimas décadas, en Brasil, también ha sido utilizada para la producción de etanol. Así, el diseño completo de las fabricas de caña de azúcar evoluciono considerablemente en esa dirección, utilizando jugo de caña de azúcar como una materia prima para los procesos de azúcar y etanol. Recientemente, por razones ambientales, económicas, sociales, en otras palabras, por razones de sostenibilidad, el mundo comenzó a buscar fuentes de energía nuevas y más limpias. Como consecuencia, el interés mundial en etanol creció espectacularmente, debido a sus cualidades medio ambientales y porque se produce a partir de la biomasa renovable. Esta situación cambió la perspectiva de la caña de azúcar: permitió a la caña de azúcar alcanzar una dimensión nueva y superior, y generar un ciclo de nuevas empresas, derivadas de productos tradicionales y nuevos. Este documento tiene el objetivo de mostrar cómo esa evolución está modificando y continuará influyendo el diseño completo de la fabrica de caña de azúcar, considerando el desarrollo tecnológico y la evolución de sostenibilidad. El documento describe una fabrica integrada de caña de azúcar con las más avanzadas innovaciones disruptivas (avance), considerando las jerarquías tecnológicas de primera, segunda y tercera generaciones, en bioelectricidad, bioetanol y producción de biodiesel integrado. También, la sostenibilidad está incorporada en el concepto de la fabrica, resultando en una solución actualizada para un diseño óptimo. En resumen, el documento tiene el objetivo de mostrar la próxima fabrica de caña de azúcar, la DSM-Dedini fabrica sostenible, diseñada para la máxima eficiencia y sostenibilidad, produciendo seis bioproductos, en el marco de una estrategia denominada "la Revolución de 6 BIOS".
DESIGNING, PRODUCING AND PROCESSING ‘ULTIMATE’ VARIETIES OF SUGARCANE

By

KEYWORDS: Sugarcane Varieties, Sugarcane Breeding,
Sugarcane Composition, Chromatographic Analysis, Alternative Products

Abstract

Many sugar industries, beet and cane, would predict that in the future they will produce a wide range of products, which could include sugar. To realise this prediction, new varieties must be designed, production practices improved and alternative processing techniques developed. Sugarcane breeding and selection has moved far beyond the ‘old days’ of crossing the best parents and hoping to select the best segregate as a potential new variety. Modern breeding procedures and biotechnology offer greater efficiency. Typically, varieties are selected on the basis of high yield of sugar and characteristics important to agronomic production and pest resistance in each growing region. The typically measured juice quality characteristics of brix and pol along with tonnage, ratooning ability and fibre content can predict yield of sugar per unit area. It is anticipated that the ‘ultimate’ variety of the future will involve much more detailed analysis than the typically measured characteristics. Once produced, high yielding varieties for various products need to be grown in a sustainable manner that provides maximum production with minimal environmental and economic impact. Processing of these varieties will need to accommodate the specific product(s) being produced whether sugar, energy, some other product or some combination of these. To demonstrate the importance of quality characteristics of future varieties, the Sugar Processing Research Institute has investigated the presence of components that could either enhance or inhibit production of various products from sugarcane. Significant variability among and within species of sugarcane and related genera have been found for starch, polysaccharides, ash, cations, invert sugars and other parameters. This paper includes these data and the potential importance of these parameters in future varieties, its importance in a sustainable production system and its importance in processing needs.

Introduction

While we often like to use the word ‘traditional’ when we speak about issues regarding the sugar industry, the fact is sugarcane industries around the world always find themselves as part of a dynamic situation. Papers that deal with sugarcane breeding and the history of breeding traditionally start with discussions about Indonesia and Barbados that once had thriving sugar industries.

Today, tradition is somewhat gone as Indonesia’s sugar production is less than half of its total use and Barbados, like much of the Caribbean, is struggling to survive as a sugar industry. Both still have significant breeding efforts, but the tradition of the industry has certainly changed.

Papers dealing with sugar industry production traditionally have listed sugar and molasses as the saleable products produced from an industry. Over the last decade we now find other columns in production tables; these include ethanol, building products from bagasse, electricity produced,
betaine (sugarbeets), acid production, and others. None of these products are new, but they aren’t part of what one remembers as the traditional sugar industry.

Production practices and pest control, while often thought of as traditional within each country, have changed, oftentimes drastically, to meet changing pest problems; climatic conditions; environmental regulations; prices for energy, fertiliser and crop protection chemicals; and, sustainability issues. When one considers this dynamic situation, the word ‘tradition’ becomes less meaningful.

This brings us to the future. What will industries in the near and long-term future be producing? How will the varieties for these products vary? What type of production practices will be required for these newer varieties with increased concerns about sustainability and the environment? How will processing practices change to most efficiently produce these products?

Much is already known about the variability and heritability that exist with yield and sugar content in sugarcane (Richard and Henderson, 1976; Heinz, 1991). Monosaccharides (glucose and fructose), total polysaccharides (gums), starch, colour, and organic acids present in the juice vary with variety, climatic conditions, extraneous matter content, age of cane, location, degradation, and other factors (van der Poel et al., 1998; Clarke and Godshall, 1988; Zhou, 2007).

Heritability of these factors is not as well understood as for major components such as sucrose content. The future of sucrose and its potential use along with other products from the sugarcane plant have been discussed for many years (Paturau, 1969; Purchase, 1995; Godshall, 2009). However, little emphasis has been given to directed breeding of sugarcane for these products.

Sugar Processing Research Institute (SPRI), located in New Orleans, USA, has attempted to answer questions concerning component analysis of sugarcane and how that might impact future breeding of sugarcane varieties.

SPRI is a unique research organisation, representing international sponsors that produce sugar, provide services and technology to the sugar industry, or use sugarcane or sugarbeet products. It conducts research in areas important to quality products coming from these segments of the sugar industry. As such, evaluation of issues important to sugar processing is a mainstay of this research organisation.

Recently, one project of SPRI was to evaluate sugarcane germplasm and sugarcane harvest treatments for potential impact on production of all products.

The objective of this research was to examine the varying levels of components contained in the juice of these varieties and harvest treatments that could then be considered as enhancing or inhibiting the production of potential final products including alcohol and sugar.

Finally, consideration was given to how varieties with these varying components could then fit into a sustainable production system and be most efficiently processed.

Materials and methods

In the first phase of the research in 2007, in collaboration with the USDA Sugarcane Research Unit (USDA SRU) in Houma, LA, SPRI began studying three sugarcane varieties. Two were commercially grown varieties, HoCP96-540 and Ho95-988, while L79-1002 was a wild type now referred to as ‘energy cane’. Each variety was harvested under three conditions: A- total biomass consisting of tops, side leaves and stalks; B- only side leaves and stalks with the tops removed; and C- only stalks with the tops and side leaves removed. Four replications were harvested by hand for each treatment, each of which was a 15-stalk sample. The samples were milled by the USDA SRU laboratory and the juice obtained for a typical analysis. The typical analysis usually performed to determine the value of sugarcane includes brix, sucrose, fibre and total recoverable sugar (TRS).
Duplicate juice samples from variety/treatment samples were then composited and analysed in greater detail at the SPRI laboratory for the parameters of pH, brix, total polysaccharide, starch, ash, sucrose, glucose, fructose, colour, turbidity, and cations (potassium, magnesium, and calcium).

As a second phase to this project, in November 2008, 29 sources of germplasm from five different species of sugarcane, along with a related genus, *Erianthus*, were harvested and analysed.

There were two species, *S. officinarum* and *S. barberi* generally regarded as cultivated species and three generally regarded as wild types, *S. sinense*, *S. spontaneum*, and *S. robustum*.

The stalks were milled by the USDA-SRU in Houma, the juice was put onto ice and immediately transported to the SPRI laboratory for detailed analysis for brix, pH, starch, polysaccharides, ash, colour and turbidity and cations (potassium, magnesium and calcium).

Test procedures, equipment, and references used for the detailed analysis were as follows:

- **pH** – Orion model # 520A meter.
- **Brix** – Bellingham and Stanley RFM81 refractometer.
- **Sucrose, glucose, and fructose** – Liquid Chromatography, BioRad HPX-87K column with 0.01M potassium phosphate (0.6 mL/min at 75°C) RI detection (Waters 2410).
- **Calcium, magnesium, potassium** – Ion Chromatography, Dionex IonPac CS12A column 20 mN H2SO4 at 1 mL/min with Conductivity detection (Dionex ED40)
- **Colour and turbidity** – ICUMSA Method GS1/3-7 (2002) Determination of the Solution Colour of Raw Sugars, Brown Sugars and Coloured Syrups at pH 7.0

**Experimental results**

In the first phase of the project, results of the typical juice analysis performed by the USDA-SRU of the three harvest treatments of three varieties indicated, as expected, that the C treatment (cane free of all extraneous matter) of each variety had the highest sugar content and the lowest fibre content.

The A treatment, consisting of the entire plant, had the lowest level of sugar and highest level of fibre. As expected, the two commercial varieties were not different for comparable harvest treatments, while the wild variety showed significantly lower sugar levels and significantly higher fibre levels.

Results of the detailed juice analysis performed by SPRI of the three harvest treatments of three varieties can be seen in Table 1. The pH ranged from 5.46 to 5.57 with no apparent difference between harvest treatments or varieties.

Varieties Ho95-988 and HoCP96-540 had similar averages in brix content consistent with commercial varieties while L79-1002 had considerably lower brix content.
### Table 1—Detailed analysis conducted by SPRI for three varieties and three harvest treatments for pH, brix, total polysaccharides, starch, ash, colour, turbidity, invert sugars and cations.

</table>

For each variety, treatment C had the lowest level of total polysaccharides with the wild type sugarcane variety L79-1002 having the highest total polysaccharide content. For the starch analysis, there was little difference among harvest treatments, although L79-1002 had much higher starch levels than the two commercial varieties. Differences in ash content were similar to that of total polysaccharides, with the wild type variety considerably higher than the two commercial types.

Juice colour in each harvest treatment was highest for variety L79-1002 as compared to the two commercial varieties. Harvest treatment A (tops, side leaves, and stalk) had the highest colour followed by treatment B. Treatment C, stalks with no leaves or tops, had substantially lower colour regardless of variety. Turbidity followed the same trend as colour.

Varieties HoCP96-540 and Ho95-988 showed comparable sucrose content for harvest treatments B and C, while Ho95-988 was slightly higher in treatment A. Variety L79-1002 had much lower sucrose levels in all three treatments. Variety L79-1002 also reported the highest invert sugar levels of the three varieties, with little difference between the two commercial varieties. Fructose levels were considerably lower in treatment C as compared to treatments A and B for the
commercial varieties, but did not vary in the wild variety. Glucose levels dropped by half from treatments A through C for HoCP96-540, while there was less difference in Ho95-988 and L79-1002.

Cation content varied widely between the three varieties with L79-1002 having the highest levels of potassium, magnesium and calcium as compared to the two commercial varieties. Overall, levels of potassium were higher than levels of the other cations measured.

In the second phase of the project, averages of the analysis of clones of the five different species of sugarcane along with a related genus are shown in Table 2 for the parameters of brix, pH, starch, polysaccharides, ash, colour, turbidity and cations. Large variations in most of the parameters were found between the averages of the different species as well as when comparing clones within the same species. It is very obvious that Erianthus along with clones of the wild species *S. spontaneum* and *S. robustum* were in a much higher range than the cultivated species *S. officinarum*, *S. barberi* and *S. sinense* for several parameters such as polysaccharides, ash content, colour, and to some degree starch and turbidity. Brix was highest for the cultivated species and lowest in the wild clones and *Erianthus*.

**Table 2**—Detailed analysis conducted by SPRI of 29 cultivars among various genera and species of *Saccharum* for pH, brix, total polysaccharides, starch, ash, colour, turbidity invert sugars and cations.

</table>

Of concern is the variation in parameters such as starch content. Domesticated species generally were less than 750, while *S. spontaneum* was 2019 and *Erianthus* was 2112 ppm on solids. Total polysaccharide analysis showed similar variation, although *Erianthus* was higher than all other tested material by a factor of at least 4. Ash content had essentially the same variability with *S. spontaneum* and *Erianthus* being substantially higher. Also of great concern were the average levels of colour for the species.

Averages for the cultivated species were less than 20 000 ICUMSA units, with the wild species higher by a factor of at least 2. *Erianthus* was much higher by a factor of 8 as compared to the cultivated species average. Turbidity showed less distinct differences, although wild species were generally higher than cultivated species and *Erianthus* was considerably higher than all other clones. Results of potassium analysis showed that domesticated species had much lower levels than wild species. The same trend was true for magnesium and calcium although differences were smaller.
To illustrate the amount of variation that existed within species, the individual clones tested of *S. officinarum* and *S. spontaneum* are shown in Table 3 for ash, starch, polysaccharides, potassium, colour and turbidity. As noted in the earlier discussion based on averages, there are considerable differences among the two species in all of these parameters. For ash content and polysaccharides, no clone of *S. spontaneum* was as low as those of *S. officinarum*. However, for starch, potassium, colour and turbidity, even though the averages between species were very different, there were individual clones of *S. spontaneum* that were as low or nearly as low as those of *S. officinarum*.

Table 3—Detailed analysis conducted by SPRI of various cultivars among *S. officinarum* and *S. spontaneum* for total polysaccharides, starch, ash, colour, turbidity and potassium.

Discussion

Based on the data from the first phase of the project for colour, turbidity, glucose and fructose, it is obvious that leaves and tops contributed negatively to the value of the cane. Based on all of the data, it is also obvious the impact that the wild germplasm has on overall quality with lower sugar content and higher levels of non-sugars and contaminants.

Of value from the data from the second phase is the fact that even within species, there was considerable variation among the clones tested. Whether this is a representative number of clones from each species is unknown and in fact, doubtful. However, it does demonstrate that this variation could allow for selection among the clones for use in breeding energy value canes as well as for routine basic breeding for varieties intended for sugar production or other products.

Based on the knowledge that the level of variability demonstrated in this project may exist among parameters discussed in *Saccharum* and related genera, thoughts should then be directed toward the most efficient breeding of sugarcane for whatever is the desired final product. Knowing that many of the parameters discussed here can have an effect by either enhancing or inhibiting the formation of sugar, ethanol, steam, electricity, and other by-products means that breeders should
begin to take into account the detailed characteristics of elite parents used in their breeding programs. No breeder wants to add another list of parameters to his/her selection criteria, but failing to do so could have severe consequences. Very recently, one sugarcane industry experienced this problem after releasing an outstanding variety for agronomic characteristics only to find out later that some characteristic within the plant did not allow for efficient production of very low colour sugar from this variety. A detailed analysis of this variety before release may have been able to diagnose this problem. It may be that detailed analytical testing could have even prevented the cross from ever having been made or perhaps one of the parents which provided the genes for this characteristic from being used.

As industries continue to look at breeding for products other than sugar, this kind of detailed analysis could become even more important. While it is widely known that factors such as ash content have a negative impact on fermentation, industries are still learning the full impact of starch and polysaccharides on fermentation. These parameters may add fermentable solids, but they can also cause issues in the fermentation process especially related to the activity of the yeast. Cellulosic conversion offers another challenge as to what characteristics would serve as inhibitors or enhancers to efficient energy conversion. Some of the parameters studied here could be considered saleable products and/or precursors to saleable products. Efficient breeding could lead to varieties that are more desirable for each of these potential products.

Biotechnology and gene transformation could perform a very important role in altering the components of sugarcane for more efficient production of final products. Equally important is the potential for sugarcane genome sequencing. Also important is the development of markers associated with these juice characteristics. These technologies could allow for the identification of the genetic basis for these compositional characteristics.

When considering the use of varieties, knowledge of these detailed analyses could lead to more sustainable production practices. Growers often fertilise sugarcane to produce the highest yield of sugarcane believing that this will lead to the highest yield of sugar, as it often does. However, variation in cations among the germplasm studied here would suggest that not all cane is alike. Whether there are different absorption rates by species is not understood but further studies could lead to more efficient utilisation of varieties, especially when considering sustainable production practices where one attempts to utilise minimal inputs to arrive at maximum yield. Water utilisation and the significance of clean ground water for the future could be impacted through a better understanding of the role of the parameters discussed in this paper. The impact of some of these parameters on pest management should also receive consideration.

Processing of varieties has always used the ‘average’ approach where an industry sets its objectives, and varieties are expected to fall into that range or else the variety is not released to that industry. These parameters are generally based on efficient production of sugar, which of course is still the highest value product that most industries can produce. However, as industries examine the production of other products, these ‘average’ levels of various parameters may need to be reconsidered. As alternative products are planned, different separation technologies may need to be considered in order to efficiently produce these materials.

During this current period of unusually high world prices of sugar, is anybody really interested in producing products other than sugar? Perhaps the level of interest or desire is not as great as when sugar prices were low and industries were struggling to survive. However, a good strategist would argue that now is the time to think about these issues, out of a position of strength and high sugar prices rather than one of weakness and low sugar prices!

Future work with detailed analysis should include more detailed fibre analysis for cellulose, hemicellulose, and lignin content for their contribution to the value of the sugarcane plant. Also a more in-depth chromatographic analysis for cations, anions, oligosaccharides, sugars, and organic
acids should be considered. Additionally, the same issues should be investigated in sugarbeets as well as sugarcane.

Résumé

DE NOMBREUSES industries sucrières, de betterave ou de canne, font la prédiction qu’elles produiraient dans le futur une vaste gamme de produits, incluant le sucre. Pour réaliser cette prédiction, de nouvelles variétés doivent être conçues, passant par une amélioration des pratiques culturales et un développement des techniques de process. La sélection et l’amélioration variétale ont progressé bien au delà des méthodes anciennes de croisement des parents avec l’espoir de sélectionner la meilleure ségrégation qui aboutissant à une nouvelle variété potentielle. Les procédures modernes de création associée à la biotechnologie offre une plus grande efficience. De façon typique, les variétés sont sélectionnées sur la base d’un haut rendement en sucre et des caractéristiques agronomiques pour la production et la résistance aux ravageurs dans chacune des zones de production. Les habituelles caractéristiques de qualité mesurées du jus - Brix et Pol - ainsi que le tonnage, le comportement en repousse et le taux de fibre, peuvent prédire le rendement en sucre par unité de surface. Il est appréhendé que l’ultime variété du futur implique davantage d’analyses détaillées que les habituelles caractéristiques mesurées. Une fois créées, les variétés à haut rendement en produits variés devront être cultivées de façon durable tout en procurant le maximum de production avec un impact environnemental et économique minimum. Le traitement de ces variétés imposera d’adapter le ou les produits spécifiques en cours d’élaboration que ce soit pour le sucre, l’énergie, d’autres produits ou des combinaisons de ceux-ci. Pour démontrer l’importance des caractéristiques de qualité des futures variétés L’institut de Recherche du Process Sucrerie a investigué la présence de composés qui pourraient soit augmenter ou inhiber la production de produits variés issus de la canne à sucre. Des variabilités significatives parmi les espèces de canne à sucre et des genres proches ont été trouvées pour l’amidon, les polysaccharides, les cendres, les cations, les sucre inversés et d’autres paramètres. Cet article présente ces données et l’importance potentielle de ces paramètres dans les futures variétés, leur importance dans un système de production durable et son importance dans les besoins de process technologique.
DISEÑO, PRODUCCIÓN Y PROCESAMIENTO DE VARIEDADES ‘SUPREMAS’ DE CAÑA DE AZÚCAR

PALABRAS CLAVE: Variedades de Caña de Azúcar, Mejoramiento de Caña de Azúcar, Composición de la Caña de Azúcar, Análisis Cromatográfico, Productos Alternativos.

Resumen
MUCHAS industrias azucareras, de remolacha y caña, podrían predecir que en el futuro producirán una amplia variedad de productos, entre ellos azúcar. Para realizar esta predicción, se debe diseñar nuevas variedades de caña, mejorar las prácticas de producción y desarrollar nuevas técnicas de procesamiento. El mejoramiento y la selección de la caña de azúcar han evolucionado mucho desde los ‘viejos tiempos’ en que se hacían cruzas de los mejores progenitores y se esperaba seleccionar los mejores segregantes como potenciales nuevas variedades. Los procedimientos modernos de mejoramiento y la biotecnología ofrecen una mayor eficiencia. Generalmente, las variedades se seleccionan con base en alta productividad de azúcar y algunas características agronómicas importantes para la producción, además de la resistencia a plagas en cada región. Las características del jugo comúnmente medidas de Brix y pol, además del tonelaje, habilidad de soqueo y contenido de azúcar, permiten predecir el rendimiento de azúcar por unidad de área. Se prevé que la variedad ‘suprema’ del futuro implicará un análisis mucho más detallado de las características que se miden de rutina. Una vez producidas, las variedades de alto rendimiento para varios productos, necesitan ser cultivadas de una forma sostenible que proporcione la máxima producción con un mínimo impacto ambiental y económico. El procesamiento de estas variedades deberá acomodarse a los diferentes productos que se obtendrán ya sean azúcar, energía, otros productos o combinación de estos. Para demostrar la importancia de las características de calidad de las variedades del futuro, el Instituto de Investigación del Procesamiento de Azúcar ha investigado la presencia de componentes que podrían mejorar o inhibir la obtención de varios productos de la caña de azúcar. Se ha encontrado variabilidad significativa tanto inter, como intraespecífica en caña de azúcar y géneros relacionados, en cuanto a contenidos de almidón, polisacáridos, cenizas, cationes, azúcares invertidos y otros parámetros. Este trabajo incluye estos datos y la importancia potencial de estos parámetros en variedades futuras, su importancia en un sistema de producción sostenible y en las necesidades de procesamiento.
EVALUATING SUGARCANE R&D PERFORMANCE:
EVALUATION OF THREE BREEDING PROGRAMS

KEYWORDS: R&D Performance, Benchmarking,
Technology Valuation, Technology Adoption.

Abstract

RESOURCES for sugarcane R&D are scarce, as they are for most agricultural R&D, and investors in R&D want a return on their investment in the form of productivity and profitability gains that arise from the adoption of new technologies. These realities motivate productive and efficient R&D programs that are a key driver of ongoing productivity improvement in sugarcane industries. Sound technical programs deliver ongoing industry benefits sustaining industry profitability and underpinning industry growth. In the context of these R&D programs, strategic and tactical decisions made during the management of R&D projects are vitally important with respect to the outcomes delivered by R&D, and their subsequent uptake by industry. We illustrate these principles using variety performance data from Australia, Brazil and South Africa. Our findings include evidence for rapid uptake of new varieties, significant improvements in yield of cane per hectare and financial benefits delivered to growers adopting these improved cane varieties. Differences existed between the R&D programs in terms of the benefits being delivered to the respective industries that could be directly connected with particular research strategies employed. R&D is an investment, not a cost, but it becomes a cost if benefits are not realised by industry.

Introduction

We undertook a study to quantify benefits being delivered to sugarcane industries in Australia (only Queensland), Brazil and South Africa by the breeding aspects of research, development and extension (RD&E) programs undertaken by BSES Limited (BSES), Centro de Tecnologia Canavieira (CTC) and the South African Sugarcane Research Institute (SASRI). The rationale for the study was as follows: investors in sugarcane research, growers, millers, governments and others, want a return on their investment. This return can be measured by the rate of uptake of new technologies and enhanced returns in the investors’ businesses following the adoption of these new technologies. In the case of our institutions, the investors are also the customers for the services, new products and technologies developed by our RD&E programs. This brings into sharp focus the performance of the technologies in the hands of our customers and the return on investment to the growers, millers and others that support our programs.

In the Australian case, growers and millers interpret the plateau in industry outputs with respect to sugar yield as a failure of the R&D programs to deliver new technologies that enhance industry performance (Figure 1). This is despite comprehensive analyses (Cox and Stringer, 2007) that support the proposition that significant rates of genetic improvement are being achieved and, indeed, that the rate of genetic improvement is increasing.
This contradiction should not be surprising. Agricultural systems are complex, and dissection of cause and effect with respect to the contribution being made by R&D to improved agricultural performance is not well developed.

Wynne and Gilmour (these Proceedings) consider first some financial metrics that can be used to estimate the performance of investments in agricultural R&D and, secondly, the relative merits of different benchmarking methods for assessing R&D performance.

A central tenet of their analyses is that broad industry statistics, such as illustrated in Figure 1, can not directly be used to evaluate RD&E performance. In short, if:

\[ P = G + E + M; \]

where

- \( P \) = a measure of crop performance (e.g. tonnes sugar per hectare); and
- \( G \) = an estimate of the genetic effect;
- \( E \) = an estimate of the environmental effect; and
- \( M \) = an estimate of the crop management effect (including the interaction effects between \( G \) and \( E \)); then

inferences about neither \( G \), nor \( E \), nor \( M \) can be made by simply measuring and interpreting \( P \).

More analytical work is required to dissect out the contribution being made by each effect and to better value how each have contributed to lowering input costs or increasing productivity.

Our study deliberately concentrates on dissecting out the value contributed to productivity improvements by genetic improvement. This is motivated by availability of data sets to perform a range of analyses relevant to objectively evaluate the value being created by genetic improvement programs being undertaken by our institutions.

Schroeder et al. (2009) have considered aspects of the contribution being made by farming systems to improved industry performance, but such considerations are not examined here.
The audiences for the studies we have undertaken are the Boards and Senior Management of our respective organisations, together with the growers, millers and other investors in the industries we serve. The study is a snapshot of some aspects of the performance of our R&D programs. The results for each program provide a relative reference point against which others can be assessed. It does not follow that a particular program should be judged superior to any other.

There is a strong temptation to make direct comparisons, but such interpretation is flawed since the strategic rationale that underpins each program is quite different. The results are specific to the settings in which each RD&E program is operating, and direct comparisons between programs should be avoided.

For example, if the research strategies and operations of BSES were transferred to Brazil, it does not follow that the same performance as is achieved in Australia will be evident in Brazil. Similarly, if the research strategies and operations of CTC are transferred to South Africa, it does not mean that results equivalent to those in Brazil will be realised.

Nevertheless, the relative performance provides an important benchmark against which the progress of each RD&E program can be assessed.

Materials and methods

Terminology

Because sugar content of cane is measured in different ways in each country, throughout the text we simply use the terms sugar content (SC), tonnes of sugar (TS) and tonnes of sugarcane per hectare (TSH) as substitutes for the country-specific measures of sugar content: CCS (Queensland), ATR (Brazil) and ERC (South Africa) unless there is a specific need to identify a specific measure. In all data presentations in tables and graphs, we specifically indicate the appropriate measure.

Data

Three data sets were compiled for each of Queensland, Brazil and South Africa to compare and contrast: (1) basic industry statistics; (2) variety adoption trends and (3) rates of genetic gain and value to growers and millers as a result of developing and releasing genetically improved varieties.

The industry statistics data set was historical industry data for 1996–2006 (inclusive) for tonnes of cane (TC) and sugar (TS) produced, and tonnes of cane (TCH) and sugar (TSH) per hectare.

The variety adoption data set was historical industry data for the tonnes of cane delivered of specific varieties to mills for Queensland (1970–2007), Brazil (1984–2007) and South Africa (1979–2007).

For Queensland (1970–2007) and Brazil (1998–2007), the data sets for estimating rate of genetic gain included data for the tonnes of cane delivered to mills of specific varieties, the sugar content of those varieties reported either as commercial cane sugar (CCS, Queensland) or total recoverable sugar (ATR, Brazil) and the number of hectares on which varieties were grown to derive TCH and TSH on an individual variety basis.

For South Africa, data were not available for the number of hectares on which individual varieties were grown, which precluded estimation of rates of genetic advance being made by sugarcane breeding using industry data. As a substitute, we used data from the SASRI variety improvement research program. The data set comprised yield data and estimated recoverable crystal / ha (t ERC/ha) for each released variety during the period 1980 – 2007.

Analytical methods

Industry production trends were examined for each country by plotting TCH and TSH over time. Variety adoption trends were examined by plotting percentage area planted to specific varieties over time. We calculated average duration in production (last year in commercial production—first year in commercial production) over all varieties, and examined the dominance of
varieties by grouping varieties into categories according to the area they occupied in commercial production. For Queensland and Brazil, we calculated a weighted average age of varieties in commercial production over time using % area planted data where:

\[ \text{Age}_i = \frac{\sum_{j=1}^{n} (C_j \times A_{ij})}{n_i} \]

where:

- \( \text{Age}_i \) = Average age of varieties in year \( i \);
- \( P_i \) = Year of production, where \( i = 1984, \ldots, 2007 \);
- \( C_j \) = Year of cross (Brazil) or year of first seedling in trials (Queensland) for variety \( j \);
- \( A_{ij} \) = Percent area planted in year \( i \) to variety \( j \);
- \( n_i \) = Number of varieties in commercial production (i.e. \( A_{ij} > 0.0\% \)) in year \( i \).

For calculating rates of genetic advance, we followed Cox et al. (2005). Briefly, this entailed the following steps. For Queensland and Brazil, where data were available for the number of hectares planted to each commercial variety, the area planted was weighted by its cube root. This has the effect of reducing the emphasis of new varieties recently in commercial production and planted to only small areas. TCH and TSH were then estimated as best linear unbiased predictors (BLUP) by fitting a mixed linear model with varieties as random effects using the software package ASREML (Gilmour, 1999). Average rates of gain over the study period were calculated by fitting a linear regression to the relationship: TCH or TSH versus year of variety release into commercial production. Rates of genetic advance were estimated for Q varieties originating from the BSES-CSIRO breeding program in Queensland, for SP and RB varieties originating from the Copersucar / CTC, and RIDESA breeding programs respectively in Brazil, and for N and NCo varieties originating from the SASRI breeding program in South Africa.

Thus:

The average rate of genetic improvement of all varieties was calculated as:

\[ \Delta G = \frac{n \times \sum_{i=1}^{n} (y_i \times v_i) - \sum_{i=1}^{n} y_i \times \sum_{i=1}^{n} v_i}{n \times \sum_{i=1}^{n} (y_i^2) - (\sum_{i=1}^{n} y_i)^2} \]

where:

- \( \Delta G \) = Average rate of genetic advance for all varieties;
- \( n \) = the number of varieties;
- \( y_i \) = Year of release of variety \( i \), where \( i = 1, \ldots, n \); and
- \( v_i \) = BLUP of the performance of variety \( i \).

The value of varieties in commercial production was calculated assuming a financial model for the performance of a hypothetical 100 ha farming enterprise as generally set out in Table 1.

**Table 1**—Financial model for calculating the value of new varieties in commercial production.

</tbody>
</table>

The benefit estimates were used to determine reasonable fees that could be charged of growers and millers on the following basis:

- Proportion of EBIT benefit retained by growing and milling sectors (W) = 80%;
- Proportion of EBIT benefit retained by breeding organisation (X) = 100–W = 20%.

Then:

- Apportionment of EBIT benefit share to breeding organisation as a grower fee (G) = 64%*X;
- Apportionment of EBIT benefit share to breeding organisation as a miller fee (M) = 36%*X.

The revenue stream due to each breeding organisation was then calculated using the respective cane production base for each organisation such that:

- Revenue (BSES) = (GB+MB)*32*10^6;
- Revenue (CTC) = (GC+MC)*309*10^6;
- Revenue (SASRI) = (GS+MS)*20*10^6.

Where the subscripts, B, C and S, refer to the respective breeding organisations: BSES, CTC and SASRI.

**Results and discussion**

**Industry production trends**

The results for the annual trend in tonnes of cane production per hectare over the period 1996 to 2006 (Figure 2) indicate that there has been an increase in productivity of 0.68 TCH in Brazil, and a decline in South Africa of 0.43 TCH. In Queensland, average productivity is higher than in either Brazil or South Africa, but the average is more volatile connected with weather events (too wet and too dry) and disease (illustrated by the 1999–2000 orange rust epidemic).
Average, industry-wide sucrose content in both Brazil and South Africa has increased from 1996 to 2006, although the relationship for South Africa is weaker than that for Brazil (Figure 3). For Queensland, sucrose content has been volatile.
For TSH, the results follow the tonnes of cane per hectare results with Brazil having an annual increase in average tonnes of sugar per hectare of 0.14 TSH/year whereas, for South Africa, there has been a decline in average TSH by 0.08 TSH/year (Figure 4). For Queensland, TSH has been higher than both Brazil and South Africa. However, it has also been volatile and declined by an average of 0.05 TSH/year over the period.

Variety adoption trends

The variety adoption trend data for Queensland (Figure 5) indicate that varieties typically have a commercial production life of approximately 20 years comprising four five-year crop cycles. There is no distinct evidence of the duration of varieties in commercial production changing over the 37-year period from 1970 to 2007.
For Brazil (Figure 6), average duration of varieties in commercial production is approximately 15 years and, like in Queensland, there is no evidence that this has changed significantly from 1984 to 2007. The data are consistent with varieties being grown for three crop cycles using a system of a plant crop and four ratoons.

In South Africa (Figure 7), the variety composition plots are dominated by two varieties NCo376 and N12. The data suggest that varieties have a very long life in commercial production, exceeding 25 years in some cases. This is consistent with the long crop cycles ranging from two to four cycles of plant crops and 7–10 ratoons.
The average crop age results illustrate the domination of the Queensland crop through the late 1990s by the variety Q124, followed by the disadoption of that variety following a race change in the orange rust population (Figure 8). In Brazil, there is evidence for average crop age increasing. This probably reflects a preference to plant older varieties in new production areas because of the availability of seed cane and the known performance characteristics of those varieties.

Fig. 8—Weighted average crop age for Queensland and Brazil.

There have been marked differences between Queensland, Brazil and South Africa in the uptake of PBR-protected varieties (Figure 9). The data indicate that uptake in Queensland was, initially, slower than in Brazil, but that since about 2003, the rate of uptake in Queensland has greatly surpassed the rate of uptake of Brazilian PBR protected varieties. Generally, the uptake of new varieties in South Africa has been very slow, mainly due to the traditionally long crop cycles (Figure 6c, see below).

Fig. 9—Rate of uptake of PBR-protected varieties in Queensland, Brazil and South Africa.
The annual average rate of genetic gain for TCH, SC and TS (Table 2) indicates that there has been significant genetic advance for TCH by varieties from the SP program and to a lesser extent, the RB program. For TCH, the Q program has had a similar rate of genetic gain to the RB program in Brazil. For South Africa, there are four subprograms that had markedly different rates of genetic advance for TCH ranging from 1.18 TCH/year for CS12 (Coastal, 12 month harvesting cycle) to 0.06 TCH for CS18 (Coastal, 18 month harvesting cycle). For SC, the data indicate improvement for Q varieties, but neutral to slightly negative progress for SP and RB varieties. For South African varieties, there are variable results for SC ranging from 0.05%/year improvement in MD24 (Midlands, 24 month harvesting cycle) to –0.08%/year regression in CS12.

The key outcome from these results is that results for improvement of TS/year were equal for varieties from the SP and Q programs (0.281 TSH/year), with modest gains also being made by the RB program. Small genetic gains were made by varieties from the South African subprograms ranging from 0.015 TSH for CS18 to 0.081 TSH for MD24. It is important to note here that the extent and nature of the data used for the analyses varied considerably from country to country. Consequently, it was difficult to make fair comparisons between countries. Further, the South African sugar industry is unique in that there are four sub-programs where selection occurs to meet the requirements for the variable agro-climatic regions. These main agro-climatic regions include the Northern Irrigated region (NI12) where the sugarcane is irrigated and harvested at 12 months of age, the Coastal long cutting cycle region (CS18) where the cane is rainfed and harvested at 18 months of age, the Coastal short cutting cycle region (CS12) where cane is rainfed and harvested at 12 months of age and then the Midlands region (MD24) where cane is rainfed and harvested at 24 months of age.

Table 2—Rate of genetic gain for tonnes of cane per hectare, sugar content and tonnes of sugar per hectare for Queensland (Q), Brazil (SP, RB) and South Africa (CS12, CS18, NI12, MD24).

These results are supported by Figures 10, 11 and 12, which show the nature of the relationship between TCH and SC for varieties released by each of the programs over the period of study. In the case of Q varieties, the data indicate simultaneous improvement of both TCH and SC (Figure 10). For the SP and RB programs in Brazil (Figure 11), the data indicate that there has been a tremendous improvement in TCH over the period of study while Pol% has been held in a narrow range without achieving a significant SC improvement in new high yielding varieties.

For South Africa (Figure 12), the data clearly indicate a strong negative correlation between TCH and SC, suggesting that improvement is being made in SC of new varieties, albeit at the expense of TCH. We believe that this may be because the South African varieties have a significantly greater contribution of *Saccharum spontaneum*, which contributes to the higher stalk populations and good ratooning ability of sugarcane varieties and which makes joint improvement of both TCH and SC difficult. It is likely that increased selection pressure for higher quality and sucrose content has been at the expense of selecting for higher cane yield.
Fig. 10—Relationship between tonnes of cane per hectare (TCH) and Pol% for varieties released in Queensland by the BSES-CSIRO breeding programs from 1962 to 2006.

Fig. 11—Relationship between tonnes of cane per hectare (TCH) and Pol% for varieties released in Brazil by the Copersucar/CTC (1983–2001) and RIDESA (1989–2001) breeding programs.

Value of varieties in commercial production

The results summarising reasonable fees that each breeding organisation could charge on the basis that 20% of the EBIT benefit delivered by those varieties is captured by the breeding organisation are shown in Table 3.

Table 3—Summary of fees that could be reasonably charged assuming 20% of the EBIT value is captured by the breeding organisation. (Currency values are US dollars).

</tbody>
</table>

The results indicate that each organisation is delivering significant value to the respective industries they serve through variety improvement alone, relative to fees currently being paid by organisation members. We estimated that reasonable fees ranged from $0.25/tonne of cane for CTC to $1.23/tonne of cane for BSES. If such fees were implemented, reasonable revenue streams could be generated by each organisation ranging from $6m per annum for SASRI to $77m per annum for CTC.

We emphasise that it is not the purpose of this paper to set out fees that our respective organisations could reasonably charge industry members for accessing research services. Many factors other than the research organisation capturing a proportion of the value delivered will impact on decisions to set fees at a particular level. The methodology set out here can be used to inform that decision in an objective way. This proposition is reasonable under the assumption that the technology, in this case, new varieties, is adopted commercially.
Conclusions

In this paper, we have set out a range of data that provide an insight into the performance of our respective research organisations with respect to the value being delivered to the sugarcane industries we serve. We chose to focus on variety improvement because of the availability of data for such a study and the ability to design an objective framework for estimating the impact of those varieties in commercial production, namely adoption of new varieties, rates of genetic advance and value delivered by new varieties in commercial production.

The study has illustrated that value is being delivered to the industries we serve by our respective organisations. There are clear differences between organisations in the quantum of value delivered, and in the rate of uptake of new varieties. It would be incorrect to conclude that these differences are a function solely of differences between the organisations. Each organisation operates in relation to specific resources to meet the strategic needs of their respective industries and into which new technologies are delivered for commercial production. What the study has done is demonstrate that research strategy and industry setting can have a major impact on realising the value being delivered by research investments. This is clearly illustrated by the contrasts with respect to joint improvement of TCH and SC, and the marked differences in the rate of uptake of new varieties.

The study was proposed by the respective Chief Executives of our organisations as an opportunity to benchmark the performance of each organisation against one another. We conclude that the study has been somewhat useful for this purpose. In the future, the approach could usefully be extended to relevant comparisons in other research areas, particularly the performance of farming systems research programs and the effectiveness of extension programs.

Acknowledgements

This study was initiated by Eoin Wallis, Nilson Boeta and Frikkie Botha. We thank Dr Joanne Stringer for the BLUP analyses. The germplasm valuation framework was developed by Brian Carrick and Andrew Wellington. The following assisted by providing data and advice regarding analytical methods and interpretation of the results: in Australia: Barry Callow, Michael Cox, Eve McDonald, James Ogden-Brown, Joanne Stringer, Xianming Wei and Trevor Willcox; in Brazil: Tadeu Andrade, Michel Choairy, Mauricio Antonio de Oliveira, Jose Perez Rodrigues Filho, Luiz Antonio Dias Paes, Adhair Ricci; and in South Africa: Carolyn Baker, Mike Butterfield, Steve Davis, Charles Dettman, Chris Gillett, Rod Harding, Aresti Paraskevopoulos and Adrian Wynne.

Résumé

LES RESSOURCES pour la R&D en canne à sucre sont rares, car elles sont principalement pour la R&D agricole et les investisseurs en R&D veulent un retour sur leur investissement en termes de gains de productivité et profitabilité liées à l’adoption de nouvelles technologies. Ces réalités stimulent la mise en œuvre de programmes R&D productifs et efficients qui sont un élément moteur pour la l’amélioration continuelle de la productivité dans les industries de canne à sucre. Les programmes techniques bien adaptés apportent des bénéfices industriels permanents soutenant la profitabilité de l’industrie ainsi que sa croissance. Dans le contexte de ces programmes R&D, les décisions stratégiques et tactiques prises durant la gestion des projets R&D sont d’une importance vitale pour les produits et résultats fournis par la R&D et leur adoption par l’industrie. Nous illustrons ces principes en utilisant des données de performance des variétés en Australie, Brésil et Afrique du Sud. Nos conclusions inclus l’évidence pour une adoption rapide de ces nouvelles variétés, des améliorations significatives de rendements en canne par hectare et des bénéfices financiers pour les planteurs adoptant ces variétés de canne améliorées. Des différences existent entre les programmes R&D en termes de bénéfices à fournir aux industries respectives qui pourraient être directement connectées à des stratégies de recherche particulières. La R&D est un investissement et non un coût, mais elle devient un coût si les bénéfices ne sont pas réalisés par l’industrie.

PALABRAS CLAVE: Desempeño de la Investigación y Desarrollo (R&D), Benchmarking, Evaluación de Tecnología, Adopción de Tecnología.

Resumen

Los recursos para realizar investigación y desarrollo (I+D) en caña de azúcar son escasos, como generalmente ocurre en el área agrícola, y los inversionistas en I+D, esperan un retorno de sus inversiones en forma de mejoras en la productividad y ganancias que deriven de la adopción de nuevas tecnologías. Estas realidades, motivan a los programas de I+D a ser productivos y eficientes y los convierten en motores clave para las mejoras en productividad que se dan en las industrias azucareras. Programas técnicos sólidos resultan en beneficios constantes que mantienen la rentabilidad de la industria y ayudan a su crecimiento. En el contexto de estos programas de Investigación y Desarrollo, las decisiones tácticas y estratégicas que se tomen durante la gestión de los proyectos de I+D son de vital importancia con respecto a los resultados obtenidos y su adopción por parte de la industria. Nosotros ilustramos estos principios usando datos del desempeño de variedades en Australia, Brasil y Sudáfrica. Nuestros resultados incluyen evidencia de la rápida adopción de las nuevas variedades, mejoras significativas en el rendimiento de la caña por hectárea y beneficios financieros que obtuvieron los productores que adoptaron estas variedades mejoradas de caña. Se determinó que hay diferencias entre los programas de I+D en términos de los beneficios que se para a las industrias respectivas y que podrían estar relacionados con el uso de estrategias de investigación particulares. I+D es una inversión, no un costo, pero se convierte en costo, si los beneficios no son conocidos por la industria.
SUSTAINABILITY AND THE AUSTRALIAN SUGAR INDUSTRY

By

MATTHEW KEALLEY and BERNARD MILFORD

CANEGROWERS Australia

KEYWORDS: Australia, Sustainability, Legislation.

Abstract

This paper reviews the legislative, environmental and social requirements faced by the Australian sugar industry. It concludes that the Australian industry probably operates under more environmental scrutiny and control than most, has less government protection than most but suffers less interference in its commercial arrangements than most.

Introduction

The sugar industry in Australia is among the world’s largest exporters of raw sugar, but internally its sugar industry is relatively small. Sugar contributes 4% to the gross value of agriculture in Australia and agriculture in turn makes up 4% of the country’s GDP. The sugar industry is scattered along the Queensland and Northern New South Wales coast and, despite its size in the overall economy, is the vital economic lifeblood of many towns and regions.

It could be described as capital rather than labour intensive, compared to many industries worldwide. Around 3800 cane growing enterprises supplying ten milling companies produce between 30 Mt and 35 Mt cane and 4.5–5 Mt sugar. The industry is close to the iconic Great Barrier Reef and several major centres of urban expansion.

Legislative

Sugar producers in Australia have no market or tariff protection; the industry competes with other sugar producing countries on the world stage and domestically. Apart from small US and EU quotas, it has no preferential markets. Specific sugar legislation is minimal and growers and millers make contracts commercially, without resort to external arbitration. There is no national ethanol mandate, but the state of New South Wales has a 2% requirement in place and Queensland has announced a 5% mandate. A national Renewable Energy Target of 20% of stationary energy by 2020, introduced in 2009, will give an impetus to cogeneration in sugar mills.

Sugar industry participants, as individuals and corporations, are bound by a substantial amount of Australian and state legislation, much of which has a strong focus on environment protection (summarised in Appendix 1).

In particular, the Environmental Protection Act 1994 establishes a general duty of care, which means growers need to take all reasonable and practical measures to minimise the risk of harm to the environment. New legislation to limit fertiliser and pesticide output from the sugar and grazing industries in the catchment of the Great Barrier Reef has recently been passed by the Queensland Parliament.

All affected farmers in these catchments, which account for over 70% of production, will be required to keep comprehensive records of their use of agricultural chemicals, fertilisers, soil conditioners and soil testing results, apply no more than the optimum level of fertiliser, and observe new restrictions on the use of some agricultural chemicals.
The industry’s social obligations require compliance with general workplace health and safety regulations and the *Trade Practices Act 1974* which regulates business activities.

Australia ratified the Kyoto Protocol in December 2007 and has made a commitment to reduce its greenhouse gas emissions to 60% of 2000 levels by 2050. The Australian Government is implementing a strategy for tackling climate change through the Carbon Pollution Reduction Scheme. The government has indicated that agriculture will be included in the scheme; this sector contributes 16% of the country’s greenhouse emissions, mainly methane from enteric fermentation in ruminants. However, the form of this participation will not be determined until 2013 and discussions are continuing.

**Positive externalities**

As noted, the sugar industry is the cornerstone of many towns and communities on the northeast coast of Australia. It is estimated that it employs directly around 5250 people on farm, 3120 in the harvesting sector and 7359 in mills. Logistics, marketing, research, representation and refining contribute another 753 people, giving a total of around 16 482 direct employees. The workforce is skilled and adaptable. Indirectly, around 30 000 persons rely on the industry for their livelihood. The centre of mass that the industry provides keeps rural communities alive and means that services such as education, health and finance are maintained.

**The industry’s ability to match sustainability criteria**

Political positioning, encroachment from urban development, increased environmental scrutiny, competition for land use from other crops and forestry and the diversity of the sugar producing regions are all factors that will affect the industry’s ability to match sustainability criteria.

The diversity of climate, geographic location, cane variety, water availability and soil conditions all dictate farm practice. For instance, in the Burdekin dry tropics, cane fires are commonplace as heavy crops and furrow irrigation make trash blanketing difficult. In most other regions, cane fires were replaced with green cane harvesting and green trash blanketing years ago. Maintaining the ability to burn cane when necessary requires an understanding of farming systems that the public and media may not be inclined to develop, leading to simplistic proposals for quick solutions.

Urban development on productive cane land and land-use change to trees or other crops create tension, particularly around production tonnages that are necessary for mill viability. Taxation incentives are available for forestry developments that are not applied to cane growing. Urban expansion into cane areas brings increased public scrutiny of farm practices such as application of fertiliser and chemicals.

We consider that the industry’s biggest challenge in terms of legislative outcomes is the rise of the urban green vote and the willingness of politicians to chase this bloc with simplistic solutions. At the same time, regional electorates are seen as unlikely to change hands with the consequence that their concerns can be largely dismissed.

This was clearly evident in an announcement during a recent Queensland State election campaign of measures to reduce pollution on the Great Barrier Reef by 50% in five years by targeting only the sugar and grazing industries.

By contrast to the legislative approach, the industry, in partnership with the Commonwealth government, other peak industry bodies and regional natural resource management groups, has committed to a program of cooperative improvements in farm practices.

The five-year Reef Rescue program will focus on new technology to assist growers make best use of their inputs of fertiliser, chemicals and irrigation water to deliver a more profitable business with greatly reduced environmental footprint. It will be responsible for the delivery of incentives for accelerated uptake of better management practices in the reef catchments.
The representative organisation, CANEGROWERS Australia, produces a Public Environment Report on a regular basis (Wrigley et al., 2008 is the latest). This is designed to provide a comprehensive reference for those interested in the growing sector’s environmental progress.

It details the risk management and continual improvement of new farm practices being undertaken by growers for economic, social and environmental sustainability. The reports measure progress and highlight growers’ willingness to continually strive to do more, provided that it is practical, is supported by science and delivers a benefit.

The organisation has also been proactive in developing booklets, DVDs and a range of communication tools to assist farmers to adopt improved management practices.

**Research**

It is fair to say that most research in the Australian sugar industry has a sustainability focus. Work on reducing fertiliser requirements, improving the targeting and effectiveness of pesticide use, drought tolerance of new varieties, and farming systems with lower inputs and lower losses are all examples of research dedicated to improving sustainability.

An examination of the research programs of BSES Limited and the Sugar Research and Development Corporation will demonstrate an almost-universal emphasis on the triple bottom line in research outcomes.

**Conclusion**

The Australian industry probably operates under more environmental scrutiny and control than most, has less government protection than most and consequently suffers less interference in its commercial arrangements than most.

It dedicates considerable resources to improving its sustainability and will continue to improve. However, it will also be likely to find its operations curtailed through political interference based on simplistic, populist environmental concerns.

### Laws, legislation and regulation relevant to agricultural farm practices in Australia

<table>
<thead>
<tr>
<th>Legislation</th>
<th>Description</th>
</tr>
</thead>
</table>
| **Water Act 2000** | - Water Licences  
- Water Allocations  
- Land and Water Management Plans  
- Regulates clearing of vegetation in and around water ways |
| **Great Barrier Reef Protection Amendment Act 2009 (Qld)** | - Legislation and regulations to improve water quality entering the Great Barrier Reef that is directed at sugarcane farmers and graziers in the Wet Tropics, Burdekin Dry Tropics and Mackay Whitsundays.  
- Regulates certain works that take or interfere with water from watercourses, lakes, springs, aquifers or overland flow  
- Development Permit required for physical construction of works to take or interfere with water in a watercourse  
- Development Permit required for bores |
| **Integrated Planning Act** | - Care and protection of native plants, animals and habitat in Queensland  
- Protects areas of environmental significance |
| **Nature Conservation Act 1992 (Qld)** | - For plants and animals declared as pests  
- Places obligations on landholders in relation to the control, sale, keeping and transport of declared pests in Queensland |
| **Land Act 1994 (Qld)** | - Places obligations on leaseholders when it comes to noxious plants eg may require the lessee to destroy plants |
| **Local Government Act 1993 (Qld)** | - Local Government Minister has power to declare any bird, animal, insect, fungus, matter or thing to be a pest within the meaning of that Act |
| **Vegetation Management Act** | - Clearing of vegetation in and around water ways  
- Clearing of vegetation on both freehold and leasehold land  
- Property Map of Assessable Vegetation |
| **Vegetation Management and Other Legislation Amendment Bill 2009** | - Management and clearing of regrowth vegetation and regrowth watercourses  
- Wet Tropics, Burdekin Dry Tropics and Mackay Whitsundays |
| **Soil Conservation Act 1986** | - Designed to conserve and prevent soil erosion |
| **Wild Rivers Act 2005 (Qld)** | - Aims to preserve river systems the State Government identifies as having all, or almost all, of their natural values intact |
| **Wild River Code** | - Sets out requirements that must be met by proposed development |
| **River Improvement Trust Act 1940** | - Designed to improve the flow of water courses |
| **Environmental Protection Act 1994** | - Protect the environment in Queensland  
- Wide range of mechanisms  
- Eg aerial spray drift |
| **Environmental Protection and Biodiversity Conservation Act 1999 (Cth)** | - Provides protection to nationally significant aspects of the environment  
- Farmers may require approvals if new activities significantly impact on matters of environmental significance  
- World Heritage Properties  
- National Heritage places  
- Wetlands  
- Threatened animal and plant species and ecological communities  
- Migratory species  
- Commonwealth marine areas |
<p>| <strong>Local laws</strong> | - By local governments |
| <strong>Fire and Rescue Service Act 1990</strong> | - Permits for burning in certain situations |
| <strong>Agricultural Standards Act 1994 (Qld)</strong> | - Imposes quality and control stands on ‘agricultural requirements’ (seed, fertiliser, lime or stock food) |</p>

Resumen
ESTE ARTÍCULO examina los requisitos legislativos, ambientales y sociales que enfrenta la industria azucarera de Australia. El informe concluye que la industria Australiana probablemente opera bajo mayor escrutinio y control ambiental que la mayoría, tiene menos menos protección del Gobierno que la mayoría, pero sufre menos interferencias en sus arreglos comerciales que la mayoría.
REPORT ON PROFIT, PEOPLE AND PLANET. HOW DOES THE SOUTH AFRICAN SUGAR INDUSTRY REACT?

By

G.W. MAHER
South African Sugarcane Research Institute
Geoff.maher@sugar.org.za

KEYWORDS: Sustainability, Protection, Environment, Social, Research.

Abstract

THE ISSCT Executive Committee has initiated a study to assist affiliates to deal with the increasing calls for sustainable production systems. Sustainability refers to the triple bottom line or the people, planet and profit philosophy. Most of the ISSCT’s endeavours of recent history have been directed at improving the profit component of that philosophy in both field and factory. The people and planet have not enjoyed as much attention. The Executive Committee decided to appoint a Task Force to report on sustainability and this report provides the results of the study in the South African Sugar Industry. Field and factory activities, which identified the Industry’s actions in respect of the stewardship of both people and the planet, were established after dialog with both the miller and grower fraternities in South Africa. Views on the successes and shortcomings are highlighted and research needs identified. In the context of the profit component, a report on the macro economics of issues such as total production, total revenue earned, grower’s total income and total numbers of employees is given.

Introduction

The South African sugar industry is diverse, combining the agricultural activities of sugarcane cultivation with the manufacture of raw and refined sugar, syrups, specialised sugars and a range of by-products.

The cane growing sector comprises approximately 42 300 registered growers farming predominantly in Kwa Zulu-Natal, with a substantial investment in Mpumalanga and some farming operations in the Eastern Cape. Sugar is manufactured by five milling companies with 14 sugar mills operating in these cane growing regions.

The industry produces an estimated average of 2.3 Mt of sugar per season. About 60% of this sugar is marketed in the Southern African Customs Union (SACU), member states being Botswana, Namibia, South Africa, Lesotho and Swaziland. The remainder is exported to markets including those in Africa, Asia and the Middle East (South African Sugar Association, 2008).

Profit component in the triple bottom line

The South African sugar industry makes an important contribution to the national economy, given its agricultural and industrial investments, foreign exchange earnings, its high employment and its linkages with major suppliers, support industries and customers.

Revenue

Based on revenue generated through sugar sales in the SACU region as well as world market exports, the South African sugar industry is responsible for generating an annual estimated average direct income of R7 billion. This constitutes R4.5 billion in value of sugarcane production.

Market competitiveness

Governments strategic support for the South African sugar industry recognises the distorted nature of the world market for sugar and the severe impact of producer support measures on price
determination on the global market. Based on these considerations government support includes intervention in the following three areas: Tariff protection against disruptively low world sugar prices; provision for the establishment of equitable export obligations for millers and growers; and the Sugar Co-operation Agreement between the members of the Southern African Development Community (SADC). Member states of SADC being Democratic Republic of Congo, Tanzania, Angola, Zambia, Malawi, Mozambique, Zimbabwe, Botswana, Namibia, South Africa, Lesotho, Swaziland, Mauritius, Seychelles and Madagascar.

**Tariff protection**

The industry is protected through a dollar-based reference price tariff system that is based on the long-term average world price for sugar, adjusted for distortions, which only delivers protection when the world price drops below this level.

**Equitable export obligations**

The South African sugar industry exports approximately 40% of its production to the world market at prices substantially below the domestic sugar price. In order to distribute exposure to the world market equitably among growers and millers, a redistribution of proceeds is effected via the South African Sugar Association. The Sugar Act and the Sugar Industry Agreement provide regulatory support for the redistribution of proceeds.

**The Southern African Development Community Sugar Co-operation Agreement**

The main objectives of the SADC Sugar Co-operation Agreement are:

- To promote, within the region, production and consumption of sugar and sugar-containing products according to fair trading conditions and an orderly regional market in sugar for the survival of the sugar industries in all sugar producing member states, in anticipation of freer global trade;
- To create a stable climate for investment, leading to growth and development of sugar industries in the member states;
- To improve the competitiveness of the sugar producing member states in the world market;
- To facilitate the sharing of information, research and training with a view to improve the efficiency of growers, millers and refiners of sugar in 7 member states;
- To facilitate the development of small and medium sugar enterprises; and
- To create stable market conditions in the member states so as to encourage the rehabilitation and development of all sugar industries with a view to facilitate direct foreign investment and the creation of employment opportunities.

**People component in the triple bottom line**

**Employment**

The South African sugar industry falls under the Sugar Industry bargaining council and all wages and salaries are negotiated accordingly for the entire industry. Direct employment within the sugar industry is approximately 77,000 jobs, which represent a significant percentage of the total agricultural workforce in South Africa.

Indirect employment in sectors such as fertiliser, fuel, chemical, transport, food and services is estimated at 350,000. Approximately one million people depend on the sugar industry for a living. Sugar mills typically employ in the region of 450 people per mill. Growers typically allocate 1 labourer per 1000 tons cane.

The sugar mills provide a diverse and intensive technical employment field and career opportunities. The skills base includes engineers and artisans, accountants, cane supply staff, human resource support, training and development staff. Involvement with local schools offering career guidance and work shadow opportunities for learners.
Social obligations

The industry’s initiatives in the areas of economic transformation could best be summarised under its commitment to Broad-based Black Economic Empowerment (BBBEE), with focus on land reform, farmer support services, employment equity and enterprise ownership.

Agricultural land made available to black growers

The industry has set a target of 30% black ownership of freehold sugarcane land by 2014. In order to achieve this, an independent land reform entity called INKEZO Land Company has been formed to help streamline the process.

Agricultural support services

The industry has a long history of promoting and supporting small-scale farmers on tribal land. Building on the extensive infrastructure and network of the growers and millers, the industry has been able to engage effectively in ongoing delivery related projects. The South African Cane Growers Association provides technical skills training for new and emerging cane growers via the Agiseta scheme, mentorship programs, accounts and financial management workshops, regional economic advisors, a grower support service officer and assistance with special VAT and diesel dispensation for small-scale growers. The milling companies provide extensive support services in support of the cane growing operations of small-scale, medium-scale and large-scale black growers. The South African Sugar Association trains emerging medium-scale growers, offers certificate courses to users in sugarcane agriculture, technology transfer and extension initiatives and various community outreach programs.

Employment equity

All participants in the industry promote compliance with the Employment Equity Act and have integrated Employment Equity and Skills Development Plans in place that are monitored and updated annually. These have targets for recruiting, developing and promoting people from designated groups.

Ownership profile

Substantial progress has been made towards improving the ownership profile of the industry. Initiatives embarked upon by major South African milling companies have resulted in black ownership of manufacturing activities being 12% and of refining activities being 7%.

Social investment

The incidence of HIV and AIDS impacts directly upon the industry and its workforce. Meeting the challenge of this disease is a priority. Activities include school education awareness programs and funding home-based care initiatives for individuals and households infected and affected by HIV and AIDS. Individual grower groups and millers have and are funding clinics and orphanages in the rural areas.

In 1965 the industry launched the Sugar Industry Trust Fund for Education (SITFE). SITFE has provided bursaries to more than 9000 students, financed school building projects, given assistance to tertiary institutions and worked closely with community based educational authorities.

Relevant social legislation

Compensation for Occupational Injuries and Diseases Act, 130 of 1993.
Competition Act, 89 of 1998.
KwaZulu Natal Heritage Act 10 of 1997
Land Reform (Labour Tenants) Act, 3 of 1996
Medical Schemes Act, 131 of 1998.
National Heritage Resources Act, 25 of 1999
Pension Funds Act, 24 of 1956.

Planet component of the triple bottom line

The South African Sugar Association (SASA) actively promotes sound and sustainable environmental practices within the industry in line with national legislation and international requirements. This is achieved through its support for Local Environmental Committees (LEC) located in the sugar producing areas and also through active involvement in promoting sustainable resource management through a Memorandum of Understanding with WWF South Africa.

The industry is involved in a Southern African Development Community wide initiative aimed at establishing a guide on environmental best management practices for the regional sugar industries.

Individual grower groups have adopted the Sustainable Sugarcane Farm Management System (SuSFarMS), an environmentally friendly farming system developed by growers in conjunction with WWF South Africa. The system is currently being rolled out to other grower groups in the industry and has been endorsed by SASA.

The various milling companies have adopted environmental management systems such as the ISO 14001 and similar local derivatives.

The industry demonstrates a very high level of environmental awareness and practices (McCarthy, 2008) and has:

- Cut back on planting in estuaries and delicate ecosystems and is now often actively leading local conservation and awareness organisations;
- Cut back on burning of cane at harvest especially where it impacts negatively on adjacent land use and has reintroduced green cane harvesting in several areas;
- Reduced the use of more harmful chemicals in weed control;
- Reduced the emissions from milling factories to the atmosphere and impacts on run-off and stream quality.

Relevant environmental legislation

Conservation of Agricultural Resources Act, 43 of 1983.
Fertilisers, Farm Feeds and Agricultural and Stock Remedies Act, 36 of 1947.
National Environmental Management Amendment Act, 8 of 2004.
Natal Nature Conservation Ordinance 15 of 1975
National Road Traffic Act, 93 of 1996.
National Roads Amendment Act, 24 of 1996.
Sugar Act, 9 of 1978.

**Short comings**
The current short comings of the South African sugar industry in relation to its ability to conform to present day sustainability are:

- Input costs are high resulting in lower profits.
- The industry is heavily reliant on natural weather conditions; global warming could have a negative effect.
- Land claims and the loss of sugarcane supply to the mills.
- Loss of sugarcane land to township development schemes.
- Loss of labour due to HIV and AIDS.
- Lack of adoption of international energy norms within the sugar mills in order to improve factory operating efficiencies and reduce fuel bills.
- Disagreement between millers and growers.

**Research requirements**
The industry will require the following research to ensure it will have the tools to be fully sustainable:

- Transport methods and supply chain efficiency.
- Need to bring national government on board to implement a suitable long term sustainable electricity tariff that facilitates and promotes the sugar industry to produce and export electricity into the national grid.
- Alternative uses of sugarcane.
- Ethanol production.
- Reducing input costs.
- Improved crop nutrition and water use efficiency.
- Land usage planning.
- Integrated pest management and bio-security.
- Farming systems in relation to environmental management.

Resumé
Le comité exécutif de l’ISSCT a initié une étude afin d’aider ses membres à faire face à l’augmentation de demandes concernant les systèmes de production durable. La durabilité se réfère aux trois principes philosophiques de base, les populations, la planète et le profit. La plupart des efforts de l’ISSCT dans son histoire récente a été orienté sur l’amélioration de la composante « profit » de cette philosophie tant au niveau du champ que de l’usine. Les populations et la planète n’ont pas jouis de la même attention. Le comité exécutif a décidé de former une équipe renforcée pour réaliser un rapport sur la durabilité et ce rapport donne des résultats sur l’étude de l’industrie sucrière Sud-Africaine. Les activités au champ et à l’usine qui ont guidés les actions de l’industrie dans le respect des intérêts des gens et de la planète, ont été établies après un dialogue avec les associations fraternelles d’usiniers et planteurs en Afrique du Sud. Les points de vue sur les succès et les défauts ont été soulignés les besoins en recherche identifiés. Dans le contexte de la composante « profit », un rapport sur les aspects macroéconomiques des questions majeures telles que la production totale, les gains économiques totaux, le revenu total du planteur et le nombre total d’employés est donné.

Resumen
El comité ejecutivo de ISSCT ha iniciado un estudio para ayudar a los afiliados para que puedan responder a las exigencias cada vez mayores de sistemas de producción sostenible. Sostenibilidad se refiere a la triple cuenta de resultados o la filosofía de gente, planeta y ganancias. La mayoría de los esfuerzos recientes de la ISSCT han sido dirigidos a mejorar el componente de ganancias de esa filosofía tanto en campo y como en fábrica. Los componentes de gente y el planeta no han disfrutado de tanta atención. El Comité Ejecutivo decidió nombrar a un grupo de trabajo para informar sobre la sostenibilidad, y este informe proporciona los resultados del estudio en la industria azucarera de Sudáfrica. Las actividades de campo y de fábrica, las cuales identificaron las acciones de la industria con respecto a la administración de la gente y el planeta, fueron establecidas después de diálogos con las organizaciones de ingenios y cultivadores en Sudáfrica. Se resaltan puntos de vista sobre los logros y deficiencias, y se identifican necesidades de investigación. En el contexto del componente ganancias, se da un informe macro económico en cuestiones tales como la producción total, total de los ingresos ganados, los ingresos totales del productor y número total de empleados.
SUSTAINABILITY IN SUGARCANE PROCESSING IN BRAZIL

By

JAIME FINGERUT

CTC- Centro de Tecnologia Canavieira Cx. Postal 162 Piracicaba SP Brazil 13400-970

KEYWORDS: Sustainability, Biofuels, Bioplastics, Residues, Productivity.

Abstract

SUSTAINABILITY involves the three ‘Ps’: People, Planet and Profit. Brazilian sugarcane is a sustainable industry that has made significant gains in its sustainability over the last 30 years. A typical mill today can process twice as much sugarcane with the same equipment and with approximately the same energy, maintenance, labour, water, etc., so that twice as much product can be produced. All residues are recycled back to sugarcane fields. The use of energy and chemicals in processing are also considerably reduced. The use of sugarcane bagasse, other carbohydrates from sugarcane, production of bioplastics and second and third generation biofuels represent new avenues for increased sustainability. The entire Brazilian sugarcane production chain has to be very well prepared for a more intense scrutiny of sustainability.

Introduction

Sustainability is a complex concept involving the so called three ‘Ps’: People, Planet and Profit.

The production and processing of sugarcane in Brazil is definitely a sustainable industry and is a very important activity in that country.

It occupies less than 10% of the commercial agricultural area or less than 2% of the total arable land, but the sector generates 1.5% of the Brazilian GNP (same order of magnitude as Uruguay).

The sector is responsible for around 1 200 000 jobs, and employees are paid better than in other Brazilian agribusiness, and have superior labour rights.

The investment needed to generate these jobs is much less than in other sectors of the Brazilian economy.

In the automotive sector, about US$80 000 is needed per job while, in sugarcane processing, only about US$12 000 is required.

Considering all jobs in the production of ethanol and cars, ethanol-driven cars generate 20 times more Brazilian jobs than the gasoline ones.

In terms of impacts on the environment, it is acknowledged that any economic activity has an impact, but the sugarcane agribusiness consistently demonstrates that its production and processing are feasible in the long term.

This is the case in São Paulo state, where 70% of the sugarcane is produced and where the environment protection agencies are more active and the legislation more comprehensive.

In São Paulo, there are many sugarcane mills that have been in operation for more than 50 years and their productivity is still increasing.

Life style indices of the population in the sugarcane cities are improving and are better than in other cities.

Sugarcane processing in Brazil can be summarised in the flowsheet presented in Figure 1.
Sustainability

The sustainability aspects that can be emphasised in the processing are:

- Productivity,
  - Producing more with the same equipment;
- Efficiency,
  - Producing more with the same raw material,
  - Reducing losses and emissions – pollution;
- Energy,
  - Producing more with the same energy;
- Water,
  - Producing more with the same water;
- Chemicals,
  - Producing more with the same chemicals,
  - Less contamination – pollution.

Due to the Oil Crisis in 1973 and a severe debt and currency crisis, Brazil established the National Alcohol Program in 1975, called the Proalcool. This program, the most important renewable energy program in the world for replacement of fossil fuels with biofuels, created a
steady demand and established the logistics needed for its use. Government support and private investment and then competitive production led to the gains in sustainability in the sugarcane sector.

In terms of investment and production costs, losses and possible development of bottlenecks, the most important part of sugarcane processing is the sugar extraction mill (or diffuser) and the distillery. Gains in productivity in sugar extraction (the most expensive and energy intensive part of processing) are shown in Figures 2, 3, 4 and 5.

![Evolution of Milling Capacity](image)

Fig. 2—Evolution of milling capacity.

Figure 2 shows that a typical mill today can process twice as much sugarcane with the same equipment and with approximately the same energy, maintenance, labour, water, etc., so that twice as much product can be produced.

At the same time as the productivity doubled, the efficiency (the amount of sugar in the juice compared with the sugar in the raw material) also increased (Figure 3).

![Evolution of Milling Efficiency](image)

Fig. 3—Evolution of milling efficiency.
The efficiency gains are driven mainly by the need to produce more with the same raw material (sugarcane) that is the main cost driver.

In Figure 4, it can be seen that the productivity in ethanol plants (measured here by the fermentation time) also almost doubled. Simultaneously, the efficiency also increased significantly (Figure 5).
The water used (from a water body) dropped considerably from 5.6 m³/tonne of cane in 1990 to around 1.8 m³/tonne of cane, through reduction and reuse (closed circuits). Water returns are now treated, with more than 98% reduction in organic matter.

All residues, including solids such as filter cake, from the juice clarification, and vinasse, from the bottom of the distillation column, are 100% recycled back to sugarcane fields, with better performance than the corresponding chemical fertilisers.

The use of energy and chemicals in processing are also considerably reduced due to the synergistic behaviour of the distillery adjacent to the sugar factory.

All streams containing sugars, even low quality, may be sent to the distillery as well as the richer molasses or even syrups, because there are no losses when this sugar is converted into other valuable products such as ethanol.

Attending to two different markets (sugar and fuel—ethanol) makes the production more flexible, robust and less dependent on subsidies. The industry is also less prone to big losses due to excessive volatility in the prices of commodities.

The use of energy is another important aspect of the processing. Because sugarcane bagasse can be used to fuel all energy needs, the amount of renewable energy in the final product (ethanol biofuel) is about nine times greater than the energy used from fossil fuels.

This is much better than when sugar beet, wheat or corn is used at the same production level.

Today the use of sugarcane bagasse represents around 16% of the total primary energy used in Brazil. There is a surplus of energy in the best processing units and electricity (and excess bagasse) is being sold in some cases, representing around 10% of the total sales of these more modern mills.

Although most energy is generated from hydroelectricity in Brazil, the surplus energy generated from sugarcane makes it possible to save water during the drier periods of the year, when sugarcane is harvested and processed.

There is considerable potential to increase electricity exports, which will add to the sustainability of the Brazilian economy.

This is because co-generation investments are much cheaper, and the electricity will be added to the grid much faster than with any other generation option.

Finally, the carbohydrates from sugarcane, as well as the ‘excess’ energy, can be used for establishing so called biorefineries, replacing practically all imported products from petroleum, such as plastics.

This will add significantly to sustainability on a global scale. Even fertilisers can be produced from sugarcane residues through gasification and other processes, as well as other biofuels such as biogas, biogasoline and biodiesel.

Production of bioplastics from plants in factories annexed to a sugarcane processing plant is the most likely to succeed. This represents a very interesting method of CO₂ (carbon) ‘sequestration’ and storage.

The so-called second and third generation biofuels, based on the use of cellulosic residues and CO₂ as a raw material, respectively, are also very likely to be competitive with the sugar-based biofuels and products, in the short or mid-term.

This will add efficiency to the entire production. For this to happen, however, considerable international research efforts are needed.

More R&D in the broad area of sustainability is an urgent need for the short term, and forums such as ISSCT can facilitate decisions on what to prioritise.

The entire sugarcane production chain has to be very well prepared for a more intense scrutiny of sustainability, particularly as biofuels become rational alternatives to fossil fuels.
DURABILITE DANS LE TRAITEMENT A L’USINE DES CANNES A SUCRE AU BRESIL

Par

JAIME FINGUERUT
CTC–Centro de Tecnologia Canavieira Cx. Postal 162 Piracicaba SP Brazil 13400-970
jaime@ctc.com.br

MOTS-CLÉS: Durabilité, Biocarburant, Bioplastiques, Résidus, Productivité.

Résumé
LA DURABILITÉ implique les trois P: Population, Planète et Profit. La canne à sucre brésilienne est une industrie durable qui a progressé significativement dans ce domaine de la durabilité depuis les 30 dernières années. Aujourd’hui une usine typique peut traiter deux fois plus de cannes avec le même équipement et avec approximativement la même énergie, maintenance, main-d’œuvre et quantité d’eau, ce qui génère aussi deux fois plus de produits. Tous les résidus sont recyclés et utilisés dans les champs de cannes. L’utilisation d’énergie et de substances chimiques dans le traitement à l’usine sont aussi considérablement réduits. L’utilisation de la bagasse et d’autres matières carbonées issues de la canne à sucre ainsi que la production de bioplastiques et les biocarburants de seconde et troisième génération représentent de nouvelles voies pour accroître la durabilité des opérations. Toute la chaîne de production brésilienne doit être très bien préparée pour une exigence accrue en matière de durabilité.

SOSTENIBILIDAD EN EL PROCESAMIENTO DE CAÑA DE AZÚCAR EN BRASIL

Por

CTC- Centro de Tecnologia Canavieira Cx. Postal 162 Piracicaba SP Brazil 13400-970
jaime@ctc.com.br

PALABRAS CLAVE: Sostenibilidad, Biocombustibles, Bioplásticos, Residuos, Productividad

Resumen
LA SOSTENIBILIDAD involucra Gente, Planeta y Rentabilidad. La industria azucarera brasileña es sostenible y ha obtenido ganancias significativas en su sostenibilidad durante los últimos 30 años. Hoy en día un ingenio azucarero puede moler el doble de la caña de azúcar de lo que hacía antes, con el mismo equipo y usando aproximadamente la misma cantidad de energía, mantenimiento, mano de obra, agua, etc., por lo que se puede obtener el doble de producto. Todos los residuos son reciclados y vuelven a los campos de caña. El uso de energía y de productos químicos en el proceso también se ha reducido considerablemente. El uso del bagazo, de otros carbohidratos de la caña, producción de bioplasticos y los biocombustibles de segunda y tercera generación, representan las nuevas líneas para el incremento de la sostenibilidad. La cadena completa de producción de azúcar del Brasil tiene que estar preparada para un escrutinio más intenso en cuanto a la sostenibilidad.
MONITORING THE HARVESTING OF SUGARCANE AND
GENERATION OF YIELD MAPS IN REAL TIME

By

J.A. CARBONELL, C.A. OSORIO and J.M. RAMÍREZ

Colombian Sugarcane Research Center,
CENICAN, A.A. 9138, Cali, Colombia, South America
jacarbonell@cenicana.org

KEYWORDS: Sugarcane, Precision Agriculture, Yield Mapping,
Wholestalk Weigh System, Harvest Monitoring.

Abstract
In a given area or plantation it is common to determine the variability in production
that exists between harvested sugarcane fields or lots. The agroindustrial sugar sector in
the Cauca River Valley of Colombia has appropriate mechanisms for determining and
managing the variability of production among the cane lots, but it has not had sufficient
alternatives for determining the variability within them. At present, the preharvest task
of cutting the cane is done manually in most of the area, while the subsequent lifting of
the stalks is done with self-driven equipment. CENICAN has developed a system that
can be installed on the cane lifters, which records the weight of each bundle and its
distribution position. The data are stored and transmitted by cell phone to a computer
where they can be visualised for carrying out a precise monitoring of the harvest and
generating yield maps. This work describes the structure of the system developed, the
methodology for obtaining and transmitting the data, and how to interpret and analyse
the yield maps. An analysis of a field harvest, for which it is known where there was
fertilisation and where not, shows the value of each weight recorded. In this case, the
best estimate of the production in the field is obtained by averaging the data from six
consecutive bundles. Both the system for obtaining the data and the methodology for
their analyses and the generation of yield maps can be implemented in other agricultural
sectors.

Introduction
Numerous studies have developed systems for monitoring and recording the yield and
generation of production maps in manual and mechanically harvested sugarcane crops. Different
tools have been developed for obtaining yield maps. Pierossi and Hassauani (1997) installed four
compression load cells on an infield (haulout) wagon in a chopper harvesting system; other studies
for producing production maps in different crops are reported by Cox et al. (1997).

Pagnano and Magahlaes (2001) used production maps to determine variability in sugarcane.
Molin et al. (2003) generated production maps of manually harvested burned cane by relating the
weight of a bundle from a mechanical loader to a georeferenced distance.

The weight of each grab was determined from the total weight of the load gathered in the
wagon and the number of grabs.

The majority of the area planted by the agro-industrial sugar sector in the Cauca River
Valley of Colombia is harvested manually, and the cane is piled in the field (windrow) to be picked
up by self-propelled loaders and deposited in wagons that are taken to the factory by tractor or
truck.

The Colombian Sugarcane Research Center (CENICAN) has been developing different
systems for the georeferenced weighing of sugarcane. In 2006 the Agronomy Program began the
instrumentation of a commercial-scale self-dumping wagon with load cells on its four sides,
together with a data storage system for weighing the Center’s experiments at the different sugar mills. In this way they could obtain the weights of each plot with its treatments, whether by manual or mechanical harvesting. Later a system for georeferencing (GPS) was installed in the system in order to generate yield maps.

In 2007, the Geomatics Area at CENICAÑA began developing a geo-referenced weighing system that also made it possible to transmit the data and generate intrafield yield maps in real time, using the instrumentation of the cane lifter. This system was designed for use in the manual harvesting of sugarcane. It is important to quantify the within-field production in different zones. This is to allow management of the crop variability and to make more efficient use of resources when taking investment decisions with respect to a production area. The GIS and geostatistics are used to quantify the differences in production within the lots and then generate isoproduction curves; while spatial analysis is used to carry out studies of economic efficiency and evaluate the differences in intralot productivity.

Materials and methods

Weighing system

A compression load cell (5000-kg capacity) was mounted in a mechanical system with four disks (Figure 1), which allowed pressure to be exerted on the cell every time that cane is picked up with the loader. The load cell then generates an electrical analog signal (millivolts), which is recorded by the weight indicator (Prometalic Scales, model PRO-1500), which stabilises the signal and sends the weight data via a serial port to a datalogger. For the georeferencing and sending the information, equipment was used that integrates a GPS and a wireless modem (Enfora Spider, model MT-G 2208). For the synchronisation, storage and transmission of the information, a datalogger (Campbell Scientific, model CR1000) was used with a dedicated a program written in CR Basic language.

![Load Cell](image)

Calibration

After mounting the load cell on the disks, a preliminary calibration of the weighing equipment was done, setting weights with predetermined values; and the corresponding voltage was
induced in the load cell. The PRO-1500 indicator was used in this process in order to establish the zero value of the weighing system.

**Data recording**

The datalogger has four serial ports, of which two are used for connecting the GPS and the load cell. The weight indicator records the signal of the load cell, displays it visually and sends it to the serial port of the datalogger. The datalogger synchronizes the recorded weight with the data on the position given by the GPS. Then the data are stored in the datalogger and sent by the modem through the GPRS (General Packet Radio Service) network to a Web server, where they are kept in a database.

The process of recording the data is controlled by the loader operator who presses a recording button that communicates with the datalogger. The end user accesses the information using a Web explorer with SVG (Scalable Vector Graphic) support. The communication between the server and the user is done via a Hypertext Pre-processor (PHP, a Personal Home Page tool).

**Sending the data**

The cellular modem uses the GPRS commercial network for sending the information that is extracted from the serial port of the datalogger, making use of AT commands for obtaining the data from the GPS, which includes the UTM (Universal Transverse Mercator) hour, geographic position and the quality of these data (Figure 2).

**Productivity maps**

The yield map is generated with the information on the weight and its geographic coordinates. This map depends on two variables:

- The number of furrows per windrow of cane (5 or 6 cut furrows piled in a single row) and;
- The distance between the furrows.

The loader obtains the data from a nominated area every time that a certain distance is run, piling the cane to be lifted later; it is necessary to obtain the starting and the end points of each run of the lifter and the respective weighing in order to determine the production area. Each production area is connected to the previous one, which means that every time that the lifting process is begun,
the operator has to mark the starting point of the windrow to establish the first production zone. Figure 3 shows the diagram for producing the yield maps in real time in each windrow.

All data are stored in a PostgreSQL-PostGIS database; and by means of a geospatial operation, the information is obtained on the plantation/lot in which the cane is being picked up.

The PHP language was used to create an application that takes into account the position, weight, the azimuth between points, and the distance parameters between furrows and number of furrows per windrow to generate the production areas.

The output format of the graphic that the PHP generates is SVG, which is an XML (Extensible Markup Language) format that can be seen on the Web explorer. The application calculates the yield for each production area in TCH (tonnes of cane per ha), classifying each area in a range of yield.

![Figure 3—Diagram for generating the yield map on-line in each windrow.](image)

**In-field evaluation**

The system was evaluated in a manually harvested field at Cenicaña (3° 21’ latitude North, 76° 18’ longitude West) in November 2008. The lot had an area of 8748 m², and was planted with variety CC 85–92, at a distance of 1.5 m between furrows.

There were two fertilisation treatments: one with fertigation (windrow 3, 6 and 8) and the other with conventional fertilisation, applied mechanically (windrow 2, 4 and 9). There was one check without fertilisation (windrow 1, 5 and 7).

Each treatment had three replications formed by six furrows along field 8. An 80-hp lifter (Metalagro, model AC-80) was used, on which the previously described equipment was installed. In total, there were nine windrows, each one formed by six furrows corresponding to each treatment and replication.

The furrows were oriented in an east-west direction, and each treatment was placed along the furrow (108 m long). In total, the equipment recorded 318 weights with their corresponding coordinates. The windrow weights were analysed, yield determined and the results graphed.

The data were analysed using descriptive statistics and Kolmogorov-Smirnov’s and Shapiro-Wilks’ normality tests. An analysis of variance was applied for the treatments, using Tukey’s test, with a 95% level of confidence.

**Results and discussion**

The descriptive statistics for each windrow are given in Table 1. Windrow 1 and 7 had values very close to the mean, the median and the mode and a coefficient of asymmetry less than 1, indicating a symmetric distribution of frequencies; thus they are near a normal distribution.

Similar results were obtained when the Shapiro-Wilks test was applied to all the windrows. All the windrows, except for 1, 7 and 9, had data discrepancies (very high), which should be revised
carefully, as well as the very low weight values in windrow 3 and 6. The null hypothesis for this test was that the weights of each windrow were characterised by a normal distribution (P-value > 0.05).

**Table 1**—Descriptive statistics for the weight (kg) of the nine windrows.

The ANOVA revealed that windrow 1, 5, 6 and 7 were similar among themselves, but different from windrow 2, 3, 4, 8 and 9.

Similar tests were done with the TCH data in accordance with data for just one weighing (one bundle), two consecutive weighings (two bundles) and so on, successively, until reaching yield values for 8 bundles together.

Table 2 shows the P-values for the Shapiro-Wilks and Kolmogorov-Smirnov tests, the average and standard deviation. The TCH values that met with a normal distribution were those for 6 and 8 bundles. Figure 4 shows the different statistical treatments carried out with the data.

(1) Shapiro-Wilks, (2) Kolmogorov-Smirnov.
If the P-value is >0.05, there is not sufficient evidence for suggesting that the data do not follow a normal distribution.
For carrying out the geostatistical analyses, work was done using the TCH data, grouping the different quantities of bundles and using the one that described a normal performance in order to guarantee greater precision in the analyses (Rey and Ovalles, 2001).

The geostatistical analysis concluded that when using six bundles, a theoretical exponential model and an anisotropic at 303°, which corresponds to the direction of the bundles in the field, the best spatial dependence was found, using the ratio $C/(C_0+C) = 100\%$; a $C_0$ of 0.00 nugget effect (sampling error); a spatial relation (sill) of 407.56; a range of 52.16 and a mean square error for the cross-validation of 0.94.

It was also found that, by increasing the number of grabs in the cluster, the proportion that measures spatial dependence $C/(C_0+C)$ increased 14% with 2 bundles to 78% with 4 bundles, and 100% with 6 and 8 bundles. Although the spatial dependence was high with 4 bundles, there are doubts as to the normality of the data; thus it was not selected.

Figure 5 is the result of the data analyses and shows the yield maps (TCH) based on the ranges of production quartiles that correspond to the yield map as is presented in real time and the result of using the method of interpolation found (exponential).

Both maps show the particular condition of the field having an unfertilised area, where the production was different but where there were spatial variations along each windrow.
Conclusions

Currently, the system is used to weigh all experimental plots in Cenicaña.

Some sugar mills are beginning to incorporate the system in their harvesting process (cane loaders and computers).

The system can be used when the harvesting is done with self-dumping equipment unlike other systems.

With the system developed, yield maps can be generated in real time based on weight values and their coordinates.

By means of a computer connected to the Internet, those who are interested in monitoring the harvesting can learn about its progress and the within-lot variability of yield in any place.

It’s necessary to analyse all dates of each lot or field because continuous data do not necessarily mean that they comply with the criterion of normality. In the analysis of the case in this document, which grouped 2, 6 and 8 bundles, there was sufficient evidence to suggest that the data followed a normal distribution.

The system can be employed for analysing production in other agricultural systems such as fruits, oil palm, rice, potatoes or similar crops.

The system is being patented initially in Colombia.

Résumé

Dans une région donnée ou une plantation, il est courant de déterminer la variabilité de production entre les différents champs ou parcelles récoltés. Le secteur agro-industriel de la vallée de la rivière Cauca de Colombie a des moyens appropriés pour mesurer et gérer la variabilité de production entre les parcelles de canne, mais n’a pas de méthode alternative pour mesurer leur variabilité intrinsèque. Actuellement, la récolte de la canne est manuelle dans la presque totalité de la zone, alors que le chargement est effectué avec des chargeuses automotrices. CENICAÑA a développé un système installé sur les chargeurs qui permet d’enregistrer le poids de canne dans chaque grappin ainsi que sa position géographique. Les données sont stockées et transmises par téléphone portable vers un ordinateur qui permet de les visualiser pour un suivi précis de la récolte et pour générer des cartes de rendement. Ce papier décrit la structure du système développé, la méthodologie pour l’obtention et la transmission des données, ainsi que la façon d’analyser et d’interpréter les cartes de rendement. L’analyse de la récolte d’un champ où les zones fertilisées ou non sont connues montre la valeur de chaque poids enregistré. Dans ce cas, la meilleure estimation de la production du champ est obtenue en moyennant les données de six grappins successifs. Le système pour obtenir les données, la méthodologie pour leur analyse et la génération des cartes de rendement peuvent tous être implémentés dans d’autres secteurs agricoles.

KEYWORDS: Wholestalk Cane Loading, Cane Loader Efficiency, Sugarcane Transport Systems, Harvest Scheduling.

Abstract

THE CANE growing area along the Nile valley in Upper Egypt has expanded. Most of farmer holdings are small, typically ranging from 0.5 to 1 hectare. Cane delivery schedules and consequently harvesting dates mainly depend on the delivery allocation and the date of harvest last season. The mill administration assigns a transport vehicle (main vehicle) for each farmer according to the schedule. Farmer/s harvest and transport cane from inside field/s (using a tractor-pulled-trailers) to temporary storage sites at which the main vehicle/s are loaded. Loader efficiency can be low due to time losses associated with travel from one storage site to another. To achieve reasonable efficiency of the loader, storage sites may be amalgamated allowing greater utilisation of loaders. This procedure may increase the infield transport distance which may reduce the rate of cane supply from fields, thus contributing to increased cane delivery delay. Farmers may have to transport a part of the main vehicle load to the storage site the previous day to secure continuous operation of the loader. In this study, loader efficiency, loading rate, the percentage of main vehicle/s load/s delayed more then 24 h and cane collection efficiency were studied. In most cases, one main vehicle is assigned to each farmer, where a trailer pulled by tractor is used to transfer cane from inside the field to the storage area. Results show that total efficiency of the loader was 75% in case of loading lorries in a large storage area and 81% in case of railway wagons loaded at a station. Average total efficiency of the loader was 61% when loading decauvelle wagons distributed in several storage areas within the same production region. Efficiency of loading tractor trailers in the field was 54%. Maximum efficiency was observed to be achieved if the loader works for the full operational day in one storage area. Cane collection efficiency was variable for the variable operating conditions. The percent of cane delayed more than 24 h was also estimated. Large temporary storage areas at which lorries are loaded with cane, and cane loading stations for railway wagons may represent more optimal conditions for loader operation. The paper discusses the efficiency of loader operation under a range of variable conditions, and related cane delivery delay. The results highlight the role of loader operation efficiency as a factor determining the adoption of mechanical loading of sugarcane. Recommendations for proper operation of cane loader are suggested.

Introduction

Due to soil and water limitations, the sugarcane growing area in Upper Egypt is limited to about 350,000 feddan (150,000 hectares). Average production has been maintained at over 120 t/ha for several years and may be classified as one of the highest cane yielding areas in the world. Cane-to-mill delivery activities are performed according to schedules (prepared by the mill administration) which determine the date of harvesting and the main transport vehicle. According to
the schedule, the common procedure is to each day assign a main vehicle to each farmer, thus allowing for low productivity of the harvesting and transport activities. Farmers harvest and transport cane to temporary storage areas at the trans-loading sites for the main vehicles. Cane has to be loaded again to the main vehicles. These temporary storage areas are the main area where mechanical loading of cane is undertaken, to load cane on the main transport vehicles to the mill.

Efforts to mechanise cane loading started more than 20 years ago when the Ministry of Agriculture initiated three mechanisation companies for sugarcane. The largest of these companies (Aswan Mechanisation Company) invested large amounts of its capital to purchase and rent cane loaders (especially Bell loaders). Despite the unlimited chances for operating these loaders, the company lost a large part of their investment and could not afford to replace the loaders at the end of their useful life. Therefore mechanical loading activities reduced from about 8% to less than 2%. Operating loaders at lower efficiency may have been one of the most important factors contributing to the loss of such investments and subsequent decline in the percent of mechanical loading. The number of workers ready to load has been declining because most of them prefer to find other easier jobs. Therefore the cost of cane loading has been constantly increasing.

Uichanco (1976) and Edilbert and Uichanco (1977) stated that cane loading is an arduous task which limits the productivity of manual cane cutters. In the Philippines, cane cutters can cut and load only one tonne a day. The wider use of mechanical loaders in the sugar industry can be an intermediate step in improving harvesting efficiency. Cochran and Whitney (1976) reported that Louisiana conditions require that sugarcane be burned and cut ½ to 1 day ahead of the loader and then transported to the mill. Libunao (1978) reported that, in the Philippines, sugarcane is loaded manually in trucks or carts for in-field transport. Cane loaders carry on their shoulders about ten to twenty cane stalks, from the ground to the trucks, through a ladder or ramp placed on any side of the truck. Manual loading complements sugarcane cleaning in the field which is also done manually.

Blackburn (1984) described the Bell self-loading trailer drawn by a wheeled tractor, designed and developed in South Africa. Cane is cut manually and formed into heaps or bundles. When loading takes place, the trailer is manoeuvred into position and its skids are dropped. A wire or chain attached to the winch is then passed around the bundle and draws it up the ramp into the trailer. Bell self-loading trailers are also used, with local modifications, in Trinidad and have been used since 1968 in the Philippines. Yang and Wang (1993) evaluated the performance of mechanical loading of sugarcane and compared it with the traditional manual loading on flat and sloping lands under two different yielding conditions. The manual loading efficiency was 0.54 t/ man/h in comparison with 23.9 t/h for mechanical loading. Saif El-Yazal and Abdel-Mawla (1994) compared mechanical and traditional loading and transporting of sugarcane. The performance of the two mechanical systems was tested. The first was a 5 tonne capacity self-loading trailer equipped with a loading boom and the second was the grab loader. The self-loading trailer transported 6.4 t/h. The locally made trailer transported 5.3 t/h from a field 0.5 km from the store location, when loaded by the grab type loader.

Hansen et al. (1998) and Eggleston et al. (2001) conducted intensive studies on the problems of deterioration due to cane delay. The authors highlighted the problems caused by deterioration with different processing stages and recommended that the transport process be accelerated to reduce delivery delay. Abdel-Mawla (2000) studied mechanical loading of sugarcane and stated that efficient management of cane area and delivery system may facilitate increasing mechanical loading productivity and control cane delivery delay. Legal and Requis (2002) reported that the South African sugar industry relies on a large number of small-scale growers for a significant part of its production. In that respect, the management of the cane harvest and supply to the mill represents the key-issue regarding both the reduction of burn to crush delays, the regularity of deliveries and the reduction of production costs.
Abdel-Mawla and El-Lithy (2006) developed an expert system approach for selecting a cane transport system. They specified the possibility of mechanical loading as one of the most important qualifiers that attract farmers for selecting the cane delivery system. Meyer (2007) stated that, in South Africa, only about 2% of the annual crop is currently harvested mechanically. It is estimated that 40% of the whole stalk sugarcane is either loaded manually onto transport vehicles or stacked in 3–5 tonne bundles to be transported by a self-loading tractor trailer/trailer combination. The remaining tonnage is mechanically loaded by grab and push-pile loaders onto a wide range of vehicles which transport the cane either directly from the fields, or indirectly from trans-loading zones to the mill.

The cane delivery process includes two transport links. In the first link the farmers use camels, carts or tractor-trailers to transport cane from inside fields to temporary stores (trans-loading sites). In the second link (according to the mill delivery schedule) a main transport vehicle is assigned to each farmer. The main vehicles may be a decauvelle-wagon or a railway-wagon if available in the region otherwise a wheel vehicle is used. In case of mechanical loading, farmers use tractor-trailers for infield transport to supply cane to the main vehicles waiting in the trans-loading site.

To maintain continuous operation of the loader, variable regulations have been arranged depending on the type of vehicles and other conditions. The study aimed to evaluate the efficiency of mechanical loading at the conditions under which the loader is operated.

**Materials and methods**

The area of cane planted for each mill is organised into regions. Each region is divided into plots bounded by irrigation channels, drainage channels, and rod system expanded in the agricultural area. Cane fields planted in the same plot may be owned by several farmers (prevailing holding sizes ranged from 0.5 to 1 hectare) and may not be of the same ratoon. Cane delivery schedules and consequently harvesting dates mainly depend on the ratoon and date of last season harvesting. Therefore, fields of the same region assigned for cane harvesting at certain dates may not be neighbours and main vehicles may be loaded at different trans-loading sites. Because cane is harvested manually and infield transport may depend on carts and such slow means, the mill administration assigns one main vehicle (daily) for each farmer. The main vehicle may be a decauvelle or a railway wagon depending on the availability; otherwise, a wheeled vehicle may be used. In case of mechanical loading, the farmers use a trailer pulled by a medium size tractor for infield transport.

A large temporary store (trans-loading site) is that in which the loader can work for a full operational day. Such sites may exist in one of the following conditions: 1) At large fields of the sugar company, governmental farms or large farmer holdings where lorries are shipped with cane. This may represent a small part of the total production area of sugarcane. 2) At the main railway line of Upper Egypt where trans-loading sites are established for transporting the cane crop of farms on both sides of the railway line. The railway wagons transport less than 3% of the total cane production.

Field measurements were undertaken at several locations in Upper Egypt. A Bell mechanical loader was used in the study. The mechanical efficiency of the Bell loader was assessed in the three most likely operational scenarios. These included:

1. Loading vehicles in one site:
   Lorries loaded in one trans-loading site.
   Railway wagons loaded simultaneously in a railway trans-loading site.

2. Loading vehicles in several sites:
   Decauvelle wagons or trucks waiting single or combined in 2, 3, 4 or 5 vehicles in the same trans-loading site.
3. Infield mechanical loading.
In the three scenarios, no time losses due to maintenance or repair were recorded. Hence, these losses are not considered in determining loader efficiency.

**Loader efficiency**

The loader efficiency was determined by multiplying the efficiency of loading an individual vehicle by the efficiency of continuous loading.

Total efficiency of loader $L_E$ may be computed as the following:

$$L_E = L_{E1} \times L_{E2}$$

where:

- **Efficiency of loading individual vehicle ($E_1$)**
  Only time lost while loading a vehicle was considered.

- **Efficiency of continuous operation ($E_2$)**
  Only time lost for the loader to shift from one vehicle to another was considered.

**Loading rate**

The loading rate for the full operational day of the loader was computed using the following equation.

$$L_R = \frac{\text{Sum vehicle loads (tonnes)}}{\text{Operation hours / day}}$$

where:

- $L_R$ = Loader rate (t/h).

**Load delays**

According to the schedule of the mill, decauvelle wagons are distributed to the locations of temporary stores before sunrise and pulled back to the mill (loaded with cane) that afternoon.

The time available for infield transport may expand till the wagon is completely loaded, and this depends on the rank of the vehicle/store considered for mechanical loading.

Where there is simultaneous loading of railway wagons, loading duration (time available for infield transport) of each vehicle may expand to be equal to the full operational day.

The time available for infield transport for a vehicle waiting for the loader, may be determined as follow:

$$T_{FT} = \frac{V_{2L} \times V_{2N} \times S_{rank}}{L_R}$$

where:

- $T_{FT}$ = Time available for infield transport, h.
- $V_{2L}$ = Average load of the main vehicle, tones.
- $V_{2N}$ = Number of main vehicles in a store.
- $S_{rank}$ = Rank of the site considered for mechanical loading.

In case of mechanical loading, the loader operator informs each farmer with the rank of loading his vehicle two days early.

The farmer may estimate the quantity of infield cane transported from the early morning till the loader starts to load his wagon and transport the rest of the vehicle load from the field to the store at the previous day.

The percent of a vehicle load to be transported from the previous day (delayed more than 24 h) to secure continuous operation of the loader may be computed as follow:
QD % = The percent of the main vehicle load delayed more than 24h,

\[ Q_D \% = 100 \left( 1 - \frac{V_{1R} \times T_{FT}}{V_{2L}} \right) \left( \frac{V_{1N}}{V_{2N}} \right) \]

\( V_{1R} \) = The rate of infield transport by a tractor-trailer, t/h.

\( V_{1N} \) = Number of infield transport vehicle/s that supply cane to main vehicle/s. The ratio of \( (V_{IN} / V_{2N}) \) in common conditions equal to the unity.

The same form may be used to estimate the quantities of infield transported while loading railway wagons simultaneously. In this case, loading duration (time available for infield transport, \( T_{FT} \)) for each wagon may be equal to the operational hours of the day.

**Cane collection efficiency**

Cane collection efficiency is a measure of cane losses due to mechanical loading. The loader performs loading cycles as fast as possible to maximise the loader rate and income. Cane stalks may be scattered from the loader grab and the loader may pass over while working. Even though a worker may be assigned to collect scattered cane, some cane may be lost or damaged. Loader collection efficiency was determined as follows:

**Results and discussion**

**Mechanical loading in large stores**

Where lorries are loaded in a large trans-loading site, the loader loads each lorry individually. Before the loader starts loading a vehicle, the full cane load should be ready in the site. Mechanical loading accelerates the transport cycle and may facilitate repeated trips of a lorry from the trans-loading site to the mill. During mechanical loading, the lorry driver adjusts the lorry to the most suitable position for the loader to manoeuvre while loading to minimise the loading cycle time and maximise loader rate. Loading lorries individually in a large site was accomplished at a maximum mechanical loading rate of 23.1 t/h. Total efficiency computed for a full operational day while loading lorries in a large site was not less than 75%.

In the case of the railway wagons, large trans-loading stations are established with a sufficient number of wagons for a full day of operation of the loader (8 h/day or more). In most cases each wagon is assigned for a farmer. The wagons may be detached and separated little distance apart to allow more room for each farmer to unload his cane opposite to the wagon. The loader operator loads several wagons simultaneously while farmers continue to transport cane from fields. To maintain continuous operation of the loader, each farmer determines the quantity of cane that could be transported within loading duration and transports the rest of the load the previous day. Loading duration for each wagon is considered equal to the loader operational hours of the full working day. A maximum operational efficiency of 81% was achieved for loading railway wagons due to the maximum use of time because of simultaneous loading. Average loading rate was 21.9 t/h.

**Mechanical loading in several stores**

If the cane is transported from inside the field to load single vehicles waiting at the road, then the loader operator has to move along the road to load vehicles one by one. Decauville wagons are distributed on the rail slide opposite to the fields before sunrise and pulled back to the mill (loaded) afternoon. The wagons considered for mechanical loading during the operational day ranked and the full load of each wagon should be ready on time. Vehicles may be combined to more than one vehicle in the same site to save the loader time losses due to travel among small sites. When decauville wagons are combined in a store, the loader operator may load all vehicles in the same site simultaneously. Similarly, trucks may be waiting on the road opposite to fields. They may also be single or combined according to the possibility of having more than one vehicle together.
Lorries are loaded individually because they perform repeated transport trips during the operational day.

The larger the number of vehicles combined in the same store, the longer the average field to store distance and the lower the infield transport rate as shown in Figure 1.

Therefore, farmers within a certain area who wish to use mechanical loading may plan to establish a common trans-loading site. It has been observed that under such conditions the maximum number of vehicles that could be combined in a common store was five while combining three vehicles may be more practical. Loader efficiency improves from 60% to 74% when loading several vehicles in one store as indicated in Figure 2.
The loader operator prepares a schedule for the loader work along the operational day that ranks sites in which vehicles are waiting for mechanical loading. The farmer determines the quantity of cane to be transported in the same day of loading and transport the rest of the vehicles load from the previous day. Therefore a percent of the vehicle load may be delayed more than 24 h as shown in Figure 3.

![Figure 3—Percent of vehicle loads delayed more than 24 h to maintain continuous loader operation.](image)

**Mechanical loading inside fields**

Several attempts to operate loaders for loading decauville wagons on a portable slide line have been tried in the experimental farm of the sugar company. Other trials to load tractor-trailers inside the field were also evaluated. The results show that mechanical loading of cane inside the field is completed at low rate and poor efficiency. This is due to the loader having to move around the stationary vehicle to collect cane piles and travel back to discharge the grab load inside the vehicle. The poor performance of the loader is mainly because of moving across furrows and irrigation channels. The irregular form and size of cane piles due to manual harvesting contributed the poor performance of mechanical loading inside the field. In these conditions, the loader rate was limited to 13 t/h. Efficiency of mechanically loading a stationary vehicle inside the field was up to 54%.

**Comparison loader efficiency**

Loader rate, loader efficiency and cane collection efficiency are the main criteria to compare the performance of the loader in certain conditions.

Figure 4 shows the loader rate in the four scenarios under which the loader was assessed. Loading lorries resulted in the maximum rate of 23.1 t/h due to the manoeuvres made by the lorry driver to facilitate accomplishing the loading cycle in shorter time. Simultaneous loading of railway wagons resulted in a loading rate of about 22 t/h due to the continuous loader operation. The rate of
loading an individual decauvelle wagon was much higher than the continuous rate computed for the operational day. The loader loses a lot of time, change arrangement, location and people that largely reduced loading rate to be 17.1 t/h.

The loading rate for decauvelle wagons on portable slide or tractor-trailers in the field was as low as 13 t/h.

Figure 4—Comparison loader rate.

Figure 5 shows loader efficiency for the four scenarios under which the loader was assessed. The large store is a yard at which the farmers bring their cane to be loaded on the main transport vehicle.

When the loader has finished loading a lorry, the loaded vehicle needs to turn around and leave.

Shifting from one lorry to another represents an inefficiency in the process. Efficiency of loading lorries in a large store was found to be about 75%.

Loading railway wagons simultaneously may represent the most suitable conditions for maximising loader efficiency.

The trial included 12 railway wagons in one station. Each farmer is assigned a wagon and he piles his cane in a windrow opposite to his wagon. Twelve tractor trailers each belong to a farmer supply cane from fields.

The loaders start loading a wagon and, when the cane for a wagon is loaded, the operator shifts to another wagon. Efficiency of loading railway wagons was as high as 81%.

Due to the time taken in travelling from one store to another, the loader efficiency of loading vehicles in several stores was limited to about 61%.

Due to difficult field conditions, the loader efficiency of infield loading was the lowest of all operations (54%).
Figure 6 shows cane collection efficiency in the four scenarios. The efficiency determined represents the cane damaged with the loader wheel in the store yard or that lost in the field. Cane losses recorded were 0.8%, 0.7%, 0.6% and 1.1% for loading lorries, railway wagons, decauvelle and infield loading respectively. Corresponding collection efficiencies were 99.2%, 99.3%, 99.4% and 98.9%. It seems that the rough surface of the field contributed more scattered cane and less collection by the labour.
Conclusion

Mechanical loading of sugarcane in the Nile Valley in Upper Egypt is required to substitute for the decreasing availability of labourers for manual loading. Farmers have been striving to increase the number of loaders available. Practical procedures can be developed which facilitate the operation of cane loaders at increased efficiency and productivity. Operational strategies which facilitate profitable operation of cane loaders will lead to a significant increase in the proportion of the crop which is mechanically loaded. The following items may represent some of the possible procedures to secure applicable efficiency of loader operation:

1. Loaders should be operated in conditions that facilitate reasonable efficiency, such as:
   a) At railway cane trans-loading sites. Operating loaders in such sites should attract more farmers to request cane transportation by railway. Consequently, more wagons would be loaded at each trans-loading site, increasing loader operation hours per day. Efficiency would be improved and cane delivery delay reduced.
   b) At large trans-loading sites (cane loading stations) such as at government farms, sugar company farms and private large farms.
   c) At farms belonging to strong cooperatives that may force their members to act as one large farm to facilitate mechanisation of such operations.

2. Efforts should be exerted to gradually adjust scheduled date of harvesting as well as the determined harvest allocation for each cane plot area. In this case, each cane growing plot will represent a large farm where a large temporary trans-loading site could be established with no reduction of infield transport rate. Early success of such a strategy is expected, since farmers have been striving for mechanical loading. Management of cooperatives and mill administration can also use their influence to convince farmers to change and optimise allocation of harvesting units to fields and harvesting dates.

3. Gradual adjustments to a common date of harvesting for neighbouring fields could be applied through the cane delivery schedules prepared annually by the mill administration.

4. Avoiding operating a loader for loading single vehicles, or at small trans-loading sites which are distributed far from each other.

5. Avoid infield mechanical loading unless the irrigation system has been developed to reduce intensive furrows, channels and transverse ridges. A system of harvesting that results in uniform windrowing or piling of cane after harvesting may help to improving infield loader efficiency.

MOTS CLES: Chargement Cannes Entières, Efficience du Chargeur de Canne, Systèmes de Transport Canne à Sucre, Planification de Récolte.

LA ZONE de culture de la canne le long de la vallée du Nil dans la Haute Egypte s’est étendue. Les parcelles des agriculteurs sont restreintes, typiquement dans une gamme de 0.5 à 1 hectare. Le planning de livraison de la canne et donc la date de récolte pour chaque champ dépend principalement du quota de livraison et de la date de la récolte précédente. La direction de l’usine attribue une unité de transport (cellule motrice principale) à chaque agriculteur en se basant sur le planning. Les agriculteurs récoltent et transportent la canne de l’intérieur des champs (avec une remorque attelée à un tracteur) vers des zones de transfert où les cellules motrices principales sont chargées. L’efficience du chargement peut être faible suite au temps perdu pendant le transport entre zones de transfert. Afin d’obtenir une efficience raisonnable du chargeur, les zones de transfert peuvent être fusionnées permettant ainsi une meilleure utilisation des chargeurs. Cette procédure peut augmenter la distance de transport à l’intérieur des champs, ce qui pourrait réduire la fréquence de livraison, contribuant ainsi à des délais de livraison accrus. Les agriculteurs pourraient avoir à transporter le jour précédent, une partie du chargement de la cellule motrice principale vers la zone de transfert afin d’assurer l’opération continue du chargeur. Dans cette étude, l’efficience du chargeur, la fréquence de chargement, le pourcentage des voyages des cellules motrices principales retardés plus de 24 heures ainsi que l’efficience du ramassage de canne ont été déterminés. Dans la plupart des cas, une cellule motrice principale est attribuée à chaque agriculteur et une remorque attelée à un tracteur est utilisée pour transférer la canne de l’intérieur du champ vers la zone de transfert. Les résultats montrent que l’efficience totale du chargeur était de 75% pour le chargement de camions dans une grande zone de transfert et de 81% dans le cas de wagons de chemin de fer chargés à une station. L’efficience moyenne totale du chargeur était de 61% pour le chargement de wagons ‘decauvelle’ distribués dans plusieurs zones de transfert dans la même région de production. L’efficience du chargement au champ des remorques attelées au tracteur était de 54%. Une efficience maximale était obtenue si le chargeur travaille toute la journée dans une seule zone de transfert. L’efficience du ramassage de la canne était variable pour les différentes conditions d’opération. Le pourcentage de canne retardé plus de 24 h fut aussi estimé. De grandes zones de transfert où les camions sont chargés de canne et des stations de chargement pour les wagons de chemin de fer pourraient offrir des conditions plus optimales pour l’opération du chargeur. Ce papier discute de l’efficience de l’opération du chargeur sous une gamme de conditions variables et le retard à la livraison qui en découle. Les résultats soulignent le rôle de l’efficience de l’opération du chargeur comme facteur déterminant l’adoption du chargement mécanique de la canne à sucre. Des recommandations pour une opération adéquate du chargeur de canne sont suggérées.
EFICIENCIA DEL CARGUE MECÁNICO DE CAÑA EN EGIPTO

PALABRAS CLAVE: Cargue de Caña Entera, Eficiencia del Cargador de Caña, Sistemas de Transporte De Caña de Azúcar, Programación de La Cosecha.

Resumen
El área de cultivo de caña a lo largo del valle del Nilo en el Alto Egipto se ha ampliado. El área de las unidades de producción es pequeña, normalmente entre 0.5 a 1 hectárea. Los plazos de entrega de caña y, en consecuencia las fechas de recolección para cada campo dependen principalmente de la asignación de entrega y la fecha de cosecha de la temporada pasada. La administración del ingenio asigna un vehículo de transporte (vehículo principal) para cada agricultor en función de la programación. El agricultor/es cosechan y transportan la caña desde los campos interno/s (usando remolques tirados por tractor) a los sitios de almacenamiento temporal en los que el vehículo principal/es es cargado. La eficiencia del cargue puede ser baja debido a pérdidas de tiempo asociadas con los viajes de un sitio de almacenamiento a otro. Para alcanzar una eficiencia razonable del cargador, los sitios de almacenamiento deberían estar centralizados de manera que permitan una mayor utilización de los cargadores. Este procedimiento puede aumentar la distancia de transporte interno, lo que puede reducir la tasa de abastecimiento de caña desde los campos, lo que a su vez contribuiría a incrementos en la demora en la entrega de caña. Para garantizar la operación continua del cargador, los agricultores pueden tener que transportar una parte de la carga del vehículo principal al sitio de almacenamiento desde el día anterior para garantizar la operación continua del cargador. En este estudio la eficiencia del cargador, la tasa de carga, el porcentaje de vehículo/s principales o carga/s retrasados más de 24 horas y la eficiencia de recolección de caña fueron estudiados. En la mayoría de los casos, un vehículo principal se asigna a cada agricultor, donde un remolque tirado por tractor, se utiliza para transferir la caña desde el interior del campo hasta la zona de almacenamiento. Los resultados muestran que la eficiencia total del cargador fue del 75% en el caso de camiones de carga en una gran zona de almacenamiento y 81% en el caso de vagones de ferrocarril cargados en una estación. El promedio de la eficiencia total de la cargadora fue de 61% cuando cargó vagones de carga decauvelle distribuidos en varias zonas de almacenamiento dentro de la misma región de producción. La eficiencia de carga de remolques de tractor en el campo fue del 54%. Se observó que se alcanzará la máxima eficiencia si el cargador trabaja el día operativo completo en un área de almacenamiento. La eficiencia de recolección de caña fue variable en condiciones de funcionamiento variables. El porcentaje de la caña con retrasos superiores a 24 horas también fue estimado. Grandes zonas de almacenamiento temporal en las que los camiones son cargados con caña, y estaciones de carga de caña en vagones de ferrocarril pueden representar las condiciones óptimas para el funcionamiento del cargador. El documento analiza la eficacia de la operación del cargador en virtud de una serie de condiciones variables, y en relación con la demora en la entrega de caña. Los resultados destacan el papel de la eficiencia de operación del cargador como un factor determinante de la adopción de cargue mecánico de la caña de azúcar. Se hacen recomendaciones para el buen funcionamiento del cargador de caña.
OPTIMAL USE OF BIOMASS IN AN ISOLATED ENVIRONMENT: CASE STUDY AT MIYAKO ISLAND, JAPAN

KEYWORDS: Biomass, Refinery System, Conversion.

Abstract

This paper briefly outlines an ongoing research project and some research outcomes focusing on sugarcane. Five research topics were identified, namely 1) development of technologies for farmland application of converted biomass from sugarcane molasses such as compost, char, digestive slurry and vinasse, 2) clarification of optimal allocation of biomass and optimal operational conditions for conversion plants, 3) development of groundwater conservation technologies with biomass, mainly focusing on nitrogen, 4) development of technologies for introduction of energy crops and optimal CO₂ gas application to crops, and 5) clarification of favourable conditions for sugar-ethanol by-production systems using greater-biomass sugarcane. Our target biomasses are bagasse and cattle wastes. Five conversion plants, including two pyrolysis, one composting, one bio-gas and one gasification, have already been installed to properly and effectively convert biomass. Farmland application technologies for char and digestive slurry with bagasse have mainly been studied. Secondly, vinasse (bio-ethanol by-product; distilled residue) is another biomass target. We analysed vinasse for return of by-products back to the farmland as a way to achieve sustainability and devote efforts to the application of vinasse to farmland. Of course, safety to crops, the soil and water environment should be confirmed first. Previous experiments revealed vinasse does not have bad impacts on crop growth. Thirdly, we conducted studies to clarify the favourable conditions for introduction of greater biomass sugarcane to develop sugar-ethanol by-production systems. A favourable new variety of sugarcane was previously selected. In addition, a sugar-yield equation for great-biomass sugarcane was developed from observed data.

Introduction

Background

Japan produces an average of about 1 million tonnes of sugarcane each year. Approximately 30% of this is produced on Miyako Island in southern Japan, 1500 km from the capital Tokyo. On this island, agriculture is the major industry followed by tourism. Sugarcane is the major crop on the island with beef cattle breeding as the next most important agricultural activity.

Recently, bio-ethanol production from sugarcane molasses has been supported by the Ministry of Environment (MOE) of Japan as a special project, called ‘E3 Project’ on Miyako Island. The aim was for an integrated project, with sugarcane as the feedstock for ethanol and all by products from all industries would be returned back to the farmland to achieve sustainability. This meant that the by-products of the bio-ethanol manufacturing process were to be applied back on the fields, providing the safety of the materials could be completely assured, i.e. an absence of hazardous materials such as heavy metals, poisonous materials, etc.

Objectives

The Ministry of Agriculture, Forestry and Fisheries (MAFF) of Japan has supported this project named ‘Rural Biomass Research Project, Biomass utilisation model, Cm6000’ for
approximately three years, commencing 2007. In this paper, the framework of the research project and some outcomes and their use are discussed.

**Methodology**

Miyako Island is located in southern Japan, and was selected as the appropriate site for the project. The total area of the island is about 140 km² and the population was approximately 47 000 as of January 2001. Fifty two percent of the area is farmland. The maximum elevation on the island is only 114.6 m, land is geo-physically almost flat and there are no big rivers. The climate is semi-tropical (average temperature 23°C, average humidity 80%) with an annual precipitation of 2400 mm. Most of this precipitation is brought by typhoons and residents suffer from occasional droughts.

Agriculture is the major industry, with sugarcane production alone averaging 300 000 tonnes annually, which accounts for almost 30% of the total Japanese sugarcane production. Tobacco, vegetables and beef are also produced, but almost all other food products are imported from mainland Japan and other islands in the Okinawa region.

The main crops and typical annual biomass production for each of the islands are listed in Table 1.

The soil on the island is almost neutral or alkaline and has a loamy texture (Shimajiri Maji-soil). Maji soil has a high clay content but relatively high permeability (10⁻⁴ cm/s). Because there are almost no mountains, the major water resource is groundwater. The island residents are concerned about the groundwater, not only its quantity but also its quality. Some sub-surface dams were constructed in the 1990s as a national irrigation project to effectively use the groundwater. After construction of sub-surface dams, farmers became enthusiastic about commercial and intensive agriculture.

The outcome of increased availability of water was that farmers attempted to increase productivity and increased the use of chemical fertilisers. This resulted in worsening of the groundwater quality. More recently, many farmers are attempting to reduce the amount of chemical fertilisers they apply and, in addition, they are compelled to properly manage livestock wastes (manure).

The target waste biomass for this project was determined to be sugarcane bagasse and cattle waste, as they are the two types of biomass available in large amounts. According to the Miyakojima Biomass Town Plan (2003), these two biomasses account for about 80% of the total amount of the whole island with a dry weight mass equal to 50 000 tonnes of carbon (C) each year on the island.

**Project strategies**

The Rural Biomass Research Project, Biomass Utilisation Model focused on five research topics, namely:
1) Development of reuse technologies for converted biomass and vinasse from bio-ethanol production,
2) Defining optimal operational conditions for the biomass conversion facilities,
3) Development of technologies for protection of groundwater from contamination with agricultural wastes,
4) Introduction of energy crops taking into consideration sustainability,
5) Determination of installation conditions for larger biomass-sugarcane to develop sugar-ethanol by-production systems.

Pilot (test) scale conversion facilities, namely two pyrolysis systems, one bio-gas system, one gasification system and one composting system, have already been installed on the island (Figure 1). We can obtain energy and materials (charcoal, acid vinegar, anaerobic digestive slurry, compost) after conversion of biomass from these facilities. We hope to apply the materials recovered from the biomass to farmland for sustainable agriculture and to increase productivity. In addition, we hope to develop technology enabling the reuse of the vinasse, a by product of bio-ethanol production. The conversion facilities should be thought as one system. Each conversion facility should link with energy and materials already used. It is necessary for us to operate the conversion ‘systems’ optimally. How shall we achieve this, taking into consideration environmental issues? What is the best way to allocate biomass among the facilities?

On the island, groundwater is a unique water resource and it is crucial for residents that the quality of groundwater is conserved. Chemical fertilisers and cattle wastes are the main sources of nitrogen pollution of groundwater sources on the island (Fujie Rie et al., 2008)). We need to achieve water quality conservation technologies with biomass. For example, charcoal from bagasse can absorb nitrate nitrogen, reported as one of the crucial contaminants of the groundwater. The question is how to reduce contamination of the water with biomass? We need to develop technologies and scenarios.

At this point in time, sugarcane molasses is the only feedstock for bio-ethanol production. We hope to propose additional energy crops to allow the conversion facilities to operate as optimally as possible throughout the year.

From the agricultural side, it is necessary to optimise the soil and water to achieve sustainability. Sweet sorghum, sweet potatoes and cassava are favourable crops we anticipate
introducing. The issue is how to introduce these crops, taking into consideration the sustainability issue of nutrient management based on traditional agricultural machinery systems. Farmers expect additional economic benefits from growing these crops.

An additional consideration is that CO₂ is obtained from various conversion processes. While CO₂ is one GHG (Green House Gas), it is also necessary for crop photosynthesis and production. Is it possible to increase productivity with CO₂ application to crops from the conversion process?

The final consideration is that high-biomass sugarcanes have been developed by our group (National Agricultural Research Center of Kyushu-Okinawa; NARCKY). We hope to use these canes as the basis for a sugar-ethanol production system, with the strategies being developed for the introduction of the system.

This research project has been carried out by researchers at (NIRE), NARCKY, University of Ryukyu, Okinawa Agricultural Research Center, Non Profitable Organisations, Semi-tropic Biomass Use Research Center and Asahi Breweries Ltd. as well as scientists from various other research fields. In the NPOs, many members are from private companies in Japan. We have been exchanging various kinds of information among central (Ministry of Cabinet) and provincial governments (namely Prefecture of Okinawa and Miyakojima City). This research project is achieved by industries, institutes and governments.

**Main research outcomes**

The project is now over half way through its life, and some outcomes have already been reported in domestic publications, as well as at various domestic and international technical meetings. Outcomes to date have included:

**Nitrate nitrogen loads from chemical fertilisers and cattle wastes (Fujie Rie et al., 2008)**

Nitrate nitrogen is a major contributor to groundwater contamination on the island. The main agricultural nitrogen resources are chemical fertiliser (applied to farmland) and improper cattle waste management (Miyakojima Biomass Town Paper).

![Fig. 2—Nitrate nitrogen loads at Sunagawa groundwater-basin in 1977, 1994 and 2005, respectively (Fujie Rie et al., 2008)](image)

Parameters relating to cropping and agriculture in the Sunagawa Groundwater Basin on the Island were defined and entered into a database using GIS. A DeNitrification and DeComposition (DNDC) model was used to estimate the leached nitrate nitrogen from the soil associated with each crop. The estimates were used in the database to estimate the amount of nitrate nitrogen leached throughout the basin. The cropping conditions for each year studied were entered in a database, using GIS to properly identify changes.

Figure 2 shows the calculated results of leached nitrate nitrogen in 1977, 1994 and 2005, respectively. The estimations indicate that the leached nitrate nitrogen fluctuates with changes in land use and agricultural parameters such as chemical fertiliser application amount and type of crop.
Calculations of nitrogen concentrations in percolated water indicate that nitrogen can quantitatively explain the changes in groundwater quality. We can, therefore, quantify the contamination load from agriculture.

In the future, trial calculations of leached nitrate nitrogen based on various cropping conditions and agricultural performances will be carried out and applied as a basin-level management method to manage agricultural activities while considering groundwater conservation.

1) **Impacts of farmland application of converted biomass**

Anaerobic digested slurry and charcoal from bagasse were applied to farmland to assess the impact on crop growth, which was assessed from both plots and field lysimeters (Chen Yan and Shinogi Yoshiyuki, 2007; Chen Yan et al., 2007; Chen Yan and Shinogi Yoshiyuki, 2005).

Application of charcoal from bagasse increased the production of sugarcane and other vegetables. It improved the root-zone soil physical properties by improving soil-water holding capacity and permeability, as well as other parameters, with the improvements continuing for at least 55 months after application. In addition, charcoal absorbed nitrate nitrogen and application of charcoal from bagasse reduced nitrate nitrogen loads to the groundwater. Therefore, charcoal from bagasse may be used to reduce the bad impact of agriculture.

In other trials, digestive slurry reduces the amount of chemical fertiliser that needs to be applied by about 30%.

**Development of vinasse use technology**

</tbody>
</table>

The main characteristics of vinasse from sugarcane molasses are reported to be 1) high organic matter, 2) high COD and BOD, 3) black-colour, 4) highly acidic. The basic characteristics are shown in Table 2. Sugarcane molasses is produced from just sugarcane so there are not likely to be hazardous materials. Preliminary tests, including incubation tests, were carried out to assess the implications of farmland application. The results indicated no negative impacts on crop production. Providing the impacts on the environment, mainly groundwater contamination are monitored, it may be possible to apply vinasse to farmland. Because of the high viscosity of vinasse, it is believed that it does not percolate deeply, allowing effective use by plants. Further research is needed to confirm this.

**Other kinds of outcomes on sugarcane**

High-biomass sugarcane was developed by our group, and initial larger scale trials have been carried out. Indications are that these sugarcanes have almost the same Brix (13–16%) as other great-biomass canes, and similar to traditional commercial sucrose varieties. These sugarcanes not only produce more sugar but also higher biomass.

In addition to establishing a sugar-ethanol by-production system, our group developed an equation called Commercial Cane Sugar at n-times Crystallisation (CCSₙ) from data collected in the laboratory. This enables us to easily estimate CCS.

**Perspectives and conclusions**

Research outcomes have been presented locally, nationally and internationally. In addition, our research projects aim to achieve real action plans and outcomes. We therefore actively communicate information to all levels of government. How can these research outcomes be utilised and, based on them, how will the residents proceed with actual action plans? The most important thing for us is the creation of real business models that use biomass on the island.

In this fiscal year, we hope to publish a manual for the application of converted biomass to farmland. In addition, we expect to transfer some research outputs to existing technologies. For
example, development of CO$_2$ application technology from the conversion facilities is expected. Proper assessment of the impacts of biomass use should also be completed. To accomplish this, integrated evaluation technologies based on the actual data and calculation tools such as Life Cycle Assessment (LCA) are necessary. Further research is required and special efforts made to approach and achieve these goals.

Résumé
Ce papier décrit brièvement un projet de recherche en cours et quelques résultats de recherches sur la canne à sucre. Cinq sujets de recherche ont été identifiés, notamment 1) le développement de technologies pour l’application biomasses converties de la mélassé de canne à sucre, tels le compost, la cendre, le lisier et la vinasse sur les terres cultivées. 2) La clarification de l’allocation optimale de biomasse et des conditions d’opération optimales pour les usine de conversion. 3) Développement de technologies de conservation de l’eau souterraine avec la biomasse, avec emphase sur l’azote. 4) Développement de technologies pour l’introduction des cultures d’énergie et d’application optimale de CO₂ gazeuse aux cultures. 5) Clarification des conditions favorables pour la production simultanée de sucre et d’éthanol en utilisant la canne à sucre a fort biomasse. Nos biomasses cibles sont la bagasse et les déchets d’élevage. Cinq usines de conversion, incluant deux par pyrolyse, une de compostage, une de biogaz et une de gazéification ont déjà été installées afin de convertir correctement et efficacement la biomasse. Deuxièmement, la vinasse (sous-produit de bio-éthanol, résidu de distillation) est une autre cible de biomasse. Nous avons analysé la vinasse pour le retour des sous-produits à la terre cultivée comme un moyen d’atteindre la durabilité et avons consacré nos efforts à l’application de la vinasse à la terre arable. Bien sûr, la sécurité aux cultures, à l’environnement du sol et de l’eau doivent d’abord être confirmés. Les essais précédents ont démontré que la vinasse n’a pas d’effet négatif sur le développement de la culture. Troisièmement, nous avons mené des études afin de clarifier les conditions favorables pour l’introduction de canne à sucre à fort biomasse pour développer les systèmes de production sucre-éthanol. Une nouvelle variété de canne à sucre favorable fut préalablement sélectionnée. De plus, une équation de rendement sucre pour la canne à fort biomasse fut développé à partir des données observées.

Resumen

ESTE DOCUMENTO describe brevemente un proyecto de investigación en curso y algunos resultados de investigación en caña de azúcar. Fueron identificados cinco temas de investigación, a saber: 1) desarrollo de tecnologías para la aplicación en tierras agrícolas de biomasa procesada a partir de melazas de caña de azúcar tales como: compost, char, purines digestivos y vinazas, 2) definir la localización y condiciones operacionales óptimas de las plantas de conversión de biomasa, 3) desarrollo de tecnologías de conservación de aguas subterráneas basadas el uso de biomasa y enfocadas principalmente en nitrógeno, 4) desarrollo de tecnologías para la introducción de cultivos energéticos y aplicación óptima de CO2 gaseoso a los cultivos, y 5) definición de las condiciones adecuadas para que los sistemas de producción dual azúcar-etanol usen una alta proporción de la biomasa de la caña de azúcar. Nuestra biomasa objetivo son el bagazo y los excrementos vacunos. Cinco plantas de conversión, entre ellas dos de pirólisis, una de compostaje, una de bio-gas y una de gasificación, ya han sido instaladas para realizar una efectiva y apropiada conversión de la biomasa. Se han estudiado principalmente tecnologías de aplicación de char y purines digestivos con bagazo a tierras agrícolas. El segundo lugar lo ocupa la vinaza (sub-producto del bio-etanol; residuo de la destilación) que es otro objetivo de uso de biomasa. Analizamos el retorno de la vinaza a las tierras de cultivo como una forma de lograr la sostenibilidad y dedicar esfuerzos a su aplicación en tierras agrícolas. Por supuesto, la seguridad para los cultivos, para el ambiente edáfico y acuático debe ser confirmada primero. Experimentos anteriores revelaron que la vinaza no tiene impactos negativos en el crecimiento de los cultivos. En tercer lugar, llevamos a cabo estudios para caracterizar las condiciones favorables para la introducción de caña de azúcar con mayor producción de biomasa para desarrollar sistemas duales para la elaboración de azúcar-etanol de caña. Previamente se seleccionó una nueva variedad de caña de azúcar. Adicionalmente, a partir de datos observados se desarrolló una ecuación de rendimiento de azúcar para caña de azúcar de alta producción de biomasa.
SOIL MOISTURE GROUPS FOR SUGARCANE MANAGEMENT

By

J.S. TORRES and J.R. CRUZ

Colombian Sugarcane Research Center, Cenicâna

jt Torres@cenicana.org

KEYWORDS: Soil, Moisture, Drainage, Permeability, Cane Management.

Abstract

CANE YIELD in Colombia is normally lower after wet years due to increased damage associated with harvest and the difficulty of post-harvest cultivation. The magnitude of the problem is impacted on by soil characteristics. To identify fields or areas requiring emphasis on irrigation or drainage and for the development of agronomic management packages, soil moisture management groups have been developed. The definition of soil moisture management groups is based on the annual balance between precipitation at 75% frequency level and soil permeability. The precipitation records from the sugarcane automatic weather network and the information from a recent detailed study of the soils of the Cauca River Valley of Colombia have been combined using the geographical information system to generate the spatial distribution of the soil moisture groups. Five groups were defined on the basis of the expected annual excess or deficit of water for sugarcane: A first group with a water deficit, a second group with an excess of water ranging from 0 to 200 mm/year, a third group with an excess of 200 to 400 mm/year, a fourth group with an excess of 400 to 600 mm/year and a fifth group with an excess of water greater than 600 mm/year. These moisture groups have been used as a backbone for the agro-ecological zoning system of the sugarcane in the Cauca Valley of Colombia. The Colombian sugar industry is committed to use a site specific agriculture approach based on the combination of the production factors on each cane field.

Introduction

The productivity of the Colombian sugar industry largely depends upon climatic conditions prevalent during crop establishment, harvesting and the first stage of ratoon crop development. Murrell and Childs (2000) indicated that it is necessary to identify the factors limiting production that can be controlled.

Critical values according to predominant environmental conditions should also be set. In wet years, those areas with heavy soils and low infiltration capacity are prone to water logging and cultural practices can not be executed on time; therefore, the expected cane yield is low.

Excessive moisture produces anaerobic conditions in the soil, reduced root respiration, demineralisation of nitrogen and poor crop growth affecting adversely the final cane and sugar yield. In flooded terrain or with high water table, the number of working days for land preparation or ratooning practices is reduced. If a crop is not established in time, it may result in a crop with increased production costs and reduced yield.

Experiments conducted by Cenicaña (1991) using percolating type lysimeters depicted a yield reduction of 35 t/ha when the static water table was maintained at 70 cm below the soil surface. If soil moisture excess occurs during land preparation, planting or harvesting, all these practices should be delayed; otherwise soil compaction, stool damage and poor cane germination/regrowth are expected, increasing production cost if replanting is necessary.
A macro analysis of cane and sugar production in the Cauca River Valley (Cenicaña, 1996) for the period 1991 to 1995 showed that cane production in most of the sugar mills in the years 1994 and 1995 were negatively affected by high precipitations that occurred during the three first months of crop development, or by the rainfall events during the last month of the previous crop cycle. When rainfall events happened during the first stage of crop development, fertilisation and/or ratooning tasks could not be executed on time or efficiently. Intensive rainfall events during the harvest of the previous crop resulted in excessive soil moisture that hampered the traffic of the harvesting machinery, inducing soil compaction and cane stool damage.

According to commercial production data from the Cauca River Valley in Colombia, it is clear that dry years are ideal for cane and sugar production. This is a result of both the availability and adequacy of the existing irrigation infrastructure, and the opportunity for more efficient and timely execution of cultural practices under dry conditions. Harvesting in wet conditions usually results in fields affected by direct stool damage, soil compaction and surface deformation. In some cases, field damage is so serious that remedial cultivation is in order to maintain crop productivity, but persistent rainfall events cause postponement of the remedial practices, resulting in idle or ‘forced fallow’ fields.

Weather conditions which make it difficult to execute cultural practices or harvesting due to excessive soil moisture have become more common, especially with the increasing presence of the El Niño phenomenon. It is therefore necessary to adopt strategies for optimum management of the cane fields under these conditions.

This study was undertaken to group the soils of the Cauca River Valley according to their ability to transmit water after a heavy rainfall event, and subsequently generate management guidelines to decrease the impact of excessive soil moisture on cane production.

**Methodology**

Field observations of the interaction between soil permeability and rainfall demonstrated that a very permeable soil will dry out quite rapidly after a heavy rainfall event, due to the high water transmitting or infiltration capacity. This characteristic allows the execution of cultural practices, or entry to the field with harvesting machinery a few hours after the rainfall. On the other hand, low permeability soils will remain wet after a light rainfall event, and there is a possibility of surface flooding after intense rainfall.

Initially, the reasoning used to develop soil moisture groups was based on the balance between the expected annual rainfall at 75% probability level, and the total annual evapo-transpiration (ET) calculated using boom stage values.

The amount of annual deficit or excess of water was established and compared with the permeability of the soil according to the matrix presented in Table 1. Six regions were demarcated within the matrix that correspond to six soil moisture groups identified as H0, H1, H2, H3, H4 and H5.

Table 1—Definition of soil moisture group regions based on the interaction between water excesses and soil permeability.
Field inspections of the prevailing soil moisture conditions at 84 observation sites distributed along and across the Cauca River Valley indicated the necessity to include other parameters. The parameters selected modified the impact of soil moisture on plant growth, and included: land slope, depth to the water table, soil colour and the presence of artificial drainage installations.

In order to adjust the soil moisture groups according to prevalent local conditions of the cane fields, a logic-based process was developed to adjust the group number according to the severity of the drainage problem induced by each individual factor. A computer program was then developed. This program is available on Cenicaña’s web site (www.cenicana.org) and is used to verify or adjust the predominant soil moisture groups based on site specific conditions.

The main purpose of the soil grouping strategy is to generate basic guidelines to mitigate the impact of soil moisture on crop production. The most basic recommendations compiled for each soil moisture group are:

**H0: Water deficit group**
This group includes zones where there is water deficit and the permeability of the soil ranges from medium to high. It is very likely that salts accumulate in the soil profile, making it necessary to avoid the presence of high water tables. Artificial drainage installation could be required for saline or sodic soil reclamation. Irrigation is essential and a salt leaching fraction should be applied to avoid soil salinity build up.

**H1: Adequate water supply group**
This group consists of those areas where the annual water excess is less than 200 mm/year. Rainfall is sufficient to supply the crop water demand and the soils have medium to high permeability.

Rainfall distribution is not uniform and it is possible to observe some water ponding due to the flat slope of the terrain when the soils have low permeability. Precision land levelling and a minimum hilling up (<10 cm) to facilitate surface water runoff at the bottom of the rows during the rainy periods are advised.

**H2: Low excess water group**
The level of excess soil moisture ranges between 200 and 400 mm/year in soils which have medium to high permeability, as well as soils with low permeability with lower soil moisture excess (<200 mm/year). It is necessary to provide adequate field conditions such as precision land levelling, medium hilling up (10 to 15 cm), and adequate infrastructure for drainage.

**H3: Medium excess water group**
This group covers areas with water excess ranging between 400 to 600 mm/year and soil with medium to high permeability. Soils with low permeability but lower soil moisture excess (200 to 400 mm/year) were also included.

This group requires more intensive work for excess water removal, including land levelling, deep open canal collectors, removal of run off water, if possible, excess water tolerant varieties, application of an extra amount of nitrogen, high hilling up (15 to 20 cm).

**H4: High excess water group**
This group covers areas with water excess above 400 mm/year, with soils of low or high permeability, clay soils and predominance of flat slopes. The furrow length should be less than 120 m, drainage tubing installations combined with the presence of mole drains, open and deep drainage collectors and drainage pumping stations at places where gravity outlets are not available.

High hilling up is considered essential, top of row planting, varieties tolerant to excess water, application of extra nitrogen and harvesting in dry periods.
H5: Very high excess water group

Areas with water excess above 600 mm/year with flat terrain and clay soils with low to medium permeability. In this group, precision land levelling is a must and furrows should be shorter than 100 m. Drainage tubing installations combined with the presence of mole drains, open and deep drainage collectors and drainage pumping stations at places where gravity outlets are not available are also necessary. High hilling up is considered essential, along with top of row planting. Varieties tolerant to excess water and the application of extra nitrogen is recommended. Manual harvesting during dry periods is recommended.

Results and discussion

The information of the soil moisture groups for the Cauca River Valley region was fed into the Geographic Information System (GIS) to obtain maps depicting the spatial distribution and area covered by each soil moisture group (Figure 1).

![Fig. 1—Spatial distribution of the soil moisture groups in the Cauca River Valley of Colombia.](image)

Most of the cultivated area within the sugarcane zone belongs to the moisture groups H0 and H1. This can be considered as a dry zone amounting to 119 025 ha, (58%) of the total of 203 778 ha of land currently planted in the valley. While all the sugar estates have cultivated areas in the dry zone, the agricultural lands of Manuelita, Providencia and Mayaguez sugar estates, which are located in the south central part of the valley, are predominantly in the H0 and H1 groups.
In these areas, in dry years, it is necessary to apply up to six or seven irrigation events per crop cycle of 13 months.

The areas of the soil moisture groups H2 and H3 can be considered a semidry zone. Most of the cane area belongs to Cauca, Cabaña, Castilla and Riopaila sugar estates in this zone, and the total area adds up to 64 300 ha, which is 32% of the total agricultural area. In this zone, there is an annual water excess ranging between 200 to 400 mm of water in the low and medium permeability soils or with a water excess of 600 mm/year in areas with high permeability soils. This semidry zone requires the installation of more artificial drainage infrastructure.

The wettest zone of the valley (H4 and H5 groups) is concentrated in the northern and southern extremes of the Cauca River Valley covering an area of 19 410 ha (10% of the total area); however, this comprises a significant portion of Risaralda, Castilla, Cabaña and Cauca sugar estates. In the wet zone, the annual water excess is above 600 mm/year.

Planting, cultivation and harvesting of the cane is difficult due to high precipitation which in general is above 2000 mm/year. In this region, it is necessary to emphasise drainage development, precision land levelling and a short furrow length. Cane and sugar yields in this area are in general low due to the negative effects of the excess moisture on crop growth and maturity, and the interference with the execution of good cultural practices.

Conclusions

The soil moisture groups presented herein have become an important tool for crop management, selection of experiment sites, identification of the best niches for the new cane varieties, generation of site specific agronomic management packages and, combined with Cenicaña’s soil management groups, have resulted in the agro-ecological zoning system for the sugarcane in the Cauca River Valley of Colombia.

The agro-ecological zones developed by Cenicaña (Carbonell et al., 2001), were presented to the sugar cane industry in 2001 and it has been well accepted by the sugar estates, and individual cane growers; it is a primary input tool for research purposes and for crop management.

**Résumé**

LE RENDEMENT canne en Colombie est normalement plus bas après les années humides suite à l’augmentation des dégâts associés à la récolte and les difficultés des opérations poste-récolte. Les caractéristiques du sol ont un effet sur l’importance du problème. Des groupements de gestion de l’humidité du sol ont été constitués afin d’identifier les champs ou zones nécessitant une emphase sur l’irrigation ou le drainage et pour le développement de packages de gestion agromonique. La définition des groupements de gestion de l’humidité du sol est basée sur la balance annuelle entre les pluies à 75% de niveau de fréquence et la perméabilité du sol. Les relevés de pluie provenant du réseau climatique automatique de la canne à sucre et l’information provenant d’une récente étude détaillée des sols de la vallée de la rivière Cauca de Colombie ont été combinés avec un système d’information géographique pour générer la distribution spatiale des groupements d’humidité. Six groupements ont été définis sur la base de l’excédent ou déficit hydrique annuels attendus pour la canne à sucre : un premier groupement avec un déficit, un second avec un excédent d’eau entre 0 et 200 mm/an, un troisième avec un excédent d’eau entre 200 et 400 mm/an, un quatrième avec un excédent d’eau entre 400 et 600 mm/an et un cinquième avec un excédent d’eau supérieur à 600 mm/an. Ces groupements d’humidité furent utilisés comme ossature pour le zonage du système agro-écologique dans la vallée de Cauca en Colombie. L’industrie sucrière Colombienne est commise à utiliser une approche spécifique de site, basée sur la combinaison des facteurs de production de chaque champ de canne.
GRUPOS DE HUMEDAD PARA EL MANEJO DE LA CAÑA DE AZÚCAR

PALABRAS CLAVE: Suelo, Humedad, Drenaje, Permeabilidad, Manejo de la Caña.

Resumen

EN GENERAL, la producción de caña en Colombia disminuye en los años de mayor precipitación debido a los daños asociados con la cosecha y la dificultad para realizar labores de cultivo después de la cosecha. La magnitud del problema se agudiza de acuerdo con las características del suelo. Para identificar los campos o áreas que requieren énfasis en riego o drenaje y para definir paquetes de manejo agronómico específico por sitio, se desarrollaron los grupos de humedad del suelo, cuya definición se basa en el balance entre la precipitación anual calculada con el 75% de probabilidad y la permeabilidad del suelo. Los registros de precipitación de la red meteorológica automática de la caña de azúcar y la información extractada del reciente estudio detallado de suelos del valle del río Cauca en Colombia se han combinado utilizando el sistema de información geográfico para generar la distribución espacial de los grupos de la humedad del suelo. Se definieron seis grupos de humedad sobre la base del exceso o déficit de humedad anual esperado para la caña de azúcar: El primer grupo de humedad es el que presenta algún déficit de agua para el cultivo de la caña, en el segundo grupo ocurren unos excesos de agua que van desde 0 hasta 200 mm/año, en el tercer grupo los excesos oscilan entre 200 a 400 mm/año, en el cuarto grupo los excesos son de 400 a 600 mm/año y en el quinto grupo los excesos de agua superan los 600 mm/año. Estos grupos de humedad han sido utilizados como base para definir el sistema de zonificación agro-ecológica de la caña de azúcar en el Valle geográfico de río Cauca, Colombia. La agroindustria de la caña en Colombia se ha comprometido a utilizar el enfoque de agricultura específica por sitio basada en la combinación de los factores de producción que intervienen en cada campo sembrado en caña.
DRIP IRRIGATION FREQUENCY FOR SUGARCANE IN THE TROPICS

KEYWORDS: Drip Irrigation, Irrigation Schedule, Water Saving, Sugarcane Production, Colombia.

Abstract
Drip Irrigation was a system initially developed for desert areas where the sandy soils have low water retention capacity and rainfall is limited. In the Cauca river valley, located in south-western Colombia, soils have a high water retention capacity and frequent irrigation results in excess moisture and poor root development, which affects crop development. The frequent application of water in the sugarcane soils of the Cauca River Valley results in excess soil water and little use of natural precipitation. The current study was conducted at the Malimbi Sugarcane Plantation, located in the driest area of the Cauca River Valley where annual precipitation is below 800 mm and soils are loamy to clayey in texture. The effect of irrigation frequency (daily, twice a week, weekly) was studied in drip-irrigated plots. A gravity irrigation system was used as check. In three consecutive cuts (plant crop and two ratoons), sugarcane production in drip-irrigated plots was 160 t/ha with daily irrigation (483 mm water applied), 165 t/ha when irrigated twice a week (356 mm water applied), and 166 t/ha when irrigated weekly (264 mm water applied). Gravity-irrigated cane produced 157 t/ha, with an average of 465 mm water applied. Average precipitation during the three cuts reached 984 mm. Results highlight the importance of taking advantage not only of the soil’s capacity to store available water but also of actual precipitation, scheduling the weekly drip irrigation of sugarcane fields in the Cauca River Valley without adversely affecting cane production.

Introduction
Given the shortage of water for irrigation and the increasing irrigation fees in the Cauca River Valley, located in south-western Colombia, sugarcane producers are now considering the possibility of investing in drip irrigation. They are, however, concerned because, in the past, they have had problems with hoses and emitters clogging up because of the build-up of iron and manganese (Franco et al., 1984) and because of the severe damage to hoses caused by harvest equipment (Cenicaña, 1984).

In parts of the sugarcane production areas where annual precipitation is below 1000 mm, the water supply is from deep wells drilled more than 15 years ago. Current flows from these wells range between 40–50 L/sec. These low flows are not sufficient to apply gravity irrigation, which uses a flow of more than 60 L/s. The dilemma arises whether to invest in the building of new wells that could yield more than 60 L/s, at a cost of US $125 000 each, or to invest in drip irrigation to take advantage of the low flow of existing wells.

In 2003, a preliminary drip irrigation trial was conducted at the La Josepilla Sugarcane Plantation, located in a low-rainfall area (700 mm/year) of the Cauca River Valley where irrigation...
requirements are high and the availability of irrigation water is low (wells producing 40 L/sec). Trials consisted of three planting systems (two with double furrows and one with single furrows), two distances between emitters (0.5 and 0.7 m), and two emitter flows (1.2 and 1.6 L/h). While the water volumes used in drip irrigation were 48% less than those used in gravity irrigation, the production of drip-irrigated cane was 20–60 t/ha higher than that of furrow-irrigated cane. The results of the preliminary trial carried out at the La Josepilla Sugarcane Plantation cannot be extrapolated to other areas because of the many mixed variables including planting configuration, spacing between emitters, emitter flows, fertiliser application rates and varieties. Therefore, in 2005, a new collaborative experiment was carried out by Cenicaña and the Malimbú Sugarcane Plantation, using emitters spaced at 0.5 m with a flow of 1.6 L/hour, three irrigation frequencies, and two planting arrangements (double and single furrows).

Materials and methods

The experimental site is representative of the driest area of the Cauca River Valley, with an average annual precipitation of 800 mm and two soil types: Rio Paila (Fluventic Haplustolls, coarse loam texture) and Manuelita (Fluventic Haplustolls, fine loam texture), both characterised as being deep, well drained, and very fertile.

A split-plot experimental design was used with the irrigation frequency treatment assigned to the main plot and the spacing between furrows to the subplot.

The following irrigation frequencies were evaluated: (1) daily; (2) twice a week; and (3) weekly. Spacing between furrows was as follows:

1. single furrow at 1.75 m;
2. double furrow with 2.6 m between pairs and 0.6 m between furrows; and
3. double furrow with 2.4 m between pairs and 0.4 m between furrows.

The check was a gravity-irrigated lot planted to sugarcane variety CC 85-92 spaced at 1.75 m. Irrigation was scheduled using the water balance method, with a K factor of 0.3 when the crop was 2–4 months old and one of 0.7 when the crop was 4–10 months old.

Forty soil samples were collected using an auger up to a depth of 1.2 m. To describe the soil profile, two sampling pits were dug and samples were collected to determine the soil’s chemical and physical properties. Based on the chemical analysis of the soil, the recommended fertilisation for the plant crop was 80 kg N, 90 kg K₂O, and 7.5 kg Fe/ha.

Once soil preparation activities were completed, the drip irrigation system was installed. The system consists of a filter-and-control station where water is taken directly from a deep well and passed through a hydro cyclone filter, a gravel filter, and two ring filters. Fertilisation equipment consists of a 1.9 cm Venturi injector with a regulator and three 2000-L plastic tanks to mix the soluble fertilisers (N, P, K). Four control valves were installed in the field. These valves can be controlled by hand from the station and also by an automatic timer. The principal pipeline consists of a PVC tube, 10 and 8 cm in diameter, to which lateral hoses (internal diameter of 1.6 cm) are connected after. Emitters are located along these lateral hoses with a water flow of 1.6 L/hour.

The crop was planted on 3 August 2005 and, because the drip irrigation system had not yet been fully installed, sprinkler irrigation was performed immediately, applying a 45-mm water sheet, to enhance crop germination. During crop development, agronomic evaluations were made at 2, 4, 6, 8, and 10 months and then again at harvest.

Results and discussion

In the plant crop, drip-irrigated cane (variety CC 85-92) produced, on average, 162 t/ha, whereas the gravity-irrigated check produced 154 t/ha, a difference of 8 t/ha in favour of drip irrigation (Table 1). As previously noted, in the drip irrigation experimental field, the first germination irrigation was applied by sprinkling because at that time the drip irrigation system had not yet been fully installed. The initial population in the drip-irrigated field was lower than that of...
the gravity-irrigated check because the germination irrigation by sprinkling was deficient—several areas presented water deficit and, at other sites, the water swept the seed away because of disconnections in the pipeline.

No significant differences were observed in other production indices—sugar yield, sugar production, tonnes of cane per hectare-month (TCHM), and tonnes of sugar per hectare-month (TAHM)—in relation to the irrigation system (drip versus gravity).

The distribution of monthly precipitation between months two and nine of the cane crop (Figure 1) was satisfactory and, as a result, only one event of gravity irrigation (148 mm) was required during crop growth.

The number of irrigations in the case of drip irrigation was high: 63 for daily irrigation and 16 for twice-a-week irrigation. In the case of drip irrigation applied daily, the total water application was 319 mm, which was more than double (115%) that of gravity irrigation whereas, with the twice-a-week frequency, the total water application was 207 mm, 40% more than with gravity.
irrigation. In the case of the ratoons, the decision was made to test weekly drip irrigation to take advantage of the rains and the soil’s water retention capacity.

In plant crops, the application of fertilisers using the drip irrigation system (fertigation) was carried out regardless of the irrigation schedule, which increased water consumption between 12% and 18%. For the first ratoon, fertilisation was synchronised with the drip irrigation schedule to avoid additional water use.

In the first ratoon, grown between 22 September 2006 and 2 October 2007 (12.3 months), the yield of drip-irrigated cane variety CC 85-92 was, on average, 147 t/ha, whereas the gravity-irrigated check yielded 150 t/ha, indicating that there was no significant differences in yield between drip irrigation and gravity irrigation (Table 1). Regarding the other production indexes (sugar yield, sugar production, TCHM, and TAHM), no significant differences were observed in relation to the irrigation system (drip versus gravity). It should be mentioned, however, that the skids of the lifters caused severe damage to the stools in drip-irrigated fields during the harvesting of the plant crop, especially in double-furrow planting. As a result, there was extensive replanting to replace the cane population.

The monthly precipitation during the first ratoon was deficient between 4–6 months and 8–10 months after planting (Figure 2). It was therefore necessary to apply five gravity irrigations for a total water application of 690 mm, whereas the total water application in the case of drip irrigation was 511 mm in the daily or conventional irrigation, 382 mm in the twice-a-week irrigation, and 334 mm in the weekly irrigation, which represents a saving of water of 26% in the daily frequency, 45% in the twice-a-week frequency, and 52% in the weekly frequency as compared with gravity irrigation.

![Fig. 2—Water conditions of the first ratoon crop of sugarcane variety CC 84-92 during a drip irrigation experiment carried out at the Malimbú Sugarcane Plantation, located in south-western Colombia.](image)

The second ratoon was grown on 2 October 2007 and harvested at 14.4 months (12 December 2008), in the case of the drip-irrigated cane, and at 16.2 months (7 February 2009) in the gravity-irrigated check. The yield of drip-irrigated cane variety CC 85-92 was, on average, 190 t/ha,
whereas the gravity-irrigated check yielded 168 t/ha, a difference of 22 t/ha (13%) in favour of drip irrigation (Table 1). Sugar yield (11.81%) in drip-irrigated fields was slightly lower than in gravity-irrigated fields (12.4%), whereas sugar production was higher (22.4 t/ha versus 20.8 t/ha). Finally, the monthly production of drip-irrigated cane (13.2 t/ha per month) was higher than that of gravity-irrigated cane (10.4 t/ha per month); monthly sugar production under drip irrigation (1.56 t/ha per month) was also higher than under gravity irrigation (1.29 t/ha per month).

Precipitation during the second ratoon was 1345 mm, surpassing by 50% the average value for the area and well distributed throughout the crop cycle (Figure 3). Plantation administrators decided to apply irrigation up to 12 months after planting, taking into account the state mill’s announcement to harvest between 14 and 15 months old because of delays in the harvest schedule. The gravity-irrigated check only required two irrigations, one at 10 and the other at 12 months, for a total water application of 240 mm. In drip irrigation, the total water application was 365 mm in daily or conventional irrigation, 329 mm in the twice-a-week irrigation, and 194 mm in the weekly irrigation. This means that there was a 19% saving in the amount of water used in the weekly drip irrigation alone as compared with gravity irrigation.

![Fig. 3—Water conditions of the second ratoon of sugarcane variety CC 84-92 during a drip irrigation experiment carried out at the Malimbú Sugarcane Plantation, located in south-western Colombia](image)

The average yield of drip-irrigated cane variety CC 85-92 for the three cuts was 166 t/ha, whereas the gravity-irrigated check yielded 157 t/ha, a 6% difference in favour of the former (Table 1). No difference was observed in sugar yield between drip irrigation (12.4%) and gravity irrigation (12.6%), whereas the sugar production of drip-irrigated cane was 20.6 t/ha as compared with gravity-irrigated cane with 19.8 t/ha, a 4% difference.

The TCHM index was 12.2 in the case of drip irrigation compared with 11.1 in the case of gravity irrigation (a 10% difference); the TAHM was 1.51 in drip irrigation and 1.39 in gravity irrigation, an 8% difference. In two of the three cuts (plant crop and the second ratoon), the monthly precipitation was above average for the area and only one gravity irrigation event (148 mm) was required in the plant crop and two gravity irrigations in the second ratoon during the period of crop growth. From 5 to 7 gravity irrigations are normally required in the area where the experiment was conducted. The average water application per crop cycle was 465 mm in gravity irrigation and 264 mm in weekly drip irrigation, representing a saving of 201 mm (43%) in the case of the latter.

Regarding the frequency of drip irrigation, no significant differences were observed in cane and sugar production over the three cuts (Table 2). However, significant differences were detected
regarding the amounts of water applied per crop cycle, especially in the first and second ratoons. In the first ratoon, these amounts were 511 mm for daily irrigation, 382 mm for twice-a-week irrigation, and 334 mm for weekly irrigation. In the second ratoon, the total water application was 365 mm for the daily drip irrigation, 329 mm for the twice-a-week irrigation, and 194 mm for the weekly irrigation. This indicates that, under these environmental conditions, drip irrigation should be scheduled based on the water balance and applied at a weekly frequency to obtain a significant saving in the amount of water used (46%) with respect to daily irrigation by taking advantage of the precipitation and the water storage capacity of soils in the Cauca River Valley.

Table 2—Production of cane variety CC 85-92 on the Malimbú Sugarcane Plantation, located in the Cauca River Valley, Southwestern Colombia, using three frequencies of drip irrigation.

*Double furrow with 2.6 m between pairs and 0.6 m between furrows
**Double furrow with 2.4 m between pairs and 0.4 m between furrows
***Single-furrow at 1.75 m
In double-furrow or paired-furrow planting systems, the skids of the lifters broke the drip hoses along several stretches and the wagons caused severe damage to the stools. Taking into account that planting in double furrows reduces the capital costs of lateral hoses by 32%, it would be worthwhile to purchase combine harvesters that adapt to this planting system.

In the second ratoon, differences in tonnes of cane per hectare (TCH) were detected which could be attributable to the frequency x spacing interaction ($\alpha = 5\%$). The highest response in terms of TCH (191 t/ha in variety CC 85-92) was found in the weekly drip irrigation in double furrows with 2.6 m between centres of the pair and 0.6 m between rows.

**Conclusions**

- In the three cuts, drip irrigation as compared with gravity irrigation generated a 43% saving in the amount of water used (2010 m$^3$/ha).
- Averaged over the three cuts (two receiving high precipitation and one low precipitation), the production of drip-irrigated cane variety CC 85-92 was 166 t/ha as compared with gravity-irrigated cane, which produced 157 t/ha, a difference of 9 t/ha (6%). Data will be more conclusive once the results of more dry years are available.
- At least five cuts should be included in the economic evaluation of drip irrigation.
- To adapt drip irrigation to the rainfall regime and the soils of the Cauca River Valley, it should be scheduled based on the criterion of a weekly irrigation to obtain significant water savings (40%) without adversely affecting cane production and sugar yields.
- In drip irrigation, the double-furrow planting system (2.6 m × 0.6 m) is economically favourable because the investment in lateral hoses would be reduced by 32%. Taking into account that the mechanical lifter causes damage to the stools and cuts hoses, it would be worthwhile to purchase a combine harvester that adapts to double-furrow planting because it would facilitate the adoption of drip irrigation.
- The fertilisation applied through drip irrigation (fertigation) represented a saving in terms of machinery and labour which should be evaluated in subsequent experiments to determine the system’s efficiency and fertiliser doses and to quantify the added value of fertigation by dripping.

MOTS-CLES: Irrigation Goutte à Goutte, Plan d’Irrigation, Economie d’Eau, Production de Canne à Sucre, Colombie.

Resume

L’irrigation goutte à goutte était initialement conçue pour les endroits désertiques où les sols sablonneux ont une faible capacité de rétention d’eau et où la pluie est limitée. Dans la vallée de la rivière Cauca au sud-ouest de la Colombie, les sols ont une forte capacité de rétention et des irrigations fréquentes produisent un excédent d’humidité et un mauvais développement racinaire qui affectent le développement de la culture. L’application fréquente d’eau dans les sols de la vallée de la rivière Cauca est la cause d’un excédent d’eau dans le sol et d’une très faible utilisation des précipitations naturelles. Cette présente étude a été conduite à la plantation de canne à sucre Malimbú, située dans la partie la plus sèche de la vallée de la rivière Cauca où la pluviométrie annuelle est au dessous de 800 mm et où les sols ont une texture loamy à argileuse. L’effet de la fréquence d’irrigation (journalière, deux fois par semaine et hebdomadaire) a été étudiée dans des parcelles sous irrigation goutte à goutte. Un système d’irrigation gravitaire a été utilisé comme contrôle. Pour trois coupes successives, (une vierge et deux repousses), la production de canne à sucre dans les parcelles irriguées par goutte à goutte était de 160 t/ha avec l’irrigation journalière (application de 483 mm), 165 t/ha irrigué deux fois par semaine (application de 356 mm), et 166 t/ha irrigué chaque semaine (application de 264 mm). Pour l’irrigation gravitaire, la canne a produit 157 t/ha avec une application moyenne de 465 mm. La précipitation annuelle moyenne pendant ces trois coupes a atteint 984 mm. Les résultats indiquent l’importance de prendre avantage de non seulement de la capacité de rétention du sol pour stocker l’eau disponible mais aussi des pluies et de la planification de l’irrigation goutte à goutte hebdomadaire des champs de canne à sucre de la vallée de la rivière Cauca, sans affecter négativement la production de canne.
FRECUENCIA DE RIEGO POR GOTEO DE AÑA DE AZÚCAR EN LOS TRÓPICOS

Por

I.C. FRAGOSO, J.H. MESA y D. DELVASTO
jrcruz@cenicana.org

PALABRAS CLAVE: Riego por Goteo, Lista de Riego, Agua Almacenamiento, Producción de Caña de Azúcar, Colombia.

Resumen
El sistema de riego por goteo fue desarrollado inicialmente para las zonas desérticas donde los suelos tienen bajas capacidades de retención de humedad (arenosos) y las lluvias son escasas. En el valle del Cauca los suelos son de alta capacidad de retención de humedad y la aplicación de riegos frecuentes resulta en excesos de humedad y en el desarrollo de un sistema radical reducido afectando el desarrollo del cultivo. La aplicación de riegos frecuentes en el trópico resulta en excesos de humedad en el suelo y en poco aprovechamiento de la precipitación natural. La presente investigación se realizó en la hacienda Malimbú, que está ubicada en la zona más seca del valle del río Cauca donde la precipitación anual es inferior a 800 mm y los suelos son de textura franca a arcillosa. Se evaluó el efecto de la frecuencia diaria, 2 veces por semana y una vez por semana en las parcelas regadas por goteo. El sistema de riego por gravedad fue tomado como un testigo de referencia. En tres cortes consecutivos (plantilla y dos socas) la producción de caña de las parcelas regadas por goteo con frecuencia diaria fue de 160 t/ha (lámina de riego 483mm), 165 t/ha para la frecuencia de 2 veces por semana (356 mm) y 166 t/ha para la frecuencia semanal (264 mm). La producción de la caña regada por gravedad fue de 157 t/ha con una lámina promedio aplicada de 465 mm. La precipitación promedio recibida durante los tres cortes alcanzó los 984 mm. Los resultados obtenidos indican la importancia de aprovechar la capacidad de almacenamiento de agua aprovechable de los suelos, la efectividad de la precipitación a partir de programar los riegos para la caña de azúcar en el valle del río Cauca siguiendo una frecuencia de riego semanal sin afectar negativamente la producción.

Abstract

The paper summarises the findings compiled from contributions of the committee members and from the proceedings of the International Society of Sugar Cane Technologists (ISSCT) Agricultural Engineering Section Workshop held between 3rd and 5th of March 2009 at The University Centre, Kamphaeng Saen Campus at Nakhon Pathom of the Kaestart University, Thailand. The opening addresses gave an excellent overview of the Thailand Industry, which globally is the second largest exporter of sugar, and has over 80% of its farms of less than 20 ha in size. The industry is in a stage of rapid development, with appropriate mechanisation for small growers being a significant issue. The demand for by-products such as ethanol is a significant catalyst for the growth of the industry. The presentations were grouped under the general headings of Machinery and Mechanisation and Management and Logistics, with a focus on mechanisation associated with smaller operations. The field visits associated with the workshop focused on the very significant development which is occurring in appropriate mechanisation for small and medium size growers, as well as the integration of rotation crops with sugarcane and irrigation systems used. In the workshopping sessions, a wide range of issues were discussed, ranging from Crop Production to the Environment. Miller–Grower ‘Politics’ and Health & Safety issues were also seen as issues which could be addressed, with discussion on the potential of ISSCT sanctioning various training courses. Overall, the most significant issue seen to be facing the industry was logistics and cost of cane transport from the field to the mill. Thailand represented an excellent venue for the workshop, because of its rapid growth and the market driven development of appropriate mechanisation for small growers.

Introduction

The Thailand industry consists of a US$2.1b pa industry with a Sugar Act which provides some regulation, which the industry believes is a constraint on progress and requires reviewing. The area under cane is 0.99 Mha, there are 47 mills, and 170 000 growers. Only 10% of the area is Miller Cum Planter, 80% of the growers are very small with farms of less than 20 ha and only a few farmers have up to 100 ha. Thailand currently grows 72 Mt of sugarcane which is harvested annually and 7.57 Mt of sugar is produced, 2 Mt of which is for local consumption. Thailand is the world’s 2nd largest exporter of sugar (5.7 Mt), mainly to Asia. Only 5% of the crop is mechanically harvested and the labour for crop production is mainly from neighbouring countries. Where water is available, they use surface irrigation and some surface type drip irrigation.
The industry strategy is to increase the area under cane by 30% and increase production from 72 Mt to 95 Mt; however, there are threats from other crops and trade barriers. The growers move in and out of cane depending on the price of other commodities.

The 9th ISSCT Agricultural Engineering Workshop was held from Tuesday 3rd March and Thursday 5th of March 2009.

The pre-workshop tour on the 2nd March focused on the area around the Capital, and visited Ayudhaya, Thailand’s world-famous former capital (from AD 1350 to 1767) and now a World Heritage Site. The tour included the ruins which have survived from this once magnificent city, as well as the ruins of Phra Maha That temple, followed by a short elephant ride around the old ruins to Wat Phra Si Sanphet, the major temple in the old Royal Palace compound. Lunch was enjoyed at a local restaurant by the river, after which Wat Yai Chaimongkol and others were visited before returning to Bangkok. The welcome dinner was a very enjoyable Chao Pra Ya river dinner cruise.

The workshop sessions were held at Kamphaeng Saen Campus of Kaestart University, which is at Nakhon Pathom, approximately 90 km West of Bangkok. The workshop included a very well organised field trip to the University farm where machinery for all facets of the industry were presented in excellent static and operating displays. The second field visit was to Chokpradit Farm, Kanchanaburi, with the final workshop session being held there. The delegates then visited the famous Bridge over the Kwai, where lunch was enjoyed before returning to Bangkok.

**Workshop theme**

The workshop addressed the topic: ‘Sugar cane Mechanisation for Profitability and Sustainability Under Environmental Conservation’ with major subject areas addressed including:

- Tillage and land preparation equipment and strategies in Thailand and other countries.
- Mechanisation of crop husbandry operations for smaller growers
- Comparative performance of irrigation strategies
- Harvesting strategies, ranging from developments in cane knife design to issues relating to cane loaders and also performance and cost of chopper harvesting.
- Transport system scheduling, and broader issues such as the role of sugarcane as an energy crop and the impact of this on harvesting and transport systems.
- Alternative uses for sugarcane by small growers.

A workshop session and a plenary session were also held. The focus of the workshop was on the issues facing the Thai Industry.

**Workshop attendance**

The workshop was attended by 40 delegates from nine countries including 17 from Thailand, 6 from Indonesia, 5 from Mauritius, 3 from each of India and Sudan, 2 from each of Uganda and Japan, 1 from Australia and 1 from South Africa. There were also 23 observers and guests from Thailand.

**Program**

Relevant and interesting issues to many industries were raised in the Machinery and Mechanisation presentation sessions.

There has been significant adoption of the New Farming System with mechanical green cane harvesting in Mauritius; however, they are keen to incorporate the trash blanket into the soil. V. Riviere discussed the success they had by using a shredder type topper on the harvester and then using what they call a Flail disc harrow to incorporate the organic matter. Experiments have shown that, although not statistically significant, there was an increase in yield for the plant and each
ratoon up to the 4th with an accumulated increase of 21 t/ha. Just as significant has been the significant increase in soil organic matter which has been observed. Further work reported from Mauritius covered the work at Belle Vue, where equipment for pulverising rocks is being used with a combination of GPS guidance and permanent beds to make a mechanisation-friendly farming system. B. Vandalall described the success being achieved by an integrated approach and the adoption of the principles of ‘New Farming Systems’.

Mechanisation in Thailand was discussed by T. Indrambarya. It was indicated that more than 80% of farms are less than 20 ha in size. They believe that mechanisation is the way to improve productivity, and machinery has been developed to be used with small conventional tractors (<40 kW) and the two-wheel walk behind type tractor. 90% of the cane is harvested manually. Depending on the area, up to 100% of the cane may be harvested as green cane. Many of the practices being developed may be relevant in countries other than Thailand.

The presentation by R. Karoonboonyanan on the development of a vibratory type Subsoiler focused on the issue of undertaking relatively heavy land preparation operations with ‘lighter’ tractors. While there was no advantage in terms of work rate or fuel consumption, the advantage of the vibratory action was that a tractor of a given weight could pull either a wider machine or a narrow machine deeper than would normally be possible, given the tractor weight.

The cane knives in Thailand have traditionally been of a short and straight design. This makes it difficult to cut the stalk close to the ground, as well as having health and safety issues. Work was thus carried out to improve the effectiveness of the knives used to manually cut cane. N. Sokudlor reported on nine different designs which were tested, and a new design known as ‘Phuvieng 4’ was found to be the most effective.

The data from field trials indicated that 41 percent of workers were satisfied with Phuvieng 4 because less cane was left in the field. Cane stalk height after harvesting was reduced from 9.5 cm to 2 cm in height and the benefit was an additional 2 t/ha, resulting in an added income of US$46/ha. This indicates that it may be possible to design an even more ergonomically acceptable knife that enables a higher productivity.

In Thailand, juice is squeezed from cane stalks to provide fresh drinking juice, which provides some small growers a higher value for their cane; however, to make the taste acceptable, the rind is removed to remove the wax. The peeling process to achieve this is labour intensive and slow. A system described by P. Pruengam was developed to grind away the outer surface of the rind before the juice was squeezed out. The simple electrically driven grinder increased a labourer’s productivity by a factor of four and 20% less juice was lost than in the peeling process.

C. Norris gave a presentation entitled ‘Sugar cane; Reconsidering Harvesting Strategies for Cost-Effective Energy Recovery’. The traditional use of sugarcane captures less than half of the recoverable energy of the crop, often with less than optimal environmental stewardship.

The increased energy costs of recent times caused many paradigms to change in sugar industries around the globe, with sugarcane trash being considered as a viable replacement for fossil fuels in many applications. He discussed an analysis of a number of different sugarcane trash recovery strategies, investigating the costs associated with each, as well as a broad range of issues including agronomic cost or benefit, the quality of the fuel delivered, and the technology requirement and availability. He argued that, while systems where trash is delivered with the cane and separated at the mill are likely to be the most viable strategy into the future, further technology development is required.

P. Lyne presented their work relating to scheduling of vehicles for the road transport of sugarcane. The paper illustrated the very significant gains which can be made with respect to total investment and cost of sugarcane transport to the mill. This work has significant relevance in a wide range of industries.
Poster session

A. Boontham showed a mechanical system that was used to detrash cane prior to manual harvesting. The cane trash extractor consisted of two cages with cable strings attached to each cage for removing the old leaves. The cane detrasher is attached to a two-wheel walk behind tractor.

There was also a concern in Thailand about fires with cane trash on the surface. There is now considerable emphasis on the development of systems to incorporate the trash after harvest. Trash incorporators can be based on a range of machines including disc harrows with notched blade discs, rotavators or disc ploughs. This technology will undoubtedly increase in relevance for other countries as they move towards green cane harvesting.

N. Sokudlor presented work on the development of various tools to be used for detrashing in place of using the knives to remove trash. The cutters could change activities during the day and there was less injury due to the continuous conventional method of cutting and trash cane. Leaf trash in the delivered product reduced from 6.9 to 2.9 percent. The equipment was also tested in farmers’ fields. About 95 percent of cutters were satisfied with the equipment because it eased their workload; however, the remainder still complained of additional work. With the detrashing tool, cutters increased daily productivity by 20 – 25 bundles/day (each bundle is 10 sticks of cane) resulting in an additional income. The operation of pre-stripping can be carried out up to 2 weeks prior to harvesting.

Y. Tarumoto from Japan described a Regional Simulation Approach for Evaluating New Sugarcane Varieties Using System Dynamics. Because the sugar industry is a very complex system, it is difficult to quantify or predict the outcome of changes. Different traits in different varieties is one example. Therefore, a System Dynamics simulation model was developed using the software Vensim to examine consequences. The steps involved included simulation of the weekly changes in sucrose for different crops, and the development of appropriate harvest quotas to maximise sucrose production and minimise industry costs. The model shows not only an industry wide effect but also detailed analysis on a field by field basis. This is useful to assist the discussion between stakeholders on issues such as crush dates or adoption of new varieties.

Chopper harvesters are used for approximately 5% of the Thailand crop, with about 250 harvesters involved. S. Khawprateep carried out a study involving 30 machines, differentiated into one of two groups by engine power, i.e., high power models with typical engine power of 240 kW, and lower power models fitted with engines of approximately 177 kW. The study was conducted over a period of 5 years, and determined productivity and fuel consumption of the different machines.

The result showed that the average sugarcane cut was 9769 tonnes/year and the average rate of fuel consumption was 2.60 litres/tonne. Analysis of the work capacity and fuel consumption between two engine sizes showed an average productivity of 8219 and 11 319 tonnes/year with the average fuel consumption at 2.53 and 2.68 litres/tonne, respectively for the low power and high power units.

Even given the average season length of 13 weeks for machine harvesting, this is considered to be a very low productivity, with small fields considered a major factor. The authors noted the target for Australian operators over this period would be 50 000 tonnes and a fuel consumption of 1 litre/tonne.

Field visits

The field demonstration at the university farm included an impressive array of machinery, ranging from tractor-drawn equipment for larger growers and contractors to equipment based on small tractors and also equipment fitted to walk-behind tractors. Each display was well organised and the accompanying posters gave very useful information.
The coverage of different systems was comprehensive yet in very useful detail. Considerable time had obviously been spent ensuring appropriate conditions were in place for each of the very wide range of machines to be demonstrated to their maximum advantage.

The field visit to Chokpradit Farm, Kanchanaburi allowed delegates to see the planting and post-planting irrigation being undertaken on a larger farm, which was also of significant interest.

Acknowledgements

The Agricultural Engineering Section Committee thanks all formal delegates and observers who participated in the Workshop, with special thanks to those who prepared and presented papers.

The committee gratefully acknowledges the enormous time input by Mr Borpit Tangwongkit and his team at the Farm Mechanisation section of the Kasetsart University, for organisation of the workshop.

The committee also acknowledges the very generous support of the major and minor sponsors of the Workshop. The Council of the ISSCT is thanked for entrusting the Agricultural Engineering Section Committee with the task of organising the Workshop and for providing necessary support.

MECANISATION POUR UNE PRODUCTION DE CANNE À SUCRE PROFITABLE ET DURABLE DANS LA CONSERVATION DE L’ENVIRONNEMENT

Résumé

Le papier résume les conclusions compilées à partir des contributions des membres du comité et du rapport du workshop de la Section de Mécanisation Agricole de l’ISSCT tenu entre les 3 et 5 mars 2009 au Centre Universitaire, Campus de Kamphaeng Saen à at Nakhon Pathom de l’Université de Kaestar, Thaïlande. Les discours d’ouverture donnèrent un excellent survol de l’Industrie thaïlandaise, qui au niveau global est le deuxième plus grand exportateur de sucre, avec 80% des unités de production d’une taille inférieure à 20 ha. L’industrie est à un stade de développement rapide, avec la mécanisation appropriée pour les petits producteurs comme problématique importante. La demande pour les sous-produits, tel l’éthanol est un catalyseur significatif pour la croissance de l’industrie. Les présentations étaient regroupées sous des rubriques générales de Machines et Mécanisation et Gestion et Logistiques, avec une emphase sur la mécanisation associée aux plus petites opérations. Les visites aux champs, associées au workshop, se sont concentrées sur le développement significatif de la mécanisation qui est actuellement en cours pour les petits producteurs et ceux de taille moyenne, aussi bien que sur l’intégration des cultures en rotation avec la canne à sucre et les systèmes d’irrigation utilisés. Dans les sessions de discussion, une large gamme de sujets variant entre la production agricole et l’environnement, ont été débattus. Les ‘politiques’ des usiniers-planteurs et les questions sur la santé et sécurité ont été considérées comme
MECANIZACIÓN DE LA CAÑA DE AZÚCAR PARA RENTABILIDAD Y SOSTENIBILIDAD BAJO EL ESQUEMA DE CONSERVACION AMBIENTAL

PALABRAS CLAVE: Caña de Azúcar, Mecanización, Cosecha de Caña Verde, Pequeños Productores, Sostenibilidad.

Resumen

EL DOCUMENTO resume los resultados compilados de las contribuciones de los miembros del comité y las memorias del Seminario de la Sociedad Internacional de Tecnólogos de la Caña de Azúcar (ISSCT) Sección de Ingeniería Agrícola, celebrado entre el 3 y 5 de marzo 2009 en el Centro Universitario, Kamphaeng Saen Campus en Nakhon Pathom, de la Universidad Kaestart, Tailandia.

Los discursos de apertura dieron un excelente panorama de la Industria de Tailandia, que a nivel mundial es el segundo mayor exportador de azúcar, y tiene más del 80% de las explotaciones de un tamaño menor de 20 ha. La industria está en una etapa de rápido desarrollo, pero un problema importante es la falta de mecanización apropiada para los pequeños productores. La demanda de productos derivados como el etanol es un catalizador importante del crecimiento de la industria. Las presentaciones fueron agrupadas bajo los encabezados generales de Maquinaria y Mecanización, y Manejo y Logística, con especial atención a la mecanización asociada con la operación en pequeña escala. Las visitas de campo relacionadas con el taller se enfocaron en el muy importante desarrollo que está ocurriendo en la mecanización apropiada para pequeños y medianos productores, así como en la integración de cultivos de rotación con caña de azúcar y los sistemas de riego utilizados.

En las sesiones de taller, fue discutida una amplia gama de temas, cubriendo desde producción agrícola hasta consideraciones ambientales. Otros puntos que se consideró podrían ser tratados fueron, la ‘Política’ de Miller para los cultivadores, y problemas de Salud y Seguridad. También se debatió sobre el potencial de ISSCT para implementar diversos cursos de capacitación. En general, se identificaron la logística y el costo de transporte de la caña desde el campo hasta la fábrica como los problemas más importantes que está enfrentando la industria. Tailandia fue un lugar excelente para el taller, debido a su crecimiento rápido y al desarrollo del mercado de la mecanización apropiada para cultivadores pequeños.
MONITORING SUGARCANE CROPS IN THE CAUCA RIVER VALLEY (COLOMBIA), USING MODIS SATELLITE IMAGES

By

P.J. MURILLO, C.A. OSORIO, J.A. CARBONELL and A.E. PALMA
CENICAÑA, Colombia
pjmurillo@cenicana.org; jacarbonell@cenicana.org

KEYWORDS: Sugarcane, Yield Forecasting, MODIS, Enhanced Vegetation Index, Time Series.

Abstract
MODIS product MOD13Q1 was used to monitor the sugarcane crop, using an enhanced vegetation index in the Cauca River Valley for a time series from 2000–2006. The product consists of images taken every 16 days (pixel size of 250X250 m), which makes it possible to work with fields larger than 6.25 ha. A methodology was developed for downloading, cutting, filtering and laying out the time series of the vegetation indices on Internet for the entire area planted with sugarcane. The relation between the time series and the information on crop establishment and harvesting of the fields indicated that the satellite data were consistent with the phenology of the sugarcane crop. Similarly, there was a high correlation between the cumulative vegetation index and cane production. Low index values were associated with low values of tonnes of cane per hectare; whereas high index values meant high production values.

Introduction
A practical and unique way of monitoring large extensions of agricultural zones is by means of remote perception. Studies done on different crops show that the MODIS (MODerate Resolution Imaging Spectroradiometer) 250-m data are correlated with productivity (Doraiswamy et al., 2005; Bastidas-Obando and Carbonell, 2006; Colditz et al., 2006; Wardlow et al. 2007). The purpose of this work was to evaluate the consistency of the MOD13Q1 product and generate a model for forecasting productivity in terms of tonnes of cane per hectare (TCH) for the sugarcane crop in the Cauca River Valley (CRV).

Methodology

Study area
The study area, which covers 212 000 ha, is located in the CRV of Colombia, between 3° and 5° latitude N and 76°22’ and 75°31’ longitude W.

Processing the MOD13Q1 product
For monitoring the cane crop in the CRV, the product ‘MODIS/TERRA VEGETATION INDICES 16-DAY L3 Global 250 m SIN GRID V004’ was used. The images were cut in the study area and projected to a Transverse Mercator using the MODIS Reprojection Tools.

The time series from February 2000 to December 2006 (360 × 931 pixels) was generated using the enhanced vegetation index (EVI). The EVI time series was interpolated from QA-SDS quality data, followed by the Savitzky-Golay smoothing filter method (Chen et al., 2004).

Statistical analyses
For the analyses, a total of 6857 pixels were selected, corresponding to an area of 43 481 ha. A regression analysis was conducted to relate the information from MODIS with the production
data, for which the area under the curve of each crop cycle was accumulated and compared with its respective TCH.

**MapServer**

A Web application was developed to compare the time series with the full information from the commercial database. This application is available for the entire area planted with sugarcane in the CRV and is updated every 16 days.

**Results and discussion**

Figure 1 shows how using the QA-SDS quality parameters and the Savitzky-Golay filter method made it possible to obtain high-quality time series information (Chen et al., 2004).

![Figure 1](image)

---

A total of 48 cumulative EVI ranges were determined, and the existing TCH data for each range were averaged. These data were used in a regression analysis, weighted for the number of data for each interval, as follows:

\[ e = 0.0005x + 53.139 \]  
(where: \( e = \text{TCH} \); \( x = \text{Cumulative EVI} \))

with a regression coefficient of determination \( r^2 = 0.83 \), which is a high value given that the ranges cover the entire variation due to variety, agro-ecological zones, agronomic practices and age at cut.
With the recorded data, cumulative EVI ranges were formed with respect to what one lot of sugarcane should have at a given crop age (in months) in order to reach a TCH value with a 95% confidence level (Table 1). This makes it possible to evaluate whether there is an anomaly in the development of the crop, thereby facilitating an early warning about its current condition.

Table 1—Monthly cumulative EVI values and their relation to final production.

Conclusions

The use of the quality data and the application of the Savitzky-Golay filter (Chen et al., 2004) improve the original MOD13Q1 time series. The information is consistent with the development of the cane crop and its productivity. Discounting the intercept, the model $TCH = 0.0005 \text{EVI} + 53.139$ revealed that, for every 10 000 cumulative EVI units, there is an increase of 5 TCH.

The effect of agronomic practices such as the application of fertilisers, herbicides, maturants and irrigation on the crop’s spectral response needs to be evaluated. Similarly, there is a need to identify patterns or cumulative values early enough in order to develop an expert system based on the MODIS data.

Résumé

Le produit MOD13Q1 de MODIS a été utilisé pour suivre la production de la canne à sucre avec un indice de végétation amélioré dans la vallée de la rivière Cauca pour la série temporelle 2000-2006. Le produit comprend des images (taille de pixel 250 × 250m) pris chaque 16 jours, ce qui permet de travailler avec des champs d’une superficie supérieure à 6.25 ha. Une méthodologie pour télécharger, couper, filtrer et étendre la série temporelle des indices de végétation sur Internet a été développée pour toute la zone plantée de canne à sucre. La relation entre la série temporelle et les informations sur l’établissement de la culture et la récolte des champs a indiqué que les données satellite étaient consistantes avec la phénologie de culture de canne à sucre. Il y avait aussi une forte corrélation entre l’indice cumulatif de végétation et la production de canne. Des faibles valeurs d’indices étaient associées avec des faibles tonnages de canne à l’hectare alors que des valeurs fortes indiquaient des fortes productions.
MONITOREO DEL CULTIVO DE LA CAÑA DE AZUCAR EN EL VALLE DEL CAUCA (COLOMBIA) USANDO IMAGENES SATELITALES MODIS

PALABRAS CLAVE: Caña de Azúcar, Predicción del Rendimiento, MODIS, Índice de Vegetación Mejorado, Series de Tiempo.

Resumen
El producto MOD13Q1 de MODIS, fue usado para realizar un seguimiento del cultivo de la caña de azúcar en el valle del río Cauca para la serie de tiempo comprendida entre 2000 y 2006 usando un índice de vegetación. El producto consta de imágenes compuestas cada 16 días con un tamaño de pixel de 250 × 250 m, lo que permite trabajar con campos mayores a 6.25 ha. Fue desarrollada una metodología para la descarga, corte, filtrado y disposición de las series de tiempo de los índices de vegetación en Internet para toda el área sembrada con caña de azúcar. La relación entre las series de tiempo con la información de establecimiento y cosecha de los campos indica que los datos satelitales son consistentes con la fenología o desarrollo vegetal del cultivo de la caña de azúcar. A su vez se evidencia una alta correlación entre el índice de vegetación acumulado y la producción de caña. Valores bajos de índice están asociados con bajos tonelajes de caña por hectárea (TCH), y por el contrario, altos valores del índice significan altos valores de TCH.
IRRIGATING SUGARCANE WITH VERY LOW FURROW INFLOW RATES

By

J.S. TORRES, A. CAMPOS and D.M. CRUZ

Colombian Sugarcane Research Center, Cenicaña

jtorres@cenicana.org

KEYWORDS: Furrow Irrigation, Sugarcane, Low Inflow, Low Cost.

Abstract

SPRINKLER irrigation of sugarcane is a common practice at the foothills of the Cauca river valley of Colombia. Energy costs are limiting the use of this irrigation system and alternative ways of irrigation using small surface springs is under evaluation. Water is applied by gravity using small furrow inflow rates in the range of 0.1 to 0.3 L/s while furrow irrigation of sugarcane on the flat areas uses inflow rates above 5 L/s. Water is diverted from the small streams and conducted to the fields using small hydraulics heads (less than 10 m). Cheap pipelines of 100 mm diameter, made of recycled polyethylene bags, are used to conduct the water at low pressure heads to the fields where water is applied to the furrows using plastic tubing of 6 to 16 mm in diameter. Furrow lengths of 100 to 120 m with slopes above 1% are irrigated during the advance phase in 20 to 24 hours applying water depths in the range of 100 to 130 mm. Cane yields in the order of 84 t/ha were obtained, which compare very well with the production of the sprinkle-irrigated plots.

Introduction

In the Cauca river valley of Colombia, there are 205 664 ha of cane planted. Of this area, 62 636 ha are in the foothills of the central and oriental mountain chains. The cropped area is characterised by the presence of shallow depth soils, and high gravel content (20 to 50%); therefore, water holding capacity and fertility levels are low. During dry spells, it is necessary to sprinkle irrigate the cane fields, which results in high energy inputs, high water consumption and high soil erosion risk due to terrain slopes above 1%.

Bohorquez and García (1985) in Venezuela applied very low furrow inflow rates to improve irrigation efficiencies in an area with low surface water availability. Díaz and Prieto (2000) evaluated the application of low inflow rates (0.1 L/s) to irrigate sugarcane in a soil with low infiltration capacity, slow internal drainage and slopes between 2–3%. They were able to increase water storage and use efficiency. As a way to adapt to the climate change in years with the presence of the El Niño phenomenon, Cenicaña has been evaluating the practicality of using surface irrigation with very small furrow inflow rates to irrigate sugarcane.

Methodology

This system, referred to as furrow irrigation with low inflow rates, uses water diverted from small streams. Typically, low hydraulic heads (less than 10 m) are available to convey the water to the fields. Cheap pipelines of 100 mm diameter, made of recycled polyethylene bags, are used to conduct the water at the low pressure heads to the fields. Water is applied to each furrow using plastic tubes of 6 to 16 mm in diameter. Water is applied by gravity using small furrow inflow rates in the range of 0.1 to 0.3 L/s. The conventional furrow irrigation practice of sugarcane on the flat areas uses inflow rates above 5 L/s. With the new system, furrow lengths of 100 to 120 m are typical, with slopes above 1%. The irrigation water advance phase is 20 to 24 hours, applying water
depths in the range of 100 to 130 mm. Water applied to the furrow inlets creates a kind of ponded zone in a distance of 2 to 3 m, and then it advances through the soil as horizontal infiltration and, after 20 to 24 hours of continual water supply, it reaches the end of the cane row. The slow application of water, using furrow inflow in the range of 0.1 to 0.3 L/s, results in a pronounced lateral movement of the water front. The water advance along the furrow length is controlled by gravity and by the presence of a coarser soil layer underneath the surface soil layer, which acts as a barrier to vertical water flow due to the high discontinuity in hydraulic conductivity between the surface and the underlying soil.

The system has been under evaluation at the foot hills of the Central mountain range in a farm (Vallecito) of Castilla sugar estate. The soil is considered as a Mollisol with skeletal clay textural family, and the field slope varies between 1.7 and 4.9%. The experiment followed a randomised complete block design with six water inflow rates (0.00, 0.06, 0.08, 0.10, 0.11 and 0.12 L/s) as treatments and four replications were established. The nearby field sprinkler irrigated and managed by the sugar estate was taken as a reference. The test cane variety was Co 421 planted by the sugar estate in this area.

Results and discussion

The hydraulic system to convey and deliver water to the cane was installed at the beginning of the fourth ratoon which was harvested at 11.5 months of age (Table 1). During the crop cycle, precipitation amounted to 1025 mm, and 1856 mm of evaporation occurred. Irrigation was applied according to Cenicaña’s water balance calculations. On average, five irrigation events were applied to the experimental area under reduced inflow rate application. The irrigation water depth varied between 205 and 956 mm. As a result of the non uniform slope of the furrows, in places where the furrow slope was higher, the water advanced faster, resulting in the applied water depth being smaller. The total amount of water received by the crop ranged from 1063 mm for the plots without irrigation up to 1981 mm for the treatment with inflow rates of 0.07 L/s. Cane yields within the plots irrigated with reduced inflow rates varied between 56 to 80 t/ha as compared with the sprinkler-irrigated field that yielded 56 t/ha with an applied irrigation depth of 70 mm for two irrigation events. It is necessary to recognise that, under the experimental area, there was high variability due to soil conditions and field slope that induced unexpected changes in water advance times, water advance velocity and total irrigation water depths.

Conclusions

The results from this evaluation are very promising, and it can be concluded that the reduced inflow rate system of irrigation could be adjusted to match the local conditions of individual fields. It is expected to improve cane yield of commercial fields by adjusting water application rates and the fertiliser rates according to the content of gravel in the soil and the available soil water holding capacity. The system opens the possibility to use depleted surface water streams and use low cost
plastic pipes which make it attractive to be used in rural area to irrigate cash crops. The system has been under evaluation by Cenicaña in different parts of the foot hills of the Cauca river valley.

MOTS CLES: Irrigation à la Raie, Canne à Sucre, Faible Débit, Coût Faible.

Résumé

L’IRRIGATION de la canne à sucre par aspersion est une pratique courante au pied des collines de la vallée de la rivière Cauca de Colombie. Les coûts énergétiques limitent l’utilisation de ce système d’irrigation et d’autres moyens d’irrigation utilisant des petites sources de surface sont en cours d’évaluation. L’eau est appliquée par gravité avec des faibles débits de raie entre 0.1 et 0.3 L/s alors que l’irrigation à la raie sur des surfaces plates utilise des débits supérieurs à 5 L/s. L’eau est déviée des petits ruisseaux et conduite aux champs avec des faibles charges hydrauliques (moins de 10 m). Des raccords bon marché de 100 mm de diamètre, fabriqués avec des sacs de polyéthylène recyclé, sont utilisés pour conduire l’eau à basse pression aux champs où elle est appliquée aux sillons avec des tubes en plastic de 6 à 16 mm de diamètre. Les sillons de 100 à 120 m de long avec des pentes supérieures à 1% sont irrigués pendant la phase d’avancement en 20 à 24 heures appliquant des profondeurs d’eau dans la gamme de 100 à 130 mm. Des rendements canne de l’ordre de 84 t/ha, qui se comparent très bien à ceux des parcelles irriguées par aspersion ont été obtenus.
RIEGO DE LA CAÑA DE AZUCAR CON MUY BAJOS CAUDALES POR SURCO

PALABRAS CLAVE: Irrigación por Gravedad, Caña de Azúcar, Bajo Caudal, Bajo Costo.

Resumen

El riego de la caña de azúcar por aspersión en los piedemontes del valle del río Cauca en Colombia. Los costos de la energía limitan el uso de este sistema y se están ensayando formas alternativas de riego usando pequeñas corrientes superficiales. El agua se aplica por gravedad usando pequeños caudales por surco entre 0.1 y 0.3 L/s mientras en el riego por surcos de la caña en las zonas planas se usan caudales por surco mayores a 5 L/s. El agua se deriva de pequeñas corrientes y se conduce a los campos usando pequeñas cabezales hidráulicas (menores de 10 m). Tuberías de bajo costo de 100 mm de diámetro, hechas de polietileno reciclado, se utilizan para conducir el agua a baja presión a los campos donde el agua es aplicada a los surcos usando tubos plásticos de 6 a 16 mm de diámetro. Longitudes de surco de 100 a 120 m con pendientes mayores del 1% se riegan en tiempos de avance de 20 a 24 horas aplicando láminas entre 100 y 120 mm. Se obtuvieron productividades de caña del orden de 84 t/ha, que compiten muy bien con la producción de las parcelas regadas por aspersión.
CHANGE OF SUGARCANE PRODUCTION AFTER INTRODUCTION OF DE-TRASHING EQUIPMENT: A CASE STUDY OF IZENA ISLAND

Abstract

This paper will discuss the relationships between an ageing population of sugarcane growers on Izena Island, the introduction of mechanical de-trashing procedures, subsequent changes in soil management practices and the implications for continuing productivity. The farming demographic in Okinawa Prefecture, and Izena Island in particular, between 1995 and the present day reveals a decrease in sugarcane production, an average farm size at 1 hectare or less, and the average age of the farmer at 65 years or more. Statistics reveal also that the succession of farm land and farming, as an occupation from one generation to the next, is not an enduring tradition. With their increasing age, sugarcane growers have been more accepting of mechanical procedures that ease the physical burden of their workload but, as this paper reveals, such procedures can sometimes have unexpected consequences. Prior to mechanical intervention, the dead leaves (trash) were removed from the cane stalks before transportation to the mill, and therefore remained on the farm where they were subsequently returned to the soil as organic matter. With the new de-trashing procedures, the trash is removed with the cane stalks to the mill, where it is composted as a by-product of the milling process. Furthermore, where previously each farm retained its own trash for composting, the mechanical processing at the mill has resulted in uneven distribution and supply of composted trash to farmers. This has raised concerns about deteriorating soil fertility, decreasing productivity and inadequate water conservation due to lack of organic material in the soil.

Introduction

Okinawa Prefecture is sub-tropical and consists of large and small islands. Izena Island is a solitary island in the northern part of Okinawa Prefecture. Sugarcane is the main industry on each island and in the economy of Okinawa Prefecture. However, the production of sugarcane in Okinawa Prefecture is decreasing, and the age of growers is on the increase.

According to previous research, there is a causal relationship between the low quantity of production and an accumulation of inadequate cultivation techniques (Fukunaka et al., 1999; Kikuchi, 2005). Moreover, implementation of fertilisation management influences the quantity of production (Kikuchi et al., 2007). Izena Island introduced de-trashing equipment early in Okinawa Prefecture. While the growers’ age was increasing, introduction of de-trashing equipment which can reduce harvest work had a big influence. However, fertilisation management suffered and production decreased. After introducing de-trashing equipment, growers ceased the return of trash to the farm at harvest, which reduced organic matter in the soil and may be responsible for reduced production. The purpose of this paper is to examine how to maintain soil fertility.
Research methods

Investigation was conducted over two years (2004 and 2008), in order to clarify a possible relationship between the use of de-trashing equipment and production trends. In November 2004, 42 households contributed data for the study. Information gathered on each household included the grower’s age, the existence (or not) of a successor to the current grower, the types of sugarcane grown, as well as details on the use of irrigation, deep ploughing, and moulding. In August 2008, 26 of the households were re-surveyed.

Results and discussion

The rate of trash, and its relation to unit crop yield

The harvested area in Okinawa Prefecture decreased to 12,485 ha in 2004 (Figure 1). Yield of cane peaked at 84.8 t/ha in 1990 and has now decreased to 60–70 t/ha.

If an ageing grower does not have a successor, the farmland may be abandoned. However, de-trashing equipment has reduced labour on the farm, so older farmers have continued to farm.

Before 1993, the leaf was peeled off before harvest, and the dead leaf was returned to the farmland. Per unit crop production was around 60 t/ha. However, after 1997, per unit crop production could not maintain 60 t/ha (Figure 2).

After 1993, when de-trashing equipment was introduced, the amount of trash for each 1 ha shows the tendency to increase because it omits the peeling off of the leaf by the grower. Before 1993, an average of 1.5 t/ha of trash was left on the field after harvest.

However, after 1994 when de-trashing equipment was introduced, an average of 6.2 t/ha of trash is returned to farmland but only to specific growers. Average fertility of soil has decreased, and production has decreased.
In Izena village, the de-trashing system is as follows. Cane is cut at the base and the cane top is removed. Cane and tops are picked up by a crane (Figure 3) and transported to the de-trashing equipment. Trash is removed in the de-trashing equipment and is processed in the sugarcane mill. Trash is taken to the compost factory, and is composted. In Izena village, the actual quantity of compost produced is from 3000 to 3500 t/year. The compost is only returned to 23.4% of the farmland.
Soil fertility must be maintained to maintain production. The compost is indispensable in maintenance of soil fertility. However, in Izena, there is a problem in the source of supply being restricted. Compared with the number of growers, the source of supply of organic matter in the village is restricted. Compost can be supplied to only about 40% of growers. Livestock faeces and urine discharged from dairy cattle in the village are processed in the compost factory. However, because there are few animals in the village, the absolute quantity of organic matter is insufficient.

All stems carried to the mill by truck are fed into the sugar mill through the cane feeder, and proceeds through the sugar mill as indicated by the red arrows (Figure 4). The first stage of trash separation is wind-powered, and the soil and sand is filtered out in the rotational separator. After passing through 3 wind-powered separators, the de-trashed raw material passes onto the clean cane conveyor and is carried into the sugar mill. The wind velocity used in the de-trashing equipment varies according to mill, and it can be adjusted in each de-trashing according to the raw materials.

*Fig. 4—De-trashing equipment. Produced by Tsukishima Co. Ltd.*

**Amount of fertiliser applied and unit crop**

Growers investigated were 42 households (2004) and 26 households (2008). This paper classified the grower by using the same index for two years (Tables 1 and 2). The full-time growers of sugarcane are farm manager husband and wife. Harvest area is 1 ha or more.

Source: From the investigation.

The age of the full-time farm manager is 60 years or less, and it is a grower who has a successor. The aged full-time grower was classified according to agricultural continuity and an age element. Those who are engaged in agriculture aged 65 and over cannot start work in other industries. It is a grower who is making agriculture a principal occupation.

A part-time farm grower is only a farm manager. Only 30–50% of these growers have a successor, and do not work full-time on the farm. The manager’s wife works in other industries and is not engaged in agriculture at all, which reduces the labour force. In addition to agricultural income, the livelihood of the grower is realised by income other than agriculture. A petty grower has a harvested area of 0.9 ha or less, and is engaged in agriculture only as a manager. The manager is also working in other industries. Agricultural income is only a part of gross income.

The full-time grower of the sugarcane should use 30–45 t/ha of organic fertiliser. However, the actual amounts of fertiliser are insufficient (Tables 3 and 4). The grower is compensating this insufficiency with chemical fertiliser. With commercial fertiliser, 500 kg/ha is required, but seems excessive. To increase crop yields, growers used a lot of commercial fertilisers.

Source: From the investigation.
The actual condition of unit crop and fertilisation management

The full-time grower of sugarcane compares 2004 with 2008 by unit crop, and most of the improvement is due to irrigation. Because the grower increased irrigation to 60%, per unit crop production became 58.9 t/ha (2004). However, in 2008, irrigation increased to 100% and per unit crop production was 93.8 t/ha. On the other hand, the aged full-time grower had 38.9% irrigation in 2004 and per unit crop production of 47.3 t/ha. However, in 2008, irrigation increased to 63.6% and per unit crop production increased to 53.6 t/ha.

Conclusion

Compared with the investigation in 2004, growers recognised the importance of fertilisation management in 2008. Therefore, crop yields have improved. The introduction of de-trashing equipment has reduced the grower's work burden. The grower can now carry out moulding and irrigation. However, commercial fertiliser is now the main source of fertiliser. Because the amount of compost has decreased, fertility has suffered. Moreover, the dead leaf is not returned to the farmland by introducing de-trashing equipment. Trash generated from de-trashing equipment is added to animal manure at the compost factory. This compost is available to only limited growers. Other growers must use chemical fertilisers. The present unit crop level is based on proper moulding and irrigation. Improving the fertilisation system leads to the possibility of improvement in unit crop. Continued research is necessary to stabilise production.

Resumen

Este artículo discutirá las relaciones entre el envejecimiento de la población de los productores de caña de azúcar en la isla de Izena, la introducción de procedimientos mecánicos de deshoje, los cambios en las prácticas de manejo del suelo y las consecuencias para la productividad continua. La demografía de los agricultores en la Prefectura de Okinawa, e Isla de Izena en particular, entre 1995 y el día de hoy revela una disminución en la producción de caña de azúcar, un tamaño medio de las explotaciones de 1 hectárea o menos, y edad media del agricultor de 65 años o más. Las estadísticas también revelan que la sucesión de las tierras agrícolas y la agricultura, como ocupación de una generación a la siguiente, no es una tradición perdurable. Con el aumento de la edad, los cultivadores de caña de azúcar tienen más aceptación de los procedimientos mecánicos que alivian la carga física de su trabajo pero, como revela este estudio, tales procedimientos a veces pueden tener consecuencias inesperadas. Antes de la intervención mecánica, las hojas muertas (basura) eran retiradas de las cañas antes de su transporte a la fábrica, por lo que permanecían en la finca donde posteriormente eran devueltas al suelo como materia orgánica. Con los nuevos procedimientos de deshoje, la basura se va a la fábrica junto con la caña, donde es compostada como subproducto del proceso de molienda. Además, anteriormente cada explotación conservaba su propia basura para el compostaje, ahora el tratamiento mecánico en la fábrica se ha traducido en desigual distribución y suministro a los agricultores de la basura compostada. Esto ha suscitado preocupaciones sobre el deterioro de la fertilidad del suelo, disminución de la productividad e inadecuada conservación del agua debido a la falta de materia orgánica en el suelo.

jou présent, révèle une réduction de la production de canne à sucre, une taille moyenne d’exploitation d’un hectare ou moins, et un âge moyen d’agriculteur de 65 ans ou plus. Les statistiques révèlent aussi que la succession de terre agricole et de la culture d’une génération à l’autre n’est pas une tradition durable. Avec leur âge croissant, les planteurs de canne à sucre ont mieux accepté les procédures mécaniques qui réduisent l’aspect ardu de leur tâche, mais ces procédures peuvent parfois avoir des conséquences inattendues, comme révélé par ce papier. Avant la mécanisation, la paille était enlevée avant le transport des cannes vers l’usine et restait sur l’exploitation où elle était retournée au sol comme matière organique. Avec la nouvelle procédure de dépaillage, la paille est enlevée à l’usine et compostée comme un sous-produit de l’usinage. De plus, quand précédemment chaque exploitation conservait sa propre paille pour le compostage, la procédure mécanique à l’usine a résulté en une distribution inégale de la paille compostée aux producteurs. Cela a suscité des inquiétudes à propos de la baisse de fertilité du sol, de la diminution de productivité et de la conservation inadéquate d’eau, dues à un manque de matière organique dans le sol.
STUDY ON FARMLAND APPLICATION OF VINASSE FROM SUGARCANE MOLASSES

KEYWORDS: Sugarcane Molasses, Pigment, Incubation Test, Tomato And Radish Cultivation.

Abstract
During bio-ethanol production from sugarcane molasses, large amounts of vinasse, which is strongly acidic with high COD and BOD, is produced as a by-product. Disposal of vinasse is one restrictive problem for sustainable bio-ethanol production. In this study, possible application of vinasse to farmland was investigated. First, the staple characteristics of vinasse were determined. Second, availability of nutrients such as nitrogen and potassium to crops and dynamics in the soil environment were studied in the laboratory and, thirdly, crop growth experiments were carried out in the field. In conclusion, 1) potassium is the most common nutrient in vinasse; 2) large amounts of chloride are also present; 3) high COD and pigment from rind of sugarcane were also observed. Farmland application of vinasse as a substitute for one third of the potassium showed no significant damage to the growth of red-raddishes and tomatoes. When large amounts of vinasse are applied to farmland as a substitute for the nitrogen in traditional chemical fertilisers, nitrogen deficiency symptoms, especially immediately after application, are expected. In addition, it is necessary to take into consideration the leaching of ions and the pigment in the vinasse for proper timing of application and soil conditions.

Introduction
Production of bioethanol from sugarcane molasses produces large amounts of vinasse, which is strongly acidic, and contains a high COD and BOD, as a by-product. Disposal is troublesome and restrictive for sustainable bio-ethanol production.

The objectives of this study were to determine the possibility of farmland application of vinasse based on the 1) characteristics of vinasse, 2) movement of organic nitrogen from vinasse in the soil, and 3) availability of potassium in vinasse by examining vegetables in laboratory and field experiments.

Materials and methodology

Vinasse
Vinasse was provided by Ryuseki Corporation in December, 2007. Vinasse was stored at room temperature until the experiments were performed.

Incubation test
The dynamics of nitrogen in the soil with vinasse or chemical fertiliser applied was investigated by an incubation experiment.

Shimajiri-maji soil (100 g) from the upland Miyako Island Branch of Okinawa Prefectural Agricultural Research Center was used in these experiments. Ammonium sulfate and vinasse (C/N ratio is 10.5) equivalent to 30 mg total nitrogen were added to the Shimajiri-maji soil. The soils were incubated at 30°C and soil moisture kept at 60%. NH₄-N, NO₃-N, and NO₂-N in the soil were measured every week.
Tomato and radish cultivation

The experiments were conducted at Kannodai, Tsukuba-shi, Ibaraki-ken, Japan. The experimental plots had been used to grow vegetables for several years. The tomatoes were planted on 12 May 2008 and harvested from 8 July 2008 to 29 August 2008. The red radishes were planted on 8 September 2008 and harvested on 12 November 2008.

Experiments (10 m² × 2)

(1) Tomato: control (only chemical fertiliser was applied), Red radish: control
(2) Tomato: vinasse (670 L/10a, 1/3 volume of potassium fertiliser replaced with vinasse) Red radish: control
(3) Tomato: control Red radish: vinasse (450 L/10a, 1/3 volume of potassium fertiliser replaced with vinasse)
(4) Tomato: vinasse (the same as experiment 2) Red radish: vinasse (the same as experiment 3)

Fertilisers:
Tomato: N: 30, P₂O₅: 20, K₂O: 30 kg/10a
Red-radish: N: 12, P₂O₅: 10, K₂O: 12 kg/10a

Measurements
Tomato: Weight of each fruit, Brix of fruit.
Radish: Weight of each radish leaf and root, Brix of radish root, and length and width of radish root.

Results and discussion

Characteristic of vinasse

The chemical propierties of vinasse are shown in Table 1. High contents of COD and TOC indicate a large amount of organic matter is included in vinasse. The characteristic of vinasse was content of COD Cr > content of COD Mn > content of BOD. BOD is the quantity of biodegradable organic matter. It was concluded that a large amount of decomposable organic matter was included in the vinasse. A problem is that some of the components, particularly those of darker colour are organic components which are difficult to decompose.

*Content of dissolved elements are shown in parentheses

The content of potassium in vinasse is high and most of it is dissolvable. It is easy to use as a potassium fertiliser. However, the content of chlorine in vinasse was even higher, indicating we must carefully consider salinisation.
Dynamics of vinasse nitrogen in the soil

Figure 1 shows changes in inorganic nitrogen of the soil. The incubation test, clearly showed that the NH$_4$–N in soil treated with chemical fertiliser was almost completely converted into NO$_3$–N within two weeks.

On the other hand, the inorganic N decreased 50% in the soil during the initial two weeks when vinasse was applied, but 30% of NO$_3$–N increased in the soil over a period of 48 days when vinasse was applied.

Therefore, nitrogen deficiency, especially just after application, can be expected when large amounts of vinasse are applied to farmland.

Tomato and radish cultivation

The yields, individual weights and Brix of tomatoes in each experimental plot are shown in Figure 2. Many small and middle sized fruits less than 200 g were harvested from the vinasse plot such that the average weight of tomatoes in the vinasse plot was lighter than the tomatoes in the control plot. The numbers of tomatoes in the vinasse plot was greater than in the control plot. As a result, the yield of tomatoes in the vinasse plot was higher than in the control plot. In addition, the sugar content of the tomatoes in the vinasse plot was slightly higher than in the control plot.

The total weight of red radishes, the ratio of the weight of the roots and leaves, and the length and width of the roots are shown in Figure 3.

The highest weight of red radish was in the control (vinasse) plot. In the other three plots, there were no significant differences in total weight and root weight of red radishes. It is apparent that tomato and red radish are not affected by the application of vinasse and chemical fertiliser.
Conclusion

This study dealt with the influence of application of vinasse to the soil on dynamics of nitrogen and tomato and red radish growth. The results showed there was no significant damage to red radish and tomato growth with substitution of one third of the potassium fertiliser requirement being substituted by vinasse. This indicated that vinasse can be substituted for potassium fertilisers. However, when large amounts of vinasse are applied to farm land, it is suspected that nitrogen deficiency, especially just after application, can be expected.

MOTS CLÉS: Mélasse de Canne à Sucre, Pigment, Tests d’Incubation, Culture de Tomates et de Radis

Résumé

PENDANT la production de bioéthanol à partir de la mélasse de canne à sucre, de grosses quantités de vinasse, qui est un sous-produit très acide avec un DCO et DBO élevés, sont disponibles. La disposition de la vinasse est une contrainte pour une production durable de bioéthanol. L’application de la vinasse aux terres cultivées a été évaluée dans cette étude. Les caractéristiques de base de la vinasse ont d’abord été déterminées. Deuxièmement, la disponibilité des nutriments tels que l’azote et la potassium à la culture et leur mouvement dans le sol ont été étudiés en laboratoire et troisièmement, des essais de croissance de la culture ont été mis en place dans les champs. Pour conclure, 1) la potasse est le nutriments principal dans la vinasse; 2) de grosses quantités de chlorure sont aussi présentes; 3) une forte DCO et des pigments provenant de l’écorce de la canne sont aussi observés. L’application au champ de la vinasse comme substitut pour un tiers des besoins en potasse n’a pas eu d’effets négatifs sur la poussée des radis-rouge et des tomates. Quand de grosses quantités de vinasse sont appliquées dans les champs, comme substitut à l’azote chimique, des déficiences d’azote sont attendues, surtout juste après l’application. De plus, le lessivage des ions, le pigment dans la vinasse ainsi que les conditions du sol doivent être considérés pour le calendrier d’application.
ESTUDIO SOBRE LA APLICACIÓN DE VINAZA DE MELAZA DE CAÑA DE AZÚCAR EN TIERRAS CULTIVABLES

Por

PALABRAS CLAVE: Melaza De Caña De Azúcar, Pigmento, Incubación, Prueba, Cultivo De Tomate Y Rábano.

Resumen
DURANTE la producción de bio-etanol a partir de melazas de caña de azúcar, se genera como subproducto gran cantidad de vinaza, la cual es fuertemente ácida y con elevadas DQO y DBO. La eliminación de la vinaza es un problema restrictivo para la producción sustentable de bio-etanol. En este estudio, se investigó la posible aplicación de vinazas a tierras de cultivo. En primer lugar, se determinaron las características básicas de la vinaza. En segundo lugar, se estudió en laboratorio la disponibilidad de nutrientes como el nitrógeno y el potasio para los cultivos y su dinámica en el entorno edáfico y, en tercer lugar, se llevaron a cabo en campo experimentos de crecimiento de cultivos. En conclusión, 1) el potasio es el nutriente más común en la vinaza; 2) también contiene grandes cantidades de cloruro; 3) se observó elevado DQO y pigmento de la corteza de la caña de azúcar. La aplicación de vinaza a tierras de cultivo de vinaza como un sustituto de un tercio del potasio no mostró ningún daño significativo sobre el desarrollo de rábanos rojos y tomates. Cuando grandes cantidades de vinaza son aplicadas a tierras cultivables como sustitución del nitrógeno contenido en los fertilizantes químicos tradicionales, se esperan síntomas de la deficiencia de nitrógeno, especialmente después de la aplicación. Además, es necesario tomar en consideración la lixiviación de los iones y el pigmento en la vinaza para encontrar el momento adecuado de aplicación y las condiciones del suelo.
A SUSTAINABLE FERTILISATION PROGRAM FOR A SUGAR FACTORY IN MEXICO: A PRINCIPLE FOR PRECISION AGRICULTURE

By

Colegio de Postgraduados – Campus Tabasco. Apdo.Postal 24. 86500 Cárdenas, Tabasco, México

salgados@colpos.mx

KEYWORDS: Saccharum officinarum, Fertiliser Recommendation, Precision Agriculture, Conceptual Model.

Abstract

This work was carried out to determine site-specific fertiliser application rates for the different types of soil in which sugarcane is cultivated in the sugar factory ‘Presidente Benito Juárez’ in Mexico. Cartographic soil subunits were identified through interpretation of aerial photographs, field observations, and soil sampling to a depth of 1.2 m. In each subunit, the agrologic profiles were described, and physical and chemical analyses were done to classify the soil according to the World Soil Map. Fertilisation rates (FR) of N, P₂O₅, and K₂O for each soil subunit were estimated using a conceptual model. This model is based on the balance of nutrient demand of the crop, nutrients supplied by the soil, and fertiliser efficiency. To estimate demand, dry matter production and N, P, and K accumulation of the sugarcane aerial biomass were determined. P and K supply was calculated from the results of soil chemical analysis, plus the N contributions from crop residues and their management. Three major soil groups were found and classified as subunits. The FR for each soil subunit were (N, P₂O₅, K₂O kg/ha): 120–60–80 for Cambisol Fluvic (Eutric Clayic), Cambisol Endogleyic (Clayic Eutric) and Cambisol Stanic (Clayic Eutric); 120–70–80 for Cambisol Endogleyic Stanic (Eutric Ferric) and Gleysol Haplic (Eutric Clayic); 160–80–80 for Vertisol Gleyic Stanic (Eutric); and 120–80–80 for Vertisol Stanic (Eutric). Fertiliser rates were adjusted based on the expected sugarcane yields for each soil subunits and soil fertility maintenance. We also generated a map of FR for each sugarcane field to allow producers to locate the relevant rate.

Introduction

‘Presidente Benito Juárez’ sugar factory (PBJ) is the largest in the Tabasco state of Mexico. From 1996–97 to 2006–07 harvest seasons, sugarcane area increased from 11 031 to 16 488 ha; during this period, the sugarcane yield (TCH) averaged 63.3 TCH and sucrose yields 6457 kg/ha. TCH at PBJ were lower than the national average of 77 TCH (CAÑEROS, 2008).

The climate is hot and humid [Am(i)’g], with annual average temperature of 26°C, and annual average precipitation of 2163 mm, with an altitude of 11 m. The soils are alluvial and lacustrine, deep, with high clay contents, poor in organic matter, with problems of superficial and internal drainage, their pH is slightly acid (< 5.5) and the topography is flat.

In the PBJ, the cane is burned for its manual harvest, it is loaded mechanically, and the transport is in trucks and carts.

After the harvest, the straw is burnt, the chisel plough is used, fertiliser is applied mechanically or manually, and weeds are controlled with application of herbicides and manually. The fertiliser application rate of 120–60–60 kg/ha of N, P₂O₅ and K₂O has been used for more than
34 years, regardless of sugarcane variety, level of yields and soil type. There is a need to improve the efficiency of the production process to increase sugar yields and to reduce production costs to make the PBJ factory more profitable. The sustainable fertilisation program of IPBJ was thus implemented through an Integrated System to Recommend Rates of Fertilisers (SIRDF), and the results are presented in this paper.

**Methodology**

The study was conducted from June 2005 to October 2008, using the SIRDF methodology performed in 6 phases (Salgado et al., 2008);

1. Polygons of Thiessen. With the annual precipitation data (mm) of nine climatic stations of the zone (data average of 29 years), previously geo-referenced on the soils map, the areas with similar precipitation were defined, using an interpolation process to form the polygons of Thiessen (Tabios and Salas, 1985). This procedure was performed digitally using Arc Gis 9 (ESRI, 2007).

2. Study of soils. The soils cartography was performed using the photo-interpretation of aerial photography on a scale of 1:75,000, and this information was transferred to a topographic map with a scale of 1:30,000. With the description of 24 profiles and the results of the physical and chemical analyses of the horizons, the classification of soils was completed according to the World Reference Base for Soil Resources (IUSS Work group WRB, 2007). The map of soils with a scale of 1:30,000 was elaborated using Arc Gis 9 of the ESRI.

3. Soil Sampling. 150 sugarcane plantations were selected and geo-referenced. In each plantation, a composite sample of soil of 0 to 30 cm of depth was obtained. The sampling was done in a zigzag formation; with a soil auger, three sub-samples were taken on the furrow and three in the inter-furrow. The samples were mixed and homogenised, and 1.5 kg of sample was used for analysis. The physical and chemical determinations were made in the Laboratory of Analysis of Soils, Plants and Waters of the Campus Tabasco-CP, with the methods described by NOM-021-RECNAT (2001). The data K interchangeable and P-Olsen were used to calculate the soil supplies with the models:

\[
SUP-N = (DEM-N*0.10) + NDS,
\]

where:

NDS: nitrogen derived from the soil = 50 kg/ha, according to the TCH obtained without fertilisation (Salgado et al., 1994).

\[
SUP-P = [P \text{ soil } (\text{ppm}) \times Ec] + [(MSS) (\text{PPF} \times 10)],
\]

where:

MSS: Dry matter of the straw; it is considered that 60% of these residues are mineralised and are those that can contribute P and K to the cane culture.

PPF: Phosphorus concentration of the foliar analysis (%).

Ec: the index of efficiency of the culture; it indicates that for each part per million (ppm) of P-Olsen, the culture absorbs 1.7 kg of P of the soils (Rodriguez, 1993).

\[
SUP-K = [K \text{ soil } (\text{ppm}) \times CK] + [(MSS) (\text{PKF} \times 10)],
\]

where:

PKF: Potassium concentration of the foliar analysis (%).

CK: the efficiency of potassium absorption; it indicates ppm of K interchangeable that the culture absorbs according to the type of soil, which is 1.4 for loam soils and 1.3 for argillaceous soils (Rodriguez, 1993).

4. The sampling of aerial biomass (stalk, tops and dry leaves) was conducted at 11 months of age in the same sites where the soils samples were obtained. A linear metre of cane was harvested and weighed (kg), the biomasses were separated into straw (top+dry leaves) and stalk, and were sampled separately; 400 g of each sample were dried in the oven to determine dry matter. The samples were ground to 2 mm, the chemical analyses of N, P and K were made...
in the LASPA-Campus Tabasco, with the methods of Jones et al. (1991). The dry matter of stalk and straw was used to calculate the demand of N, P and K for soil subunits.

\[
\text{DEM (kg/ha)} = \frac{\text{MSS (kg/ha)}}{100} \times (\% \text{ nutrient straw}) + \frac{\text{MSST (kg/ha)}}{100} \times (\% \text{ nutrient stalk})
\]

where:

MSST = Dry matter of the stalk

The weight of stalk was used to calculate the TCH. The potential TCH corresponded to the maximum yields of cane obtained by soil subunits.

5. Determine fertiliser rates using the conceptual model; Rate of Fertiliser = (Demand - Soil Supplies)/Efficiency (Rodriguez, 1993).

The efficiency for N is 50% (Garcia, 1984), for phosphorus 30 and 40% in argillaceous and loam soils respectively, and for potassium 60% in argillaceous soils (Salgado et al., 2005; Bolio et al., 2008).

6. Generate recommendations for a fertiliser program, considering soil subunits, soil pH, fertiliser source and costs of fertilisers (Salgado et al., 2006).

Fig. 1—Areas of differing precipitation near the PBJ factory’s supply zone.

Results and discussion

Thiessen polygons

Five polygons were identified, with precipitation ranging from 1640 to 2227 mm/year (Figure 1). These defined areas are useful for scheduling the harvest and irrigation in the study area (Tabios and Salas, 1985), as areas with more precipitation require less irrigation.
Soil study

Figure 1 also presents the soil subunits found in the study area. The specific soil subunits identified were Cambisol Fluvic (Eutric Clayic), Cambisol Endogleyic (Clayic Eutric), Cambisol Stanic (Clayic Eutric), Cambisol Endogleyic Stanic (Eutric Ferric), Gleysol Haplic (Eutric Clayic), Vertisol Gleyic Stanic (Eutric), and Vertisol Stanic (Eutric) (IUSS Grupo de Trabajo WRB, 2007).

Compaction in upper soil horizons, high clay content, humidity retention, low infiltration, little soil slope, low CEC, medium to low organic matter content and assimilable phosphorus, and slightly acidic pH are the main soil factors limiting sugarcane yields in PBJ factory’s supply zone.

Fertilisation rates

The demand for N and K showed great variation between soil subunits, contrary to the supply of these nutrients, indicating possible extractive differences between cultivated varieties of cane; when combined with the low yield, it produced an underestimation of the demand for N, P and K (Table 1).

TCH of soils described above is (in decreasing rank): Vertisol > Cambisol > Gleysol. However, Cambisols with high clay content have reduced TCH. The nutrient supply from these soils is K>N>P (Table 1).

</table>

SD: Standard deviation
The 0.40 straw/stalk ratio indicates a poor crop development, with stalk showing a lower nutrient concentration for Ca and Mg (data not shown).

In the straw, the concentrations of N, P, K and Mg were low in comparison with those reported for ‘Santa Rosalía’ factory (Salgado et al., 2005); indicating that the soils are of low fertility.

The fertiliser rates estimated from the conceptual model (Table 1) were lower in P and K than the recommended rate of 120–60–60 used by the PBJ factory (Rojas et al., 1984), and the rates of fertilisers 240–60–240, 240–30–240, 240–30–120, and 240–60–120, recommended for yields 100 to 120 t/ha in PBJ sugar factory (Ortiz, 2005).

If the drainage of the soils is improved, TCH will be increased; for that reason, rates of the conceptual model were fitted on the basis of the potential TCH (Table 2), with the contents of P and K of each soil subunit.

The experimental results obtained through field tests indicated that there is no response to higher rates of 80 kg/ha for both K₂O and P₂O₅ (Salgado et al., 2003). The fertiliser sources 17–17–17 and Urea are recommended in order to supply the nutrients required by the crop (Table 2), and this option is a more economic fertiliser source (Salgado et al., 2006).

Figure 2 shows the distribution of rates of fertilisation adjusted for the PBJ factory supply zone.

### Table 2—Rates of fertilisation recommended for the PBJ factory’s supply zone, according to the soil subunits of ground; yield and cost.

U: Urea, SPT: Triple Calcium Superphosphate, KCl: Potassium chloride, 20-10-10 EM and Triple 17: Complex enriched with micronutrients.

The costs are calculated to 01/08/2008 in Mexican pesos (1 USD=12.5 Mexican pesos).
**Conclusions**

Five Thiessen polygons were established based on precipitation for the PBJ factory supply zone. Soil subunits identified in the study area are Cambisol Fluvic (Eutric Clayic), Cambisol Endogleyic (Clayic Eutric), Cambisol Stanic (Clayic Eutric), Cambisol Endogleyic Stanic (Eutric Ferric), Gleysol Haplic (Eutric Clayic), Vertisol Gleyic Stanic (Eutric) and Vertisol Stanic (Eutric). The fertility diagnosis established that soils in the PBJ factory supply area have low fertility, the limiting factors being: compaction, excessive clay, humidity, and superficial acidity. Biomass sampling revealed a straw/stalk ratio of 0.40 which is considered inadequate and accounts for the low TCH. Four fertiliser rates were formulated, which take into account soil subunit features and a precision agriculture map generated for the PBJ factory supply zone.

**Acknowledgements**

Thanks are extended to Fundación Produce Tabasco, A.C. and the Committee of Production and Sugarcane Quality of the PBJ factory’s for its economic and logistical support.

Resumen

Este trabajo realizó para determinar índices de aplicación de fertilizante para los diversos tipos de suelo en que se cultiva caña de azúcar en la fábrica ‘Presidente Benito Juárez’ en México. Se identificaron subunidades cartográficas de suelo, por medio de la interpretación de fotografías aéreas, observaciones de campo y muestreos de suelo a una profundidad de 1.2 m. En cada subunidad, los perfiles agrológicos se describieron y se realizaron análisis físicos y químicos para clasificar el suelo de acuerdo al Mapa Mundial de Suelo. Se estimaron los índices de fertilización (FR) de N, P₂O₅ y K₂O para cada subunidad de suelo utilizando un modelo conceptual. Dicho modelo se basa en el balance de demanda de nutrientes del cultivo, nutrientes aportados por el suelo y eficiencia del fertilizante. Para estimar la demanda, se determinó la producción de materia seca y acumulación de N, P y K en la biomasa aérea de la planta de caña de azúcar. Se calculó el aporte de P y K de los resultados del análisis químico de suelo y el del N proporcionado por los residuos del cultivo y su manejo. Se encontraron tres grandes grupos de suelos y se clasificaron en subunidades. El índice para cada subunidad de suelo fue (N, P₂O₅, K₂O kg/ha): 120–60–80 para Cambisol Fluvic (Eutric Clayic), Cambisol Endogleyic (Clayic Eutric) y Cambisol Stanic (Clayic Eutric); 120–70–80 para Cambisol Endogleyic Stanic (Eutric Ferric) y Gleysol Haplic (Eutric Clayic); 160–80–80 para Vertisol Gleyic Stanic (Eutric); y 120–80–80 para Vertisol Stanic (Eutric). Los índices de fertilizante se ajustaron con base en los rendimientos esperados para cada subunidad de suelo y el mantenimiento de la fertilidad del suelo. Además, se generó un mapa del índice FR de cada plantación para permitir a los productores localizar el índice de su interés.
DIVERSIFICATION OF SUGARCANE VARIETIES FOR CATTLE FEED AND SUSTAINABILITY

KEYWORDS: Cattle Feed, Digestibility, Dry Matter, Soils, Abiotic Stress.

Abstract

The paper reports results of a study of 44 sugarcane genotypes, evaluated as cattle feed, at 13 months of age, in the first ratoon crop, at Villa Clara–Cienfuegos Territorial Sugar Cane Research Station and the Sancti Spíritus National Breeding Center in Cuba. Fourteen traits were evaluated by means of multivariate analyses (Principal Components and Discriminant Function), and also a simulation was conducted of agro-ecological regionalisation for the allocation of the sugarcane varieties according to the main limiting factors (drought and poor drainage) on a cattle producing farm. Results showed that the variables, percentage of stalk fresh weight (% of stalks) and of tops (% of tops), had high influence in the first principal component, whereas the genetic disease (smut and rust) resistance had high influence in the second component. It should be pointed out that the percentage of digestibility of the dry matter showed very little variability, which indicates a high stability of this trait. The Discriminant Function Analysis allowed classification of cultivars into three groups: varieties of low forage value (below 40% digestibility of the dry matter), varieties of intermediate forage value (between 40–50%) and varieties of high forage value (above 50% digestibility). Results allowed the recommendation of 21 new genotypes, characterised by their resistance to main diseases and their high forage value, and nine were superior to the control My5514, four suitable for waterlogging stress and three for drought stress. The simulation of the agro-ecological regionalisation enabled spatial location and modelling for the appropriate establishment of individuals, in agreement with their digestibility, tolerance to the two environmental stresses (waterlogging and drought) and their disease resistance.

Introduction

Population growth is a problem in the world today. It is probable that population will increase to 830 000 in 2025 (FAO, 1998).

This must be viewed in the context of a decrease in the area of arable land committed to food production because of competition for application of pasture and grain crops to energy production.

Mankind has knowledge and technologies to confront this crisis, but policies of unequal distribution of wealth have resulted in some negative environmental and social impacts (FAO, 1996).

Sugarcane constitutes an alternative to be used for animal nutrition. Countries like Colombia, Brazil and Costa Rica maintain that the technical and biological basis exists to use sugarcane to replace cereals in intensive animal production systems, thus allowing the release of great quantities of foodstuffs for mankind.
This paper was developed to characterise a group of varieties of sugarcane for use as animal food and for identifying suitable agro-ecological environments for them to be used as cattle producing units.

**Materials and methods**

The study was developed in two provinces of the country (Villa Clara and Sancti Spíritus) at the Sugar Companies Ifraín Alfonso and Melanio Hernández, in soil Eutric Cambisol (FAO – UNESCO, 1994).

Forty-four recently recommended new varieties of sugarcane from the Sugarcane Research National Institute for Sugar Production were studied.

The plots were of 64 m$^2$, with five replications in the first ratoon crop harvested at 13 months of age. Fourteen variables relating to crop morphology and the probable relationship with the digestibility of the biomass were evaluated.

Genetic resistance against two important diseases, brown rust and sugarcane smut, was also quantified.

The digestibility of the dry matter of each variety was determined by the *in vitro* technique of KOH (Kesting, 1977).

The statistical analysis was performed using the multivariate analyses of Principal Components and Discriminant Functions, in which the digestibility of the dry matter was used like a group variable, with three groups: $<40\%$, $>50\%$ and the correspondent interval.

The varietal performance was assessed by comparing means of the percentage digestibility of dry matter with the control variety My5514.

The software MapInfo 8.0 was used for the agro-ecological zoning simulation on a cadastral base map of 1:10000 scale.

The utilisation of 90% of the area of the unit was assumed for cattle raising, and the distribution of the nutrition of the cattle mass was distributed in the following way: 57% improved pasture land, 26% King Grass (CT–115) and 17% sugarcane for animal nutrition.

We also took into account soil types in relation to the impact of physical properties such as soil depth, water holding capacity and drainage capacity on the suitability for production of the various sugarcane varieties.

Then we established the following premises: to obtain a fodder balance for fattening 1880 head of bulls to a finished live weight of 450 kg, equivalent to 1692 units of greater cattle (UGC), that represent one charge of two cattle per ha.

We considered that sugarcane fulfills 43.7% of the requests for foodstuff in the period of minor availability (212 days).

**Results and discussion**

Of the 14 variables used for the evaluation of the use of the variety of cane as an alternative for the feeding of cattle, Principal Components Analysis indicated that 9 of the variables across three factors contributed 64% of the total variation (Table 1) and they were considered sufficient in that objective.

The proportion of variance explained by top stems and the stems of the total biomass allowed separation of the varieties and allowed recommendation of more disease resistant and productive varieties than the standard commercial clone.

In the second component, the digestibility of the dry matter was ranked as the next most important variable (Eigenvector 0.43) after the previous variables.

These results explained enough of the variation to allow easy selection of suitable varieties.

</tbody>
</table>

The result of 76.7% of good classification from Discriminant Function Analysis (Figure 1) corroborated the importance of the morphologic and physiological variables that were used in the evaluation of the varieties as possible indicators of the fodder value.

The results agree with those of Suárez (2002) who considered varieties to be acceptable for the nutrition of cattle if digestibility of dry matter were greater than 50%.

Twenty one of the 44 genotypes showed more than 50% digestibility of dry matter and tolerance to the principal sugarcane diseases (Table 2).

These can be used for animal nutrition (Jorge et al., 2002). Thus a range of suitable varieties of sugarcane are available for commercial production.

The dendrogram representative of automatic classification of the 21 cultivars presenting higher digestibility of dry matter over 50% allowed the observation of two groups, which passed the threshold of 2.36. The first (group 2), that included the tester cultivar My5514, was characterised by a higher phenological relation of top and dry leaves than the other group, for which the digestibility was higher (Figure 2).
Table 2—Characteristics of the 21 varieties that were similar or better than the control variety for digestibility %.

DMS = Digestibility dry matter, IRT = Increment in relation to the control varieties, SP = Stems percentage, STP = Top stems percentage, R = Resistant, I = Intermediate, S = Susceptible, *= Control variety.

Fig. 2—Dendrogram of the classification of the cultivars.
According to Paretas (1990), 40% of the Cuban cattle area is susceptible to drought stress, because of low water holding capacity of the soils, and this contrasts with the 30% of the area that is poorly drained (Figure 3).

Nine of the varieties from this study can be used for animal nutrition in areas of cane production subject to abiotic stress, C89-176, C86-503, C86-12, C86-165, C90-530 to drought and C137-81, C86-503, C132-81, C86-12, Co997 for poor drainage, and they are likely to be important in those regions.

Simulation of zoning agro-ecological
The varieties, C86-12 and C132-81, were located in a 40.4 ha area of bad drainage and C90-530 in an adjoining 36.1 ha, also with poor drainage (Figure 4). Areas of 30.3 and 34.2 ha of soils potentially affected by drought were planted to C90-317 and C89-176, respectively (Figure 4).
Conclusions

- The percentage of fresh weight of the stem and percentage of the fresh weight of the top stem in sugarcane biomass, along with resistance to rust and smut, were the variables which best characterized the studied population for variability in the percentage of dry matter digestibility. This enabled the selection of varieties for use in the animal nutrition.

- The classification of the varieties for the percentage of the digestibility of dry matter showed that 21 of the 44 varieties had more than 50% digestibility, making them suitable for use in the nutrition of cattle.

- The agro-ecological zoning allowed the varieties to be recommended for locations that matched tolerance of drought or waterlogging stresses.

DIVERSIFICATION DES VARIETES DE CANNE A SUCRE POUR L’ALIMENTATION ANIMALE ET LA DURABILITE

Par

H. JORGE, O. SUÁREZ, H. GARCÍA, I. JORGE et L. BENITEZ
Instituto Nacional de Investigaciones de la Caña de Azúcar, Habana, Cuba

hector@inica.minaz.cu

Resume

Ce papier rela te le s r é sultats d’u ne étude su r 44 génotypes de canne à sucre, évalués pour l’alimentation animale à l’âge de 13 mois en première repousse, à la station territoriale Cienfuegos de recherche sur la canne à sucre de Villa Clara et au centre national de création variétale de Sancti Spiritus à Cuba. 14 traits furent évalué s a u moyen d’analys es multivar iées (Analyses en composantes principales et discr iminante) et une sim ulation de ré gionalisation agro-écologique fut aussi réalisé é. Cette d é rnière co ncerait l’allocation des variétés se lon le s f acteurs lim itants principaux (sécheresse et faible drainage) sur une ferme d’élevage. Les résultats montrèrent que les variables, teneurs en eau des tiges (%) et d es sommets (%) avaient une influence importante sur la première composante principale, tandis que la résistance aux maladies (rouille et charbon) avait une
influence importante sur la seconde composante. On a remarqué que le pourcentage de digestibilité de la matière sèche pré sentait peu de variabilité, montrant ainsi une grande stabilité de ce trait.

L’analyse discriminante a permis de classer les variétés en trois groupes: des variétés à valeur fourragère faible (en dessous de 40% de digestibilité de la matière sèche), les variétés à valeur fourragère intermédiaire (entre 40% et 50%) et les variétés à haute valeur (supérieures à 50% de digestibilité). Les résultats permirent d’établir des recommandations pour 21 nouveaux génotypes caractérisés par leur résistance aux principales maladies et leur faible valeur fourragère, pour 9 variétés qui étaient supérieures au témoin My5514, pour 4 variétés résistantes à l’excès d’eau et pour 3 variétés résistantes à la sécheresse. La simulation de la zonification agro-écologique a permis une distribution spatiale des individus appropriés à chaque localité, pour leur digestibilité, leur tolérance à deux stress environnementaux (excès d’eau et stress hydrique) et leur résistance aux maladies.

DIVERSIFICACIÓN DE LAS VARIEDADES DE CAÑA DE AZÚCAR PARA EL GANADO, ALIMENTACIÓN Y LA SOSTENIBILIDAD

Por

H. JORGE, O. SUÁREZ, H. GARCÍA, I. JORGE y L. BENITEZ

PALABRAS CLAVES: Ganado, Alimentación, Suelos, Estrés Abiótico.

Resumen

SE PRESENTAN los resultados del estudio de 44 genotipos de caña de azúcar evaluados con 12–14 meses de edad en la cepa de retoño en suelos Pardos con carbonato (Cambio eútrico) de la Estación Territorial de la Caña de Azúcar (ETICA) Villa Clara-Cienfuegos y el Centro Nacional de Hibridación de Sancti Spíritus (CNH), con vista a su recomendación para la alimentación animal. Se evaluaron 14 caracteres mediante Análisis Multivariado (Componentes Principales y Factorial Discriminante), también se realizó una simulación de zonificación agroecológica para la ubicación de las variedades de caña de azúcar, de acuerdo a los principios factores limitantes (sequía y mal drenaje) de una unidad productora de ganado vacuno. Los resultados reflejan que las variables porcentaje del peso fresco del tallo (% de tallo) y el cogollo (% cogollo) tuvieron una alta influencia en la primera componente, mientras que la resistencia genética a las enfermedades (carbón y roya) lo fueron para la segunda. Es de destacar que el porcentaje de digestibilidad de la materia seca muestra muy poca variabilidad, lo que puede indicar un alto estabilidad de este carácter. El Análisis Discriminante permitió clasificar los cultivares en tres grupos: Variedades de bajo valor forrajero (menor de 40% de la digestibilidad de la materia seca), Variedad de medio valor forrajero (entre 40–50%) y Variedades de alto valor forrajero (mayor de 50%). Los resultados permitieron recomendar 21 nuevos genotipos caracterizados por su resistencia a las principales enfermedades y su alto valor forrajero, donde 9 de ellas se adaptan a condiciones de estrés ambiental. La simulación de la zonificación agroecológica permitió la ubicación espacial y la modelación en cuanto al correcto establecimiento de los individuos en correspondencia a su tolerancia con los factores limitantes antes mencionados.
STRATEGIES FOR THE OPTIMAL USE OF NITROGEN FERTILISERS IN THE SUGARCANE CROP IN GUATEMALA

KEYWORDS: Nitrogen, Optimisation, Green Manure, N Biological Fixation.

Abstract

The objective of this work is to present practical criteria that will help sugarcane growers to optimise their investment in nitrogen fertilisers in the sugarcane crop in Guatemala. The importance of this objective is in relation to the general increase of fertiliser price and particularly of nitrogen fertiliser. The criteria are based on knowledge of crop response to N application in the region after 14 years of experience in research on the topic. Crop N response is a function of cane yield, soil fertility, crop age or crop cycle and other variables associated with agronomical practices and soil condition. As a result, N rate used in sugar mills’ fertilisation programs can be adjusted by comparing the current relation of kg of nitrogen per tonne of cane (N:TC), with reference ratios recommended for different soils according to organic matter content (OM) and other factors. Besides, N rates must be adjusted to fertiliser and sugar price for different production groups. As an alternative to reduce dependence on nitrogen fertilisers, there are practices that must be taken into account and be optimised in the short term. These practices consist of usage of species of green manure adapted to the intercropping system, the use of co-products and, in the mid and long term, there is potential for N biological fixation in the sugarcane crop.

Introduction

Nitrogen use in Guatemala is generalised in the sugarcane production as in most cane producing countries. In Guatemala, it is estimated that, in the 2006–07 harvest season, there were approximately 20 000 tonnes of nitrogen applied over 210 000 hectares (Pérez, 2007). The nitrogen fertiliser item is gaining importance in the crop production cost because of the increase in nitrogen fertiliser price that, only in the past year (2008), increased over 80% while the sugar price stood relatively constant. Under these circumstances, sugar mills have seen themselves forced to make adjustments in their budgets, requiring an effective and judicious use of fertilisers to ensure maximum advantage of investment.

The objective of this work is to present some practical strategies for sugarcane growers to support their decision-making process to maximise investment on nitrogen fertilisers, beginning with current fertilisation programs and presenting some options that will help in the future to reduce dependence on chemical fertilisers.

Generalities of Guatemala sugarcane region and yield potential

Based on the physiographic features that respond to a natural landscape of plain terrain and foothill, there is a gradient in terms of temperature, amount of rainfall, solar radiation, forms and slopes of terrain and presence of Allophane in soils, varying from the proximity to the mountain
chain towards the Pacific Ocean, in a North–South direction. These gradients are captured with regional altitudinal stratification and are expressed in yield potentials of sugarcane as shown in Table 1. Table 1 shows that the higher yield potentials are in the lower zones of the region decreasing with altitude where there is lower temperature, more cloudiness associated with higher rainfalls, soils with undulating relief, and there are greater amounts of Allophane clays (Andisols).

There is a particular relationship between OM and cane yield under the sugarcane growing area of Guatemala. The OM contents are greater in the middle and higher zones of the region in which Andisol soils predominate and decrease in the coastal zone in Mollisol and Entisol soils. Although amounts of OM in Andisol soils are higher, they are not associated with greater yields. This is because of the presence of other limiting factors like climate, terrain relief and soils that make yield potentials in these soils lower.

There are features in Guatemala’s sugarcane zone regarding the relationship between altitude, climate, relief and soil and their relation with yield. The results are interesting when yield is stratified in ranges for the estimation of fertiliser doses as is currently made in mills, simultaneously with other factors associated with these yields.

### Crop response to N application

With regard to soil fertility, it has been found that, in the sugarcane region of Guatemala, the OM is a factor that explains responses of nitrogen applications (Table 2).

Data in Table 2 show that, in 94% of cases, an increase in tonnage is achieved (higher than 20%) when OM contents in soil are lower (OM <3.0%) whereas, in soils with higher OM contents (>5.0%), in 100% of the cases the increase is lower than 11%.

In soils with medium OM content, responses were variable, but in most of the cases they were lower than 20%. As was indicated before, lower values of OM are found in the coastal zone where high yield Mollisol and Entisol soils are located which are the areas with high response to nitrogen.

In Table 3, nitrogen dose recommendations for Guatemala sugarcane zone are presented, based on defined OM criteria and crop responses found in plant cane and ratoon cane in different experimental and validated tests carried out by sugar mills (Pérez, 2007; La Unión Mill, 2005).

Nitrogen recommendations for plant cane crop varies from 60 to 80 kg of N/ha whereas, in ratoon crops, recommendations are higher depending on OM in soil and yield potential of the sugarcane plantation.

In soils with lower OM content (<3.0%), it has been found that there is a need of 1.14 kg of N per tonne of produced cane (Nitrogen Cane Tonne Ratio: N:TC) whereas, in soils with medium and high OM contents, N:TC ratio is lower (1.0) (Perez, 2007). These two values from now on will be named Reference N:TC ratios.

N recommendations (kg/ha) for different OM categories in Table 3 indicate the fluctuation in nitrogen doses in less productive plots (doses lower range) to more productive plots (doses higher range).

Nitrogen dose adjustment according to N:TC ratio

Nitrogen doses adjustment in current fertilisation programs involves a better way to optimise investment in chemical fertilisers used in sugar mills, avoiding overdose in lower response areas and adapting doses in areas that have higher probabilities to respond.

Given that nowadays all of the Guatemalan sugar mills use sugarcane plantation yield criteria and crop age to establish N doses to be used in defined fields, it was decided to review current N:TC ratios adding OM content as a decision criterion in recommendations.

This criterion is expected to result in N dose adjustments that will have greater economical impact on fertilisation programs mainly in ratoon crops given by the variability that exists in N:TC ratios for the same cane yield range (same yield group).

Current ratio variations will depend on range cane yield amplitude that is being used, and it would be wider variation in cases where only two categories exist (high and low yield).

Nitrogen dose adjustments will depend on crop cycle. In plant cane, adjustment has less impact, due to the fact that sugar mills currently fertilise according to the recommendations given in Table 3; however, a different situation applies in ratoon crops.

Table 4 shows a typical case of ratoon cane where the current fertilisation program is based exclusively on cane yield (TCH) with three different groups: low (< 90 TCH); intermediate (90–110 TCH) and high (>110 TCH) with applications of 100, 120 and 140 kg of N/ha respectively.

As a result, N:TC ratios vary from >1.12, 1.33 to 1.09 and < 1.26 for the three yield categories: low, intermediate and high, respectively.

Inside the three main groups of TCH, N:TC ratios increase as yield decreases, due to the fact that N dose remains constant. Variations in N:TC are greater as yield ranges are extended.

1Current relation N:TC ratios = Current N dose/TCH intra-group.

As mentioned, current fertilisation programs generally are based only on TCH categories. However, N dose adjustment is proposed according to N:TC ratio based on OM content applied in four categories. Table 5 shows an example of how to optimise N:TC ratio variability, introducing first a new approach consisting of an extra cane yield category into the current intermediate category and second by using as a reference OM contents of the soil. The reason why two new intermediate categories are proposed is because the average TCH of the Guatemala industry is in this range. Thus, as a result, the new intermediate category groups have more yield data, so any variation will have better impact on adjustments.

Table 5—Adjusted N doses by using Reference N:TC ratios and intra-group variation of N:TC ratios adding a new cane yield category.

1Adjusted N dose = estimated from superior TCH in each Intra-group multiplied by respective reference N:CT ratio (1.14 and 1.00). 2Adjusted N:TC ratio = Adjusted N dose/TCH intra-group.

In Table 5, it is observed that splitting the intermediate original category (90–110 TCH) in two: from 90 to 100 and from 101 to 110 TCH and adjusting N dose with Reference N:TC ratios 1.14 and 1.0 for soils with OM < 3.0% and soils with OM > 3.0%, respectively, a better balance of N doses is achieved. It is also observed that, in soils with high OM content (> 3.0%), N recommendations are reduced significantly compared to the original recommendations shown as current N doses (kg/ha) in Table 4. Additionally, for soils with less than 3.0% OM, N recommendations are better distributed when four TCH classifications are considered.
Obviously better adjustments could be achieved by introducing more categories to fertilisation programs. N recommendations would be advisable to the parcel level (specific site recommendations). The above improvements can be obtained by taking into consideration that all Fertilisation Programs must be operative and functional based on real possibilities and that the programs have economic feasibility.

It is advisable that each Guatemalan sugar mill reviews its current fertilisation program and then makes the necessary recommended N dose adjustments. Afterwards, the recommended programs must be adjusted slightly according to particularities inherent to site and agronomical management. Finally, it is important to emphasise the need for review and supervision of applications in order to make them correctly, including calibration of fertiliser machines, the seasons, and methods of fertiliser application.

**N dose review as a function of fertiliser price variations**

N optimal economic doses (NOED) must relate to N price variations and current sugar prices. However, this NOED variation with given prices changes depending on crop N response. When N response is high, NOED variation is smaller than in lower responses. In Table 6, NOED adequacy from one year to another according to fertiliser and product price update for different N response in terms of OM in soils is presented.

**Table 6**—NOED variation from 2007 to 2008 according to N price variation.

</table>

\(^{1}\)Price relationship I/P = Price relationship of: US$ 1qq Urea/US$ 1 t of cane. \(^{2}\)NOED: Nitrogen optimal economic dose: Estimated from regression functions for soils with low, medium and high OM content.

When the price of a quintal (45.45 kg) of fertiliser increases from US$19 to $35 and in the presence of a relatively constant sugar price (in price per tonne of cane terms), NOED are reduced invariably. Nevertheless, NOED percentage reduction is lower in high N response soils (OM < 3.0%), 8% reduction compared with a 13% reduction necessary for soils with lower response (OM >5.0%).

**Alternatives to reduce dependence on chemical nitrogen fertilisers**

Options and practices that can be mentioned and used to reduce the crop’s nitrogen fertiliser need are: green manure, vinasse, filter mud, and biological nitrogen fixation.

**Green manure use**

Green manuring constitutes one of the most viable options to reduce sugarcane crop N use, and it is a practice that helps improve cane yield and sustainability. Introduction of a leguminous crop in a conventional sugarcane system brings a series of direct and indirect benefits on breaking sugarcane monoculture (Garside and Bell, 1999; Wiseman 2005).

*Crotalaria juncea* and *Canavalia ensiformis*, planted as green manures in sugarcane nurseries as a crop rotation, allow 100% of nitrogen fertilisation savings, with an expected increase of cane seed production. In Guatemala, in a Mollisol soil, four and 11% cane seed yield increases were obtained when *C. juncea* and *C. ensiformis* were rotated in relation to the control without
rotation (Cengicaña, 2009). In Australia, increases are reported of 20 and 30 percent of tonnage with soybean and peanut rotations in sugarcane plantation renewals. (Garside et al., 2001)

In Guatemala, under an superficial Andisol, it has been demonstrated that C. juncea monoculture could accumulate up to 235 kg of N/ha in its aerial bio-mass in only 65 days, while C. ensiformis N accumulation is slightly slower (175 kg of N/ha) (Pérez et al., 2008). On the other hand, it has been shown that C. ensiformis, intercropped between sugarcane rows in plant cane and ratoons, could be an option in high OM content soils such as superficial Andisols in the region (Table 7).

Table 7 shows that cane yield was not affected by the intercropping of any of the legumes as compared with the control, even when they were not chemically fertilised. Rather, it appears that cane yields were on average slightly higher (though not significant at P: 0.05) than the control at the end of four years, particularly with Canavalia.

</tr>
</tbody>
</table>

In any column, means followed by a common letter are not significantly different (Tukey 0.05).

Green manures represent a great potential in sugarcane crop N savings. In the short term, it is recommended to initiate these practices in sugarcane nurseries, because their designated areas are without any use for three to four months. In the sugarcane crop of Guatemala, the potential of this technique is estimated to be the 5000 hectares which are designated for nurseries in a year. While leguminous management is becoming familiar and experience is achieved, the thought of its use will be possible in renewable areas where there is time pressure between harvest and planting a new plantation, and more research will be needed. Finally, the intercropping system will have to be focused in marginal areas where sugarcane growth is slower due to limiting climatic conditions, and in areas susceptible to erosion and pests and diseases.

Vinasse use

Vinasse is an industrial residue from the alcohol distillation process and basically it is made up of water, OM and mineral salts. It is being used in sugarcane crop fields because it increases yield, reduces fertiliser use and, generally, improves soil. (Pennati et al., 2005)

Possibilities of reducing N doses used in sugarcane crop fields with vinasse could be important. Table 8 presents an average of TCH observed in four years with different and successive vinasse applications under different N doses in a Guatemalan sugarcane Andisol.

<table>

<td>118.0 (a)</td>
<td></td>
</tr>
</tbody>
</table>

³The means of this column are interpreted separately from 0, 50 and 100 N (kg/ha)

Means followed by a common letter are not significantly different (Tukey 0.05)
In Table 8, it is observed that, in absence of vinasse, tonnage increased with variable N doses from 103.8 to 111.1 TCH with 0 and 100 kg of N/ha respectively. However, in presence of any vinasse level applied, the effect of nitrogen is lower.

Although the nitrogen content of the vinasse is low, it is possible that the addition of this energy-rich material in soils with high carbon content such as Andisols of Guatemala has a ‘priming’ effect, thus increasing the availability of nitrogen to the crop.

On the other hand, trying to explain why there is a positive effect due to increased vinasse applications, there is an indication that the effluent is contributing to the nitrogen crop needs and it would be correcting at the same time other limiting nutrients in these soils.

Due to the fact of existing soil diversity in Guatemala, it is recommended to have wider evaluations and validate promising treatments at semi-commercial levels in order to reduce N doses where vinasse is applied. This approach will help growers to have information in the short term for their decision-making process over N optimisation and vinasse use.

**Nitrogen biological fixation**

N biological fixation (NBF) in sugarcane crops is a recent and interesting subject due to the great potential depicted by crop nutrition and nitrogen economy. NBF in sugarcane is supported by the discovery of endophytic diazotrophic bacteria, being *Gluconacetobacter diazotrophicus*, the most studied species related to the process.

The most recent progress refers to the end of the *Gluconacetobacter diazotrophicus* genome sequence (Guedes et al. 2008). In the near future, this advance will allow information about bacterial genes interaction with sugarcane genotypes. When the gene decoding process is finished, it will be possible to increase NBF efficiency using Biotechnology (Segundo Urquiaga, personal communication).

In Guatemala, *Gluconacetobacter* sp has been isolated in most sugarcane cultivars, and it has been found that some cultivars like PGM89-968, at an experimental level, is capable of obtaining 50% or more N via NBF (Pérez et al. 2005)

**Conclusions**

The use of reference N:TC ratios of 1.14 and 1.0 for soils with OM<3.0% and soils with OM>3.0% respectively as a decision criterion in nitrogen recommendations permit the optimisation of the investment in chemical nitrogen fertiliser in the sugarcane crop in Guatemala. On the other hand, N doses must be adjusted to fertiliser and sugar prices according to crop N response.

To reduce dependence on nitrogen fertilisers, there are practices that must be taken into account and be optimiced in the short term.

These practices consist of usage of species of green manure adapted to the intercropping system, the use of co-products and, in the mid and long term, there is potential for nitrogen biological fixation in the sugarcane crop.

Résumé

L’OBJET de ce travail est de présenter des éléments pratiques qui aideront les producteurs de canne à sucre à optimiser leur investissement en matière d’engrais azotés pour la culture de la canne à sucre au Guatemala. Cette étude est importante à cause de l’augmentation générale du prix des engrais et plus particulièrement celui de l’engrais azoté. Les critères ont basés sur la connaissance de la réponse de la culture à la fertilisation azotée dans la région après 14 années de recherche sur le
La respuesta a la azote es función del rendimiento de cana, de la fertilidad del suelo, de la edad y del ciclo de la cultura, así como de otras variables en relación con las prácticas agronómicas y el suelo. Ainsi, el nivel de fertilización azotada en uso en los programas de fertilización de las industrias sucrieras puede ser ajustado en comparación con la cantidad de azote en kg por tonelada de cana (N:TC), con tasas de referencia recomendadas para diferentes tipos de suelo según su contenido en materia orgánica (OM) y otras factores. Paralelamente, las cantidades de azote deben ser ajustadas en relación con el precio de los fertilizantes y de la cana para diferentes grupos. En alternativa a reducir la dependencia a los fertilizantes azotados, existen prácticas que deben ser tomadas en cuenta y optimizadas a corto plazo. Estas prácticas incluyen el uso de fertilizantes de cultivo intercalado, el uso de co-productos y, a mediano y largo plazo, el potencial de la fijación biológica de azote en el cultivo de cana a azúcar.
LUMAX®: AN ALTERNATIVE TO ATRAZINE FOR PRE- AND POST-EMERGENCE CONTROL OF WEEDS IN SUGARCANE

By

S. SEERUTTUN, C. BARBE and A. GAUNGOO
Mauritius Sugar Industry Research Institute, Réduit, Mauritius
sseeruttun@msiri.intnet.mu

KEYWORDS: Mesotrione, Terbuthylazine, S-Metolachlor.

Abstract

ATRAZINE has successfully been used for more than 40 years in various tank-mixes for both pre- and post-emergence control of weeds in sugarcane. However, the product is banned in the EU for environmental reasons. Lumax, consisting of three active ingredients namely mesotrione (0.0375 kg a.i./L), terbutylazine (0.125 kg a.i./L) and s-metolachlor (0.375 kg a.i./L), has been evaluated as a substitute for atrazine in Mauritius in ten field trials in both plant and ratoon sugarcane. Lumax at rates varying between 3.5 and 5.0 L/ha proved effective on a wide spectrum of broad-leaved weeds and some grasses, including *Digitaria horizontalis*. In general, Lumax was superior to the standard s-metolachlor + atrazine and comparable to the tank-mixes tebuthiuron + atrazine and oxyfluorfen + diuron. In post-emergence of weeds, although Lumax tank-mixed with 2,4-D amine salt showed a better control of weeds than atrazine tank-mixed with s-metolachlor + 2,4-D amine salt, it was slightly inferior to the other standards containing hexazinone or tebuthiuron. In all situations, Lumax provided a residual activity varying between 10 and 12 weeks and showed no phytotoxicity on the various sugarcane varieties tested. Lumax has been recommended as an alternative to atrazine at rates varying between 4.0 and 5.0 L/ha.

Introduction

Traditionally, weed control in sugarcane in Mauritius has been achieved by application of at least two herbicide treatments from planting or harvest up to complete canopy closure (MSIRI, 2004). While the first application consists solely of pre-emergence, subsequent applications also include a post-emergence herbicide such as 2,4-D amine salt in the tank-mixes. Atrazine has been one of the most-used pre-emergence herbicides during the last 50 years; it is normally tank-mixed with selective grass herbicides to broaden the spectrum of control and, together with a post-emergence herbicide, also provides early post-emergence control of weeds. The extensive use of atrazine is also associated with its broad tolerance by sugarcane varieties as compared to diuron which is restricted to tolerant ones (Mc Intyre and Barbe, 1995).

Although atrazine does not represent any risk of contamination of underground waters as reported elsewhere (MSIRI/ACIAR, 2001) and has no weed resistance being reported yet in Mauritius, there has been growing pressure to seek alternatives to it and several of its tank-mix partners which are no longer authorised in the EU, where the main importing countries of Mauritian sugar are found.

Lumax® consists of mesotrione, terbuthylazine and s-metolachlor. Mesotrione is a member of the trikete family and is a selective herbicide used for pre- and post-emergence control of broad-leaved and some grass weeds in field corn (Armel et al., 2001; Mitchell et al., 2001). The formulation of Lumax tested in this study contained 37.5 g mesotrione, 375 g s-metolachlor and 125 g terbuthylazine per litre of product. At rates varying between 3 to 4 L/ha, Lumax has been reported to provide satisfactory control in both pre- and early post-emergence of weeds in maize
(Rapparini and Fabbi, 2005). The objective of this study was to evaluate the efficacy of Lumax in pre- and early post-emergence of weeds in sugarcane and to assess its potential as an alternative to atrazine.

**Materials and methods**

Ten trials were conducted in both plant and ratoon sugarcane to evaluate the efficacy of Lumax in pre- and early post-emergence of weeds. The first four trials (Trials 1 – 4) involved pre-emergence control of weeds in plant cane where Lumax at 3.5, 4.0, 4.5 and 5.0 L/ha was compared to three standards, namely, oxyfluorfen + diuron (0.5 + 2.0 kg a.i./ha), tebuthiuron + atrazine (1.6 + 2.4 kg a.i./ha) and s-metolachlor + atrazine (1.4 + 2.4 kg a.i./ha), and to an untreated control. The same treatments were also assessed in ratoon cane in two other trials (Trials 5 and 6). The remaining trials (Trials 7 – 10) involved post-emergence control of weeds in plant cane (Trials 7 and 8) and in ratoon cane (Trials 9 and 10). For the post-emergence trials, the four rates of Lumax were tank-mixed with 2,4-D amine salt at 3.0 L/ha and were compared to three standards, namely, hexazinone + atrazine + 2,4-D amine salt (0.6 + 2.4 + 2.2 kg a.i./a.e./ha), tebuthiuron + atrazine + 2,4-D amine salt (1.3 + 2.4 + 2.2 kg a.i./a.e./ha) and s-metolachlor + atrazine + 2,4-D amine salt (1.4 + 2.4 + 2.2 kg a.i./a.e./ha). A non-ionic adjuvant @ 0.025% v/v was added to all post-emergence treatments. The characteristics and details of all trial sites are given in Table 1.

* According to Parish and Feillafé (1965).

Spraying was carried out using hand-operated knapsack sprayers, delivering 350 L/ha at 300 kPa. The statistical design was a completely randomised block with three replicates; each plot consisted of four 1.6-m rows 10 m long (plot size of 64 m²).

For pre-emergence trials, data collection comprised visual observations at four and eight weeks after spraying (WAS) to record weed species appearing in the various treatments, followed by two weed surveys between 12 and 16 WAS using the ‘Frequency Abundance Method’ (Rochecouste, 1967). The level of control by each treatment on predominating weeds at each site was also highlighted. Regular visual observations on possible phytotoxicity on sugarcane were also made, followed by cane measurements in the plant cane at 12 WAS to determine any effect of Lumax on cane growth and tillering.

For post-emergence trials, a weed survey was carried out prior to spraying about eight weeks after planting or harvest in each individual plot to identify and quantify all weeds present. Following spraying, a second weed survey was carried out as from 4 WAS to assess the post-
emergence efficacy of each treatment; the percent weed kill was calculated by dividing the difference in weed infestation using the ‘Frequency Abundance Method’ between the two surveys by the initial infestation. The second survey made around 12 WAS was focused on assessing the length of residual activity of Lumax treatments with respect to the standards.

Results

Efficacy of Lumax in pre-emergence of weeds

In plant cane

At all four sites, the predominant broad-leaved weeds included *Ageratum conyzoides*, *Bothriospermum zelanicum*, *Chamaesyce hirta*, *Phyllanthus* sp., *Oxalis* spp., *Solanum nigrum* and *Youngia japonica*. *Digitaria horizontalis*, *Paspalum urvillei* and *Panicum subalbidum* were the main grass species in the untreated plots in Trials 2, 3 and 4 respectively. *Cyperus rotundus* was present in Trials 2 and 4 whereas *Kyllinga bulbosa* and *K. erecta* were recorded in Trial 3.

Observations made at 4 WAS revealed that the Lumax treatments were almost similar in efficacy to the standards and no difference among the four rates was apparent. At 8 WAS, the level of control obtained by the Lumax treatments were either similar or slightly inferior to the two standards, oxyfluorfen+diuron and tebuthiuron+atrazine; Lumax showed some superiority over the third standard, s-metolachlor + atrazine, due to its better efficacy on some broad-leaved weeds (Table 2).

The weed surveys made between 12 and 16 WAS revealed that the efficacy of Lumax, particularly at the two higher rates, was comparable to the standard oxyfluorfen + diuron and slightly inferior to tebuthiuron+atrazine (Figure 1). Irrespective of sites, control with Lumax was superior to s-metolachlor+atrazine; this indicates the contribution of mesotrione in the new product. Although the good performance of Lumax is explained by its efficacy on broad-leaved weeds which were predominant at those sites (Table 2), some weaknesses were observed on grass species such as *P. subalbidum*. For *D. horizontalis*, a good level of control was obtained with the two higher rates. Comparing the four rates of Lumax between 12 and 17 WAS showed that the highest rate of 5.0 L/ha had a slightly longer residual activity. The relatively better control obtained by Lumax at FUEL (Trial 4) may be explained by a longer residual activity associated with the dry conditions which prevailed throughout the duration of the trial at that site. Cane measurements made at all sites showed no difference in growth and tillering among the treatments; this confirms that this new herbicide is not phytotoxic to the sugarcane varieties tested.

+ Poor ++ Fair +++ Good ++++ very good
oxyf+diuron= oxyfluorfen + diuron, teb+atraz= tebuthiuron + atrazine; s-meto+atraz = s-metolachlor + atrazine
In ratoon cane

The two trials carried out in ratoon cane confirmed the results from the plant cane trials. The two higher rates of Lumax were again more effective than the lower rates and were comparable to the three standards (Figure 2). The survey carried out at 17 WAS in Trial 6 showed that the residual activity of Lumax was shorter than that of oxyfluorfen + diuron under more humid conditions. It was found to provide a similar level of control to the standards of *D. horizontalis* at the highest rate tested.

### Fig. 2—Pre-emergence control of weeds by Lumax in ratoon cane and expressed as percent of weed infestation in the untreated control.
Efficacy of Lumax in early post-emergence of weeds

In plant cane

The predominating weeds before spraying in Trial 7 consisted of *Cleome viscosa*, *C. rotundus*, *D. horizontalis*, *C. hirta*, *Ipomoea obscura*, *Phyllanthus sp.* and *Vernonia cinerea*.

Near complete eradication of most weeds except *D. horizontalis* was obtained 2 WAS with the lowest rates of Lumax. *V. cinerea* was only partly scorched; efficacy on this weed species improved with increase in dosage and, at the highest rate, was comparable to the two standards hexazinone + atrazine + 2,4-D amine salt and tebuthiuron + atrazine + 2,4-D amine salt.

The third standard was slightly inferior to Lumax due to a less effective control of *C. hirta*. The percent weed kill determined as from 4 WAS showed the standard hexazinone + atrazine + 2,4-D amine salt to be the best treatment, closely followed by the two other standards (Figure 3).

Control by Lumax was on the whole very satisfactory with more than 70% weed kill in Trial 7 (Figure 3). No significant difference between the four rates of Lumax was apparent.

Predominating weeds at Rose Belle (Trial 8) consisted of *A. conyzoides*, *Crassocephalum rubens*, *D. horizontalis*, *D. radicosa*, *Eleusine indica*, *Kyllinga bulbosa*, *Lobellia cliffortiana*, *O. debilis*, *O. corniculata*, *Paspalum urvillei*, *Solanum nigrum* and *Youngia japonica*.

A good knockdown of broad-leaved weeds was obtained 2 WAS with Lumax, irrespective of rate, and was comparable to the standard s-metolachlor + atrazine + 2,4-D amine salt (Figure 3). The two other standards were superior due to a more effective control of grasses.

In both trials, the tank-mixes with Lumax were shown to be safe to cane varieties R 570 and M 1394/86. Cane variety R 570 which is known to be very susceptible to some post-emergence herbicide treatments showed some phytotoxicity towards the standard tank-mix hexazinone+atrazine+2,4-D amine salt (Figure 4).

Fig. 4—Effect of post-emergence application of Lumax on plant cane. Error bars show standard error of means.

The residual activity of the Lumax treatment, following the knock-down of weeds present at spraying, was found to increase with higher dosage; the highest rate of Lumax was better or as good as the best standard in the two trials.

**In ratoon cane**

Broad-leaved weeds were predominant in Trial 9 and *P. subalbidum* was the only grass present. Five WAS, Lumax, irrespective of rate in the tank-mixes, had completely eradicated *Solanum nigrum*. Species of the Euphorbiaceae family, namely *Phyllanthus* sp., *C. hirta* and *C. prostrata* were partly defoliated and had stunted growth whereas *P. subalbidum* was unaffected. Lumax treatments were in general comparable to the s-metolachlor tank-mix but inferior to the two other standards (Figure 5).

---

![Graph](image-url)

**Fig. 5**—Post-emergence control of weeds by Lumax in ratoon cane.
With the predominance of broad-leaved weeds in Trial 10, very good control was obtained with Lumax, irrespective of dosage. Only two species were not totally controlled, namely Drymaria cordata (severely scorched) and Clidemia hirta (showing partial chlorosis and scorching). The best treatment was the standard tebuthiuron tank-mix with near eradication of most weeds except C. hirta. The two other standards were comparable to Lumax treatments (Figure 5).

Visual observations made throughout the duration of trials revealed all Lumax treatments to be safe to sugarcane varieties M 1400/86 and R 579. The latter, classified as a moderately susceptible variety to some post-emergence herbicide treatments, showed some phytotoxicity to the tank-mix containing hexazinone.

Discussion

Pre-emergence potential of Lumax

In general, the level of control obtained with Lumax was found to improve with increasing rates. The three higher rates tested were often superior to the standard s-metolachlor + atrazine; the superiority of Lumax over s-metolachlor+atrazine has also been demonstrated by Palacio-Vazquez et al. (2004). Compared to the two other standards of oxyfluorfen + diuron and tebuthiuron + atrazine, Lumax showed some potential under drier conditions at FUEL, where it provided the best pre-emergence control. However, tebuthiuron + atrazine proved to be more effective than Lumax at all remaining sites. Lumax was comparable to oxyfluorfen + diuron at sites where broad-leaved weeds predominated and inferior to the latter and tebuthiuron + atrazine on some grasses except *D. horizontalis*. The efficacy of Lumax on the latter weed complements observations reported by Armel et al. (2001) where *D. sanguinalis* is listed among weeds controlled by mesotrione. Despite its relative efficacy on *Kyllinga erecta*, Lumax was generally ineffective on sedges, including *Cyperus rotundus*. The latter concurs with results reported by Earl et al. (2004) showing mesotrione to be less effective than MSMA and halosulfuron on *C. esculentus*. As the three standards are also ineffective on *C. rotundus* and some other sedges, the potential of Lumax as a pre-emergence treatment for general weed control cannot be underestimated.

The trials have also revealed that Lumax has a relatively long residual activity up to 16 WAS. There seemed to be no significant difference among the three higher rates which implies that the highest rate of 5.0 L/ha is not justified and the optimum rates would be between 4.0 and 4.5 L/ha.

Post-emergence potential of Lumax

Lumax tank-mixed with 2,4-D amine salt proved particularly effective on broad-leaved weeds and was found to be as good as the standard s-metolachlor tank-mix and slightly inferior to the two other standards due to a less effective control of grasses.

No significant difference between the four rates of Lumax was observed. However, as the residual activity following the initial kill is also an important factor in weed management, the lowest rate of Lumax proved less effective. The highest rate of Lumax did not improve significantly the residual activity over the mid-rate.

The tank-mix Lumax + 2,4-D amine salt was well tolerated by the sugarcane varieties tested. As two of the trials consisted of susceptible varieties (R 570 and R 579), this implies that Lumax can be safely applied in post-emergence of both plant and ratoon sugarcane.

Conclusion

Based on results obtained in the ten trials, Lumax has a potential for use in pre- or post emergence of broad-leaved weeds and some grasses such as *D. horizontalis* in both plant and ratoon sugarcane. Lumax is a good alternative to conventional treatments such as s-metolachlor or acetochlor + atrazine which have been used since the early 1980s. Lumax has been recommended as an alternative to atrazine at rates varying between 4.0 and 4.5 L/ha in post-emergence of weeds, and the same rates of Lumax may be tank-mixed with 2,4-D amine salt @ 3.0 L/ha.

MOTS-CLÉS: Mesotrione,
Terbuthylazine, S-Metolachlor.

Résumé
L'ATRAZINE a été employée avec succès pendant plus de 40 ans dans différentes mélanges afin de maîtriser l’enherbement en canne à sucre, à la fois en pré et post émergence. Cependant le produit n’est plus homologué en Europe pour des raisons environnementales. Le Lumax, un mélange comprenant 3 molécules actives, la mesotrione (0.0375 kilogramme m.a./L), la terbutylazine (0.125 kilogramme m.a./L) et le s-metolachlor (0.375 kilogramme m.a./L), a été évalué comme produit de remplacement de l'atrazine à l’île Maurice, dans dix essais au champ à la fois en canne
plantée et en repousses. Du Lumax, à des doses variant entre 3.5 et 5.0 L/ha s’est montré efficace sur une vaste gamme de mauvaises herbes à larges feuilles et de quelques graminées, comprenant Digitaria horizontalis. Généralement Lumax s’est montré supérieur au mélange standard s-metolachlor + atrazine et comparable au mélange de tebuthiuron + atrazine et de oxyfluorfen + diuron. En post émergence des mauvaises herbes, bien que le Lumax mélangé à un sel de 2,4-D amine ait provoqué une meilleure maîtrise des mauvaises herbes que l’atrazine mélangée à du s-metolachlor + un sel de 2,4-D amine, ce premier mélange à base de Lumax fut légèrement inférieur aux autres produits standards contenant de l’hexazinone ou du tebuthiuron. Dans toutes les situations, le Lumax a présenté une activité résiduelle variant entre 10 et 12 semaines et n’a montré aucune phytotoxicité sur les variétés de canne à sucre testées. Lumax a été recommandé comme alternative à l’atrazine à des doses variant entre 4.0 et 5.0 L/ha.

LUMAX®: ALTERNATIVA A LA ATRAZINA PARA CONTROL EN PRE Y POST-EMERGENCIA DE MALEZAS EN CAÑA DE AZÚCAR

Por

S. SEERUTTUN, C. BARBE y A. GAUNGOO

Mauritius Sugar Industry Research Institute, Réduit, Mauritius
sseeruttun@msiri.intnet.mu

PALABRAS CLAVE: Mesotrione, Terbutilazina, S-Metolacloro.

Resumen

La atrazina ha sido utilizada con éxito por más de 40 años en variadas mezclas de tanque para control, tanto en pre y post-emergencia, de malezas en caña de azúcar. Sin embargo, el producto está prohibido en la UE por razones ambientales. Lumax, consistente en tres ingredientes activos llamados mesotrione (0.0375 kg i.a./L), terbutilazina (0.125 kg i.a./L) y s-metolacloro (0.375 kg i.a./L), ha sido evaluado como un substituto de la atrazina en Mauricio, en diez ensayos de campo tanto en caña de azúcar planta como soca. Lumax, en dosis que varían entre 3,5 y 5 L/ha, probó su efectividad en un amplio espectro de malezas de hoja ancha y algunos pastos, incluyendo Digitaria horizontalis. En general, Lumax fue superior a la mezcla estándar s-metolacloro + atrazina y comparable a las mezclas de tanque tebuthiuron + atrazina y oxyfluorfen + diuron. En post-emergencia de malezas, a pesar que la mezcla de tanque de Lumax con 2,4-D sal amina mostró un mejor control de malezas que la mezcla de tanque de atrazina con s-metolacloro + 2,4-D sal amina, fue levemente inferior a otras estándares que contienen hexazinone o tebuthiuron. En todas las situaciones, Lumax proveyó una actividad residual que varió entre 10 y 12 semanas y no evidenció fitotoxicidad en las diferentes variedades de caña de azúcar evaluadas. Lumax ha sido recomendado como una alternativa a la atrazina en dosis que varían entre 4 y 5 L/ha.
INTERACTIONS BETWEEN SEED DEPTH, THICKNESS OF TRASH BLANKET AND HERBICIDE TREATMENTS ON EMERGENCE OF VINE WEEDS IN SUGARCANE

By

A. GAUNGOO, S. SEERUTTUN and C. BARBE
Mauritius Sugar Industry Research Institute, Réduit, Mauritius
sseeruttun@msiri.intnet.mu

KEYWORDS: Ipomoea spp, Sulfentrazone, Diclosulam, Pre-Emergence Control.

Abstract

Vine weeds are appearing more frequently in sugarcane fields, particularly with the increasing adoption of green cane trash blanketing (GCTB). Current control measures are not effectively providing adequate control of these weeds. A project to develop strategies for managing vine weeds has been initiated and included three trials studying the factors influencing emergence of three Ipomoea species sown in trays. In the first trial, seeds of I. triloba and I. obscura were found to emerge at depths beyond 8 cm while germination of I. nil was reduced at seed depths greater than 4 cm. In the second trial, emergence of the three vine species was found to be unaffected by a trash layer of 5 cm whereas a significant reduction was observed as trash thickness was increased to 10 cm. An interaction between depth of the vine seed and thickness of trash layer was also noted; i.e. emergence of seeds at depths between 2 and 4 cm was reduced by more than 75% when covered by a trash layer of 10 cm. In the third trial, six pre-emergence herbicide treatments namely atrazine, atrazine + hexazinone, sulfentrazone, amicarbazone, trifloxysulfuron + ametryn, and diclosulam were tested for their efficacy against I. triloba sown at soil depths of 2, 6 and 10 cm. At 6 weeks after spraying (WAS), irrespective of seed depth, all herbicide treatments provided satisfactory control. The interaction between herbicide treatment and seed depth was significant at 12 WAS; irrespective of sowing depths, only sulfentrazone provided less than 5% germination over a period of 18 WAS. These results indicate that both thickness of the trash layer and choice of the herbicide treatment should be taken into consideration in the development of strategies to control vines in sugarcane under GCTB.

Introduction

Vine weed infestations are increasingly reported in sugarcane fields. Unlike other broad-leaved weeds, grasses and sedges normally present in sugarcane, vines have the ability to develop late in the season and spread long distances both horizontally and vertically, making control difficult. Vine infestations are often associated with green cane trash blanketing (GCTB) in both mechanised and manually harvested fields. The development of vine weeds is becoming a serious drawback to the adoption of GCTB, which is an economically and ecologically sustainable system in sugarcane (Seeruttun et al., 1992; Morandini et al., 2005).

The presence of vines in sugarcane is not new; studies date back to 1954 when Thakar and Singh (1954) reported that Ipomoea hederacea infestations caused losses of 20–25% in sugarcane in the Pusa area of Bihar by twining around clumps, bending the cane, damaging tops, causing stalks to remain undeveloped, and interfering with the harvest. In Australia, the problem emerged in the 1980s following the adoption of mechanised harvest in green cane (Calcino, 1986). Studies conducted in Brazil have shown that a trash cover of up to 20 t/ha did not totally prevent the emergence of Ipomoea spp. (Azania et al., 2002; Manechini et al., 2005). Ipomoea coccinea has
been reported as the most common and troublesome broad-leaved weed in Louisiana sugarcane fields (Jones, 2006); its competition with the crop can reduce yield as much as 30% over a season (Millhollon, 1988).

In Mauritius, *Paederia foetida* and *Passiflora suberosa* have always been found as localised infestations in sugarcane fields; these perennial species are effectively controlled by the recommended post-emergence herbicide tank-mixes (Seeruttun *et al.*, 2005). Several new and more invasive vine species have been observed in recent years; these are partly attributed to changes in some cultural practices including trash management (Ismael *et al.*, 2008). The new species which have been favoured by the more conducive conditions include *Ipomoea triloba*, *I. nil*, *I. hederifolia* and *I. obscura*. These vines are annuals and reproduce exclusively by large amounts of large seeds. *I. nil* and *I. triloba* are the most commonly found species and occur mainly in the humid and subhumid regions of the island. Earlier, it was thought that the rapid expansion of these two vines was due to the non-use of a pre-emergence herbicide treatment under GCTB conditions. However, it is observed that even in cases where pre-emergence herbicide treatments are applied several weeks after harvest when the trash has decayed, the vines are still ineffectively controlled. As several of the currently used pre-emergence herbicides are known to be effective on vines, the poor control remains unexplained. Furthermore, the use of post-emergence herbicides for the control of vines is not very practical as several flushes can emerge and application in well-developed or tall cane is not easy. This study has been initiated to investigate the individual and combined effects of seed depth, thickness of trash cover and some pre-emergence herbicide treatments on the germination and emergence of *Ipomoea* spp. in sugarcane with the final aim of developing appropriate management strategies.

**Materials and methods**

Three trials were established in fibreglass trays in 2008 at the Réduit Experimental Station of the Mauritius Sugar Industry Research Institute. *Ipomoea nil*, *I. obscura* and *I. triloba* were included in the first two trials whereas only *I. triloba* was involved in the third trial. The seeds of *I. nil* and *I. triloba* were obtained from vine plants grown on the station in 2007 whereas seeds of *I. obscura* were collected in a locality 10 km away where the agro-climatic conditions were similar to those prevailing at Réduit. To ensure a homogeneous germination, all seeds used were scarified with 98% sulfuric acid (Suwakhetnikom and Julakasewee, 2004). The fibreglass trays, which had holes pierced at the bottom to allow drainage of excess water after irrigation, were filled with soil collected from the same experimental station. The soil used is equivalent to an Oxisol, containing some 80% clay and 4.7% organic matter (Parish and Feillafé, 1965; Soil Survey Staff, 1999).

**Trial I—Vine species × sowing depths**

Trial I was established on 3 March 2008 and each tray (0.60 m × 0.30 m × 0.16 m) was partitioned into five compartments with metal sheets. Each compartment represented the experimental unit where 10 vine seeds were buried at depths of 0, 2, 4, 8 and 12 cm.

Each vine species was sown in a separate fibreglass tray. Each treatment was replicated four times in a split-plot design with vine species as the main plot and sowing depths as the sub-plot. The trays were placed in the open air and irrigated when required. Germination counts were carried out every 3 days after sowing over three weeks, during which the mean minimum and maximum temperature was 20°C and 27°C respectively. The rainfall recorded over the three weeks of experimentation was 154 mm. At the end of the trial, the seedlings of each vine species and at varying sowing depths were cautiously uprooted to measure the length of the hypocotyl.

**Trial II—Vine species × trash layer × sowing depths**

Trial II was set up on 28 March and the trays (0.90 m × 0.45 m × 0.25 m) were placed outdoor in a split-split plot design with vine species as the main plots, trash layers as the sub-plots and sowing depths as the sub-sub-plots. Each tray was divided into two compartments along the
length with iron sheets and each compartment was further sub-divided into five equal sections in which the same sowing depths as tested in Trial I were randomised. Two such trays represented the main plot where 10 seeds of I. nil, I. obscura and I. triloba were planted at the different depths. Three of the four compartments were afterwards covered with 5, 10 and 15 cm layers of dry trash from the commercial sugarcane variety M 1176/77. The height of each compartment was extended with iron sheets in order to accommodate the various trash layers. Samples of trash were also oven-dried to determine the dry matter equivalents for each layer. The fourth compartment did not receive any trash cover and represented the control. Each treatment was replicated four times.

The trial was watered when required and germination counts were undertaken on a 3 day interval over a period of 3 weeks where the mean minimum and maximum temperatures was 19°C and 28 °C, respectively. The total rainfall recorded during that period was 63 mm.

**Trial III—Herbicide treatments × Sowing depths**

Trial III was initiated on 9 October 2008 and lasted 18 weeks to study the efficacy of different herbicide treatments on the germination and emergence of I. triloba sown at three dates within that period. This trial was carried out under a shed where only the roof was covered with perspex sheets and temperatures were similar to the ambient conditions. The trays (0.90 m × 0.45 m × 0.25 m) were displayed in a split-plot design with three replicates. Seven herbicide treatments (including an untreated control) were imposed as the main-plot treatment whereas the sub-plots represented three sowing depths. The trays were divided into two equal parts along the length to accommodate the two main-plot treatments; they were partitioned using metal sheets. The latter were further divided into three to represent the sub-plot treatments in which 10 seeds of I. triloba were sown at depths of 2, 6 and 10 cm. Each main-plot was afterwards sprayed with the respective herbicide treatments using the Micron Autodos precision sprayer (MSIRI, 2007) equipped with an air-injet nozzle.

The herbicide treatments consisted of atrazine @ 4.0 kg a.i./ha, atrazine + hexazinone @ 2.4 + 0.6 kg a.i./ha, sulfentrazone @ 1.5 kg a.i./ha, amicarbazone @ 1.05 kg a.i./ha, trifloxysulfuron + ametryn @ 0.037 + 1.463 kg a.i./ha and diclosulam @ 0.09 kg a.i./ha. After spraying, the trays were watered regularly.

Seed germination and emergence of the seeds sown at the start of the trial were monitored over a period of 6 weeks after which the I. triloba seedlings were harvested for dry weight determination. A second batch of I. triloba seeds was sown on the same day in the same respective treatment; the seedlings were harvested six weeks later for assessing the effects of the various herbicide treatments on emergence and development. A third batch of seeds was sown and monitored in the same way as for the first two six-week periods before dry weight determination. The respective mean minimum and maximum temperatures for each assessment period (of 6 weeks) were respectively 18, 20, 22 °C and 26, 28, 29 °C.

**Data analysis**

Statistical analyses were carried out using GenStat Release 7.2 DE (PC/Windows XP) (GenStat, 2007). In trials I and II, data for the final germination count at the end of the three-weeks study were analysed and the means were compared at P<0.05 for statistical significance. Values for the dry weights at the three dates of sampling in Trial III had to undergo the transformation \((x+0.5)^{0.5}\) to mitigate the large coefficient of variance due to the presence of zero values in the data (Steel et al., 1997). After analysis, the transformed data were de-transformed.

**Results**

**Trial I—Vine species × sowing depths**

The germination count, made 3 weeks after sowing, revealed that I. obscura and I. triloba had a significantly greater ability to germinate and emerge from the different sowing depths than I. nil (Table 1). In general, a significant reduction in the rate of seedling emergence of the three
Ipomoea spp. was apparent beyond a soil depth of 4 cm; this was more important for I. nil than the other two species with a reduction of more than 20% in the mean number of plants that emerged (Table 1).

Emergence of I. obscura and I. triloba was unaffected until their seeds were found deeper than 8 cm in the soil, causing a sharp decrease of more than 37% and 50% respectively in the mean number of seedlings (Table 1). No germination and emergence of I. nil at 12 cm depth was recorded.

Measurements revealed that the three Ipomoea species had the ability to produce longer hypocotyls in order to emerge from greater soil depths (Figure 1). Extension of the hypocotyl was particularly important when seeds were found at 4 cm in the soil or deeper.

At each depth, no difference in length of the hypocotyl was noted between the three vine species. No measurements were made for the length of the hypocotyl at 12 cm depth as only a few seedlings of I. obscura and I. triloba had emerged.

Values are means of four replications. Standard error of difference (s.e.d.) of means for main plot—vine species (d.f. = 6) = 0.870 and s.e.d. of means for subplot treatments—depth of sowing (d.f. = 36) = 0.632. S.e.d. for comparing between means with same level of vine species = 2.220 (d.f. = 36). Mean values in the same row or column not sharing the same letter are significantly different at P < 0.05 (LSD test).

Fig. 1—Length of hypocotyl of Ipomoea spp. at different sowing depths.
**Trial II—Vine species × trash layer × sowing depths**

The higher ability of *I. obscura* and *I. triloba* to emerge compared to *I. nil* was again demonstrated in the second trial (Table 2).

This trial showed that, irrespective of vine species, a trash cover of 5 cm did not impede the growth of the vine species; emergence was found to be significantly reduced at 10 cm and more drastically with a 15 cm trash layer (Table 2).

**Table 2**—Combined effects of different trash layers and sowing depths on the germination of *Ipomoea* spp. seeds 3 weeks after sowing.

Values are means of four replications. Standard error of difference (s.e.d.) of means for main plot —vine species (d.f. = 6) = 0.218, s.e.d. of means for subplot treatments – thickness of trash layer (d.f. = 27) = 0.273 and s.e.d. of means for the sub-sub-plot treatments – sowing depth (d.f. = 144) = 0.285. S.e.d. of means for the interaction between vine species × thickness of trash layer = 0.473 (d.f. = 27); for interaction between thickness of trash layer × sowing = 0.493 (d.f. = 144).

Irrespective of the vine species and trash cover, emergence was not adversely affected when seeds were sown at 4 cm depth or less (Table 2). As from 8 cm depth, emergence was significantly reduced and this was even more pronounced at 12 cm depth. These results were similar to those observed in Trial 1.

The interaction between thickness of trash cover and depth of sowing was significant. With a trash cover of up to 5 cm, no reduction in vine emergence was observed for seed sown at depths...
of less than 8 cm (Table 2). Beyond this depth, vine emergence was significantly reduced and was more pronounced at the 12 cm. As trash cover was increased to 10 cm, emergence of vines was significantly reduced when seeds were sown at depths of 4 cm or more.

With a 15 cm trash layer, emergence was significantly reduced at all depths including those seed sown at the surface. The presence of a trash cover of 5 cm was also found to be more conducive for seeds germinating from the surface.

**Trial III—Herbicide treatments × sowing depths**

**Efficacy of herbicides 6 WAS**

The residual effect of the various herbicide treatments during the first six weeks is expressed as the dry weight of all seedlings of *I. triloba* (Table 3).

Irrespective of the sowing depths, no significant difference in the efficacy of the six herbicide treatments was observed; all treated plots provided a very good level of control as compared to the untreated one.

The good control obtained for the seeds sown deeper in the trays was not necessarily due to the efficacy of the various herbicide treatments, as germination and growth were also significantly reduced at the 10 cm depth within the untreated control (Table 3).

**Table 3**—Effects of herbicide treatments 6 WAS on the emergence of *I. triloba* (expressed as detransformed data for dry mass) sown at 2, 6 and 10 cm depths. Values in parentheses represent transformed data.

Values are means of three replications. Standard error of difference (s.e.d.) (transformed data) of means for main plot – herbicide treatments (d.f. = 12) = 0.069 and s.e.d. (transformed data) of means for subplot treatments – depth of sowing (d.f.= 28)= 0.053. S.e.d. of means (transformed data) for the interaction between herbicide treatment × sowing depth = 0.135 (d.f.= 40).

**Efficacy of herbicides 12 WAS**

For the second batch of seeds sown 6 WAS and harvested six weeks later, no significant differences were observed among the main-plot treatments (herbicide treatments), but a reduction in the dry weight of the seedlings emerging from a depth of 10 cm was observed (Table 4).

The interaction between herbicide treatments and sowing depth was also positive. The efficacy of the various herbicide treatments varied for seeds sown at 2 and 6 cm deep; at these depths the tank-mix hexazinone+atrazine and sulfentrazone provided the best control.

Diclosulam also showed some control of *I. triloba*; the level of control was significantly superior to the untreated control at the 6 cm depth (Table 4). At 12 WAS, the residual activity of atrazine alone and the tank-mix trifloxysulfuron+ametryn had elapsed, thus providing poor control of *I. triloba*. The emergence of *I. triloba* seeds was again suppressed when they were sown 10 cm deep in the trays.
Table 4—Effects of herbicide treatments 12 WAS on the emergence of *I. triloba* (expressed as detransformed data for dry mass) sown at 2, 6 and 10 cm depths. Values in parentheses represent transformed data.

(transformed data) of means for the interaction between herbicide treatment × sowing depth = 0.316 (d.f. = 25).

**Efficacy of herbicides 18 WAS**

The residual activity of the various herbicide treatments tested over a period of 18 weeks revealed that only sulfentrazone was effective against *I. triloba*; sulfentrazone was found to be significantly superior to the control for seeds sown at a depth of 2 cm (Table 5). At 18 WAS, all seeds sown deeper than 6 cm showed no response to the herbicide treatments.

**Discussions and conclusions**

This study has revealed that vine species growing in sugarcane fields have the ability to emerge from depths of up to 12 cm although this was found to decrease relative to 8 cm. The three vine species displayed the same capacity for producing longer hypocotyls at depth beyond 4 cm. Roberts (1982) reported that most annual weeds, with seed weights between 0.1 and 5.0 mg, usually emerge from depths of less than 5 cm, although seedlings of larger-seeded species such as...
**Polygonum convolvulus** may do so from 10 cm or more. The seeds of *I. nil*, *I. obscura* and *I. triloba* form part of the latter category with mean seed weight of 18.6, 22.2 and 10.6 mg respectively (unpublished data). Furthermore, the bigger size of the *Ipomoea* seeds is associated with a greater food reserve enabling the seedlings to reach the surface by producing longer hypocotyl than small-seeded weed species (Roberts, 1982). Although *I. nil* produces bigger seeds than *I. triloba*, it was found to have a lower ability to germinate and emerge than the two other vine species in both Trials I and II. A recent study comparing germination and development of three vine species under three agroclimatic conditions of Mauritius has shown an interaction between species and climatic conditions (Chummun, 2009). The climatic conditions prevailing at Réduit may have been more conducive for the development of *I. obscura* and *I. triloba* as compared to *I. nil*.

The presence of a trash layer thicker than 5 cm had an adverse effect on the emergence of the vine species. This result concurs with that obtained in Brazil by Manechini *et al.* (2005) where trash cover equivalent to the 5 cm layer was ineffective in controlling *Ipomoea* species (*I. quamoclit*, *I. purpurea*, *I. grandifolia*, *I. hederifolia*, and *I. nil*).

The interaction between thickness of trash layer and sowing depth clearly indicates that vine control in sugarcane fields may be addressed by managing the thickness of the trash cover. Cane trash at 20 t/ha, representing approximately a 10 cm layer, has been found to reduce presence of *I. quamoclit*, *I. purpurea*, *I. grandifolia*, *I. hederifolia*, *I. nil* and *M. cissoides* by 82, 65, 62, 70, 60, and 88%, respectively (Azania *et al.*., 2002).

From our study, very effective control of vines may be achieved by uniform trash layers of approximately 15 cm or more; in fields where lower cane yields will result in less trash and thinner trash layers, trash windrowing may be an alternative. The latter was a common practice in Mauritius where trash was raked and aligned on alternate interrows in layers reaching 20 cm or more after green cane harvesting. This may explain partly the good control of vines obtained previously in Mauritius.

Satisfactory control of *I. triloba* was achieved by all the herbicide treatments tested only within the first six weeks. Atrazine was already ineffective at the second assessment (12 WAS) as compared to sulfentrazone and the tank-mix atrazine+hexazinone. This rapid decline in the efficacy of atrazine against vine weeds has previously been reported by Jones (2006). For a longer residual activity to control *I. triloba*, only sulfentrazone was found to be effective 18 WAS; sulfentrazone is already recommended in Mauritius for its long pre-emergence control of a broad spectrum of weeds (Seeruttun *et al.*, 2001). Although this better efficacy of sulfentrazone was restricted for seeds germinating at 2 cm depth, the option of using this herbicide for managing vine weeds may be considered, as emergence of seeds from greater depths is less important.

Although the findings of this study need to be confirmed at the field level, there is an indication that both the thickness of the trash layer and choice of the herbicide treatment are important parameters that should be taken into consideration in the development of strategies to control vines in sugarcane.

MOTS-CLÉS : Ipomée spp., Sulfentrazone, Diclosulam, Contrôle de Pré Émergence.

Résumé

LES LIANES apparaissent de plus en plus fréquemment dans les parcelles de canne à sucre, en particulier depuis l'adoption croissante de paillis de canne (GCTB). Les mesures actuelles de contrôle ne sont pas efficaces sur ces lianes. Un projet ayant pour but de développer des stratégies de contrôle des lianes a été initié. Il inclut trois expérimentations étudiant les facteurs influençant l'apparition de trois espèces d'Ipomoea semée en barquettes. Dans le premier essai, des graines de I. triloba et de I. obscura ont germé pour des profondeurs supérieure à 8 cm tandis que la germination de I. nil était réduite à des profondeurs supérieures à 4 cm. Dans le deuxième essai, l'émergence des trois espèces de lianes fut gênée par un paillis de 5 cm tandis qu'une réduction significative de l'émergence fut observée avec des paillis de 10 cm. Une interaction entre la profondeur des graines de lianes et l'épaisseur du paillis a également été notée ; ainsi, l'émergence de graines aux profondeurs entre 2 et 4 cm fut réduite de plus de 75% avec un paillis de 10 cm d’épaisseur. Dans le troisième essai, six traitements herbicides de pré émergence comprenant l'atrazine, l’atrazine + hexazinone, sulfentrazone, amicarbazone, trifloxysulfuron + ametryn, et diclosulam ont été testés pour leur efficacité contre le I.trilobad semé à des profondeurs 2, 6 et 10 centimètres. Six semaines après pulvérisation, indépendamment de la profondeur de la graine, tous les traitements herbicides ont montré un contrôle satisfaisant des lianes. L'interaction entre le traitement herbicide et la profondeur de semis fut significative 12 semaines après pulvérisation, indépendamment des profondeurs de semis. Une germination inférieure à 5% ne fut observée qu’avec le sulfentrazone après 18 semaines. Ces résultats indiquent que l'épaisseur du paillis et le choix du traitement herbicide devraient être pris en compte dans le développement de stratégies de maîtrise des lianes en canne à sucre sous GCTB.
INTERACCIONES ENTRE PROFUNDIDAD DE SEMILLA, ESPESOR DE LA CAPA DE RESIDUOS DE COSECHA Y TRATAMIENTOS DE HERBICIDAS SOBRE LA EMERGENCIA DE MALEZAS DE ENREDADERA EN CAÑA DE AZÚCAR

Por
A. GAUNGOO, S. y C. SEERUTTUN BARBE

Instituto de Investigación de la Industria Azucarera de Mauricio, Réduit, Mauricio
sseeruttun@msiri.intnet.mu

PALABRAS CLAVE: Ipomoea spp, Sulfentrazone, Diclosulam, Control De Pre-Emergencia.

Resumen
Las malezas de enredadera están apareciendo con más frecuencia en los campos de caña de azúcar, en particular con el incremento en la adopción de la cobertura con residuos del corte de la caña en verde (GCTB). Las medidas de control regulares no están controlando efectivamente estas malezas. Se inició un proyecto para desarrollar estrategias para el manejo de las malezas de enredadera que incluyó tres ensayos para estudiar los factores que influyen en la emergencia de tres especies de Ipomoea sembrada en bandejas. En el primer ensayo, se encontró que las semillas de I. triloba y I. obscura emergen desde profundidades superiores a 8 cm, mientras que la germinación de I. nil se redujo con una profundidad de siembra de más de 4 cm. En el segundo ensayo, se encontró que la emergencia de las tres especies de enredadera no era afectada por una capa de residuos de 5 cm pero se observó reducción significativa cuando el grosor de la capa se incrementó a 10 cm. También se observó interacción entre la profundidad de la semilla de la enredadera y el espesor de la capa de residuos, es decir, la emergencia de las semillas a profundidades entre 2 y 4 cm, se redujo en más del 75% cuando estaban cubiertas por una capa de residuos de 10 cm. En el tercer ensayo, seis tratamientos de herbicidas en pre-emergencia, atrazina, atrazina + hexazinone, sulfentrazone, amicarbazona, trifloxysulfuron + ametryn y diclosulam fueron probados para determinar su eficacia contra I. triloba sembrada a profundidades de 2, 6 y 10 cm. A las 6 semanas después de la aspersión (SDA), independientemente de la profundidad de siembra, todos los tratamientos de herbicidas proporcionaron control satisfactorio. La interacción entre el tratamiento con herbicida y la profundidad de siembra fue significativa a las 12 SDA; independientemente de la profundidad de siembra, sólo sulfentrazone redujo a menos del 5% la germinación en un periodo de 18 SDA. Estos resultados indican que tanto el espesor de la capa de basura como la elección del tratamiento con herbicidas deben tenerse en cuenta en la elaboración de estrategias para el control de las enredaderas en la caña de azúcar bajo GCTB.
USE OF VINASSE FOR SOIL RECLAMATION AND ITS IMPACT ON
ELEMENTAL LOADS IN VERTISOL SOIL AND GROUNDWATER

By

MARCO ANTONIO GIRON TEJADA
Imecol S.A.
magiron@yahoo.com

KEYWORDS: Vinasse, Sugarcane, Soil, Groundwater, Soil Reclamation.

Abstract
A STUDY was carried out to evaluate the contamination of soils and groundwater through the use of vinasse in the reclamation of saline soils with trace elements such as Fe, Cu, Mn and Zn to sugarcane soils. The soils at the experimental site were located in the flat area of Valle del Cauca, Colombia and consisted of the Vertisols of the Galpón series characterised with a Loam Clay texture and problems of salinity and sodicity. Vinasse containing 10% total solids was applied at the rate of 1500 m$^3$/ha. The trace element contents in the soil increased compared to their initial values but did not reach levels that are considered as deleterious to the soils. Similarly, the concentration of trace elements in groundwater was not significantly increased and remained below the threshold values according to the Colombian Environmental Legislation. In conclusion, in this type of soil there were no contamination problems with heavy elements in soil and groundwater from the application of vinasse with 10% solids on the reclamation of saline soils.

Introduction
The Colombian government approved law 693 of 2001 and the 3510 CONPES (2008) for alcohol production and use of biofuels in motor vehicles with a mixture of 10% alcohol in gasoline and 5% in diesel to reduce the effects of pollution generated by fossil fuels. Therefore, fuel ethanol distilleries were installed to meet consumption needs. The area planted with sugarcane is 208 161 ha (Cenicaña, 2007) for the production of sugar, molasses, and alcohol fuel.

The average production of ethanol for use as a fuel is 1 100 000 litres per day (Conpes 3510, 2008) and vinasse containing 10% total solids is generated as a waste product at a rate of 12 to 13 litres for every litre of ethanol that is produced. Vinasse can be produced at concentrations between 10% and 55% (Quintero, 2004) with varying amounts of organic matter and chemical oxygen demand (COD) (Rossi, 2007) which is considered as an environmental pollutant.

Numerous studies have shown that vinasse is a highly corrosive waste product with a high content of organic matter (OM), potassium (K) and calcium (Ca) (Alfaro and Alfaro, 1996; Garcia, 2007) and their contents of micro-elements such as Iron (Fe), Copper (Cu), Manganese (Mn) and Zinc (Zn) (Gnecco, 2007); in view of its high content of minerals, the vinasse has the potential to pollute soil and groundwater. However, the chemical composition of vinasse depends on the raw material used, the soil type and the process of preparing the alcohol (Rossi, 2007; Leal et al., 2003). Furthermore, it has been reported by Garcia (2007) that vinasse can be used as an amendment in the reclamation of saline and sodic soils. Vinasse is enriched with other fertiliser nutrients for use in the fertilisation of sugarcane (Quintero, 2004). The rates of application for reclamation (Garcia, 2007) and fertilisation for sugarcane are variable, as reported by Alfaro and Alfaro (2008), Quintero
(2004), and Gomez (2007) and depend on soil type, sugarcane variety and the concentration of the vinasse.

The trial was conducted in Moraima farm in the municipality of El Cerrito, Valle del Cauca, Colombia under sugarcane and pasture on Vertisol soils with problems of salinity, sodium toxicity and Loam Clay texture. The vinasse with 10% total solids was applied at a rate of 1500 m$^3$/hectare. This study seeks to assess the use of vinasse on reclamation of soils that are saline or have sodium toxicity and to evaluate its effect on contamination of soil and groundwater with heavy elements such as Fe, Cu, Mn and Zn.

**Materials and methods**

The study area is located in the municipality of El Cerrito, Valle del Cauca Department, Colombia on the Moraima farm between latitude 3°43’20.97” N and 76°23’22.46’ W near the Cauca River. It has an average temperature of 24°C, an average annual precipitation of 1200 mm and a mean annual average evaporation of 1700 mm. The project area consists of Vertisol soils of the series Galpòn (GL). This soil is saline and has problems with sodium.

In the process of reclamation a network of internal drainage with corrugated plastic pipe of 4’ diameter, 1.5 m deep and gravel filter was designed and built. Later, pools were built with 30 x 30 m dimensions and 50 cm high using a tractor and implement used in rice crops. These pools were flooded to 10 to 15 cm of vinasse. The vinasse was from the company CALSA located in Palmira (Valle), and contains 10% total solids with chemical characteristics that are shown in Table 1. The vinasse was applied every 15 days, to reach infiltration of the vinasse. This process was repeated three times to reach 1500 m$^3$/ha.

The soil samples were collected at depths 0–20, 20–40 and 40–60 cm because the cane roots are located down to 60 cm according to the studies of Dominguez (1990). The water samples were collected in the external part of the installed internal drainage. These analyses of soil and water were sent to the Chemical Laboratory at Field Providencia sugar mill. The samples of soil and water were collected after application of the vinasse 15 days later when the infiltration of the vinasse finished.

The Colombian Environmental Legislation in ordinance 1594 of 1984 was used for evaluation of soil and groundwater pollution with the vinasse application.

Results and discussion

Soils

Table 2 compares the analysis of soil before and after the final application of vinasse 10%. These values are discussed one to one according to the report of laboratory analysis of soil.

Application of vinasse resulted in an increase in soil pH that ranged from 8.4 in the 0–20 cm layer up to 9.0 in the 40–60 cm layer. The pH increase is due to the oxidation of organic components of the vinasse in the soil. These values are in accord with Montenegro (2008), Bautista et al. (2000), Rodriguez and Chaves (1999).

The electrical conductivity (EC) found was 0.47 dS/m in the 0–20 cm layer; this value decreased showing a strong washing in this layer of soil. Information above is according to the study of Garcia (2007), showing a quick wash with products with high salt content and high doses. However, with vinasse applications with low doses, the EC value tends to increase, according to Bautista et al. (2000), Rodriguez and Chaves (1999) and Rossi (2007). Therefore, care must be taken with the processes of salinisation of the soil when vinasse is applied with low doses.

The Organic Matter (OM) in soil was found to be 3.15% in the 0–20 cm layer an increase over the initial value, indicating the great contribution of vinasse to soil due to high concentrations of OM. Therefore, the soil acts as a filter for the OM not to reach the groundwater. This information is consistent with Montenegro (2008), Bautista et al. (2000), Rodriguez and Chaves (1999) and Rossi (2007).

Following the application of 1500 m$^3$/ha of vinasse, the increase in cation exchange capacity (CEC) in the top 0–20 cm to 27.16 cmol/kg and 37.10 cmol/kg in 40–60 cm layer indicates contributions of cations from the vinasse.

The observations made in this study were in accordance to those observed by Montenegro (2008), Bautista et al. (2000) and Rodriguez and Chaves (1999).

The exchangeable sodium percentage (ESP) changed from 5.74% in 0–20 cm layer to 18.06% in 40–60 cm layer; these percentages decreased considerably compared to the initial values of 24.51% in the 0–30 layer and 53.68% in the 30–60 cm layer.

This shows that the process of washing the soil with 1500 m$^3$/ha of vinasse in the reclamation of sodic soil is good and concurs with findings reported by García (2007) and Marulanda (1992).

**Amount of micro-elements**

The concentration of iron (Fe) found was 17.73 ppm in the 0–20 cm layer and 15.83 ppm in the 40–60 cm layer and increased with the application of 1500 m$^3$/ha of vinasse 10%. This increase in the soils is consistent with observations by Bautista et al. (2000), Montenegro (2008) and Quintero (2004). Meanwhile, the Environmental Legislation in Colombia has no records for this element in soils.

The concentration of copper (Cu) in the soil decreased to 1.85 ppm in the 0–20 cm layer while, in the 40–60 cm layer, this value increased slightly to 3.32 ppm. These values are considered low in the soil according to the Colombian Environmental Legislation that has the maximum value of 1200 ppm.

It is, therefore, considered that there is no soil contamination by copper. Increases of this element in the soil by application of the vinasse also were found by Bautista et al. (2000) and Rodriguez et al. (2003).

The concentration of manganese (Mn) found increased to 6.34 ppm in the 0–20 cm layer. The Colombian Environmental Legislation has not recorded this element as a problem in the soil. Information reported by Rodriguez and Chaves (1999), Montenegro (2008) and Bautista et al. (2000) is consistent with the increase in manganese with the applications of vinasse to soil.

The concentration of zinc (Zn) increased in the 0–20 cm layer to 1.39 ppm and to 1.28 ppm in the 40–60 cm layer. The value is low according to Colombian Environmental legislation.

Studies by Quintero (2004), Rodriguez and Chaves (1999), Bautista et al. (2000) and Montenegro (2008) found increases in zinc with the application of vinasse.

**Groundwater**

In Table 3 below are details of water analysis before and after the last application of 1500 m$^3$/ha of vinasse. These values are discussed according to water pollution and possible human consumption or agricultural use, according to Colombian Environmental Legislation.

The pH value increased from 7.5 to 7.8. These values show the increase in the washing of soluble cations with the application of vinasse. There are no restrictions with use for agriculture or livestock because the maximum value is pH 9.0.

The electrical conductivity (EC) increased over the initial data from 0.47 to 0.49 dS/m. The value established by law is less than 0.5 dS/m. We see how the water is increasing in salinity during soil reclamation with the application of vinasse.

The concentration of Sodium (Na) increased from 2.39 ppm to 5.51 ppm after application of vinasse 10%. This is in accordance with Garcia (2007).

</tbody>
</table>

**Amount of micro-elements**

The concentration of Iron (Fe) initially was 0.78 ppm and, after the application of vinasse, the concentration was 0.66 ppm. This indicates that the groundwater did not increase its iron level after vinasse application at a dose of 1500 m³/ha. The groundwater does not meet the conditions for human use by environmental regulations. The limitation is 0.30 ppm while, for agriculture and livestock, there are no limitations for use.

The Copper (Cu) concentration was 0.02 ppm, and remained with the same value, showing that there were no inputs of this element by the application of vinasse. The value contaminant is 1.0 ppm for human consumption, 0.5 ppm for use in agriculture and 0.2 ppm for livestock; consequently this water can be used in any activity.

The Manganese (Mn) concentration found in the groundwater after the application of vinasse is 0.24 ppm, a slight decrease. According to the classification, this item should be below 0.10 ppm for human consumption and 0.20 ppm for agricultural use. The use of this water for human consumption is restricted to agricultural use and livestock and can be used with caution.

The Zinc (Zn) concentration decreased to 0.07 ppm, indicating that this element was not provided by application of vinasse to groundwater. Its limit value should be 5 ppm for human consumption; agricultural use is 2 ppm and 25 ppm for livestock.

**Conclusions**

The saline and sodic soils were reclaimed with the application of 1500 m³/ha vinasse with 10% total solids.
The concentration of heavy elements such as Cu, Zn, Mn and Fe increased in the soil with the soil reclamation with application of 1500 m$^3$/ha vinasse with 10% total solids but did not reach pollution problems.

The concentration of heavy metals such as Cu, Zn, Mn and Fe did not increase in the groundwater during the soil reclamation with application of 1500 m$^3$/ha vinasse with 10% total solids.

Résumé
UNE ÉTUDE a été réalisée pour évaluer la contamination des sols et de la nappe phréatique par des oligoéléments tels que le Fe, le Cu, le manganèse et le Zn, lors de l'utilisation de vinasse pour la mise en valeur de sols salins sous culture de canne à sucre. Les sols du site expérimental étaient localisés dans la zone plate de la Vallée del Cauca, en Colombie, comprenaient des Vertisols de la série de Galpón caractérisés par une texture argilo-limoneuse et des problèmes de salinité et de sodicité. De la vinasse contenant 10% de solides totaux fut épandue à raison de 1500 m³/ha. Les teneurs en oligoéléments du sol ont augmenté mais n'ont pas atteint des niveaux considérés comme nuisibles pour les sols. De même, les concentrations en oligoéléments des eaux souterraines n'ont pas été sensiblement augmenté et sont restée au-dessous des valeurs seuil selon la législation environnementale colombienne. En conclusion, sur ces sols salins, il n'y a pas eu de problèmes de contamination du sol et des eaux souterraines par les éléments métalliques issus d’épandage de vinasse contenant 10% solides totaux.

USO DE VINAZAS PARA LA RECUPERACIÓN DE SUELOS Y SU IMPACTO SOBRE LA CARGA DE ELEMENTOS MENORES EN SUELOS VERTISOLES Y EN AGUAS SUBTERRÁNEAS

PALABRAS CLAVE: Vinaza, Caña de Azúcar, Suelo,
Agua Subterránea, Recuperación del Suelo.

Resumen
SE REALIZÓ un estudio para evaluar la contaminación de suelos y aguas subterráneas al usar vinaza en la recuperación de suelos salinos con oligoelementos como Fe, Cu, Mn y Zn en suelos de caña de azúcar. Los suelos del sitio experimental se encuentran en la zona plana del Valle del Cauca, Colombia y consistieron en Vertisoles de la serie Galpón caracterizados por textura franco arcillosa y problemas de salinidad y sodicidad. Se les aplicó vinaza con el 10% de sólidos totales a una tasa de 1500 m³/ha. El contenido de elementos menores en el suelo aumentó con respecto a sus valores iniciales, pero no alcanzó niveles considerados perjudiciales para los suelos. Del mismo modo, la concentración de oligoelementos en el agua subterránea no aumentó significativamente y se mantuvo por debajo del umbral de los valores de acuerdo a la legislación ambiental colombiana. En conclusión, en este tipo de suelo que no hubo problemas de contaminación en los suelos ni en las aguas subterráneas con elementos pesados por aplicación de vinaza con 10% de sólidos para la recuperación de suelos salinos.
CONCEPTS AND VALUE OF THE NITROGEN GUIDELINES
CONTAINED IN THE AUSTRALIAN SUGAR INDUSTRY’S
‘SIX EASY STEPS’ NUTRIENT MANAGEMENT PROGRAM

Guidelines, Validation, Value.

Abstract

THE AUSTRALIAN sugar industry currently faces unprecedented scrutiny of its use of
nutrients due to initiatives to protect the Great Barrier Reef from excess nutrients and
sediment from agricultural activities along the Queensland coast. However, this quest
needs to be viewed in conjunction with the need for a sustainable sugarcane industry. A
comprehensive program for nutrient management (the SIX EASY STEPS program) has
been developed recently for the Australian sugar industry. It replaces the previous
general guidelines that did not differentiate between regions or soil types and lacked
precision. The new system supports profitable and sustainable sugarcane production,
enhances environmental awareness, and is consistent with best practice. The paper
summarises the alternative N management strategies that occur within the Australian
sugar industry. It describes best-practice nutrient management and the concepts that
underpin the SIX EASY STEPS program, and explains the principles of the N
management guidelines used within the SIX EASY STEPS program and link this to N
use efficiency. It also assesses the value of the SIX EASY STEPS N management
guidelines. Trial results presented indicate that the SIX EASY STEPS N guidelines are
robust and much more in line with the concept of sustainability than any of the other
strategies considered. Calculation of the target N-use efficiency factors across the full
range of SIX EASY STEPS N guidelines, especially when all possible sources of N
within the soil/plant environment are included, strengthens the SIX EASY STEPS as an
appropriate and fully comprehensive nutrient management package. This is confirmed
by the results of the economic analyses of data from both small plot experiments and
commercially-based replicated strip trials conducted on-farm.

Introduction

The Australian sugar industry currently faces unprecedented scrutiny of its use of nutrients
due to recent Australian and Queensland Government initiatives to protect the Great Barrier Reef
from ‘excesses’ of nitrogen, phosphorus and sediment that may be derived from agricultural
activities along the Queensland coast (Calcino et al., 2010). However, this government/political
imperative (Anon., 2008), which appears to be driven by environmentalists and lobbyists, should be
viewed in conjunction with the need for a sustainable sugarcane industry that forms the economic
backbone of many of the regional centres of tropical coastal Queensland.

Sustainable nutrient management that aims at profitable cane production in combination
with environmental responsibility (Schroeder et al., 2006) will enable both the above-mentioned
objectives to be met without disadvantaging either sector. A comprehensive approach to nutrient management, the SIX EASY STEPS program, was recently developed within the Australian sugar industry for this purpose (Schroeder et al., 2008). It replaced the previous general guidelines that did not differentiate between regions or soil types and lacked precision.

Although the government-led nutrient reduction strategy focuses on N and P outflow into the Great Barrier Reef Lagoon, this paper will only cover aspects of N management because of its prominence at present. However, it is important to note that the P and other nutrient guidelines (contained within the SIX EASY STEPS program) are also based on principles of best-practice nutrient management (Schroeder et al., 2006). In this regard, the SIX EASY STEPS program advocates the concept of ‘balanced nutrition’ that aims to have all essential plant nutrients present in sugarcane-producing soils at optimum levels.

Here we:
- summarise the alternative N management strategies that occur within the Australian sugar industry;
- describe our understanding of best-practice nutrient management and the concepts that underpin the SIX EASY STEPS program;
- explain the principles of the N management guidelines used within the SIX EASY STEPS program and link this to N use efficiency;
- report on specific studies that have been undertaken to assess the value of the SIX EASY STEPS N management guidelines.

Alternative N management strategies

Several strategies for determining N application rates occur within the industry (Schroeder et al., 2009a). They include the following, each with their own objectives and criteria (Table 1):
- Traditional (previous industry guidelines).
- Grower-developed (strategies developed by growers to minimise risk of production losses on-farm).
- SIX EASY STEPS (current BSES guidelines aimed at sustainable sugarcane production).
- N-replacement (currently under investigation by researchers working within the CSIRO).

Table 1—Different N management strategies used within the Australian sugar industry (Schroeder et al., 2009a).

</tr>
</tbody>
</table>
The current imperative for sustainable N management has highlighted the need for the selection of the most appropriate N input strategies on-farm. Importantly, growers need to apply N at appropriate rates, which lead to neither under- nor over-fertilisation and provide the best economic returns.

**Best-practice nutrient management and the SIX EASY STEPS program**

**Best-practice nutrient management**

Although best-practice agriculture is generally considered to be a continuous improvement process, the large number of associated terms and standards often leads to a confused understanding of the overall concept. In describing best practice management, Williams and Walcott (1998) suggested that best-practice management encompasses an underlying process, appropriate changes that may (or may not) have to be sought externally, and an agreed framework for successful implementation.

In recognising these components, a contemporary definition of ‘best management practice’ (BMP) states that it is ‘an economically viable management practice that has been determined to be the most cost effective and practical means of preventing or reducing pollution and thus environmental harm’ (Smith, 2008). We suggest that best-practice nutrient management is linked directly to the concept of ‘risk’. It should be thought of as an overall combination of input strategies and processes that enables minimising the risk of losses in productivity (loss of yield), profitability (loss of income), nutrients (leaching, run-off and/or gaseous losses), and soil resources (erosion and fertility losses). Despite the apparent focus on losses, this definition also covers over-application of nutrients, or nutrients that are applied when not needed, because they could ultimately contribute to losses of nutrients and profitability.

**SIX EASY STEPS program**

The SIX EASY STEPS program is an integrated nutrient management package that enables the adoption of best-practice nutrient management on-farm (Schroeder et al., 2006). The overall objective of the program is to provide guidelines that lead to sustainable, site/soil specific and balanced nutrient management across the industry. The SIX EASY STEPS consist of:

- Knowing and understanding our soils.
- Understanding and managing nutrient processes and losses.
- Soil testing regularly.
- Adopting soil-specific nutrient management guidelines.
- Checking on the adequacy of nutrient inputs (e.g. leaf analyses).
- Keeping good records to help interpret trends in production and modify nutrient inputs when and where necessary.

The program is being delivered to industry through grower-orientated short-courses called ‘Accelerating the adoption of best-practice nutrient management’ (Schroeder et al., 2007b). These courses provide growers (and their advisors) with comprehensive details of the SIX EASY STEPS process and information on how to develop nutrient management plans for each block of cane on their farms. The training program is supported by other SIX EASY STEPS initiatives such as:

- Soil reference booklets that provide information on soil-specific nutrient management guidelines for sugarcane production within districts (Wood et al., 2003; Schroeder et al., 2007a).
- Replicated on-farm strip trials for growers to compare their current fertiliser programs with best-practice inputs for their soils (Salter et al., 2008, Schroeder et al., 2009b).
- NutriCalc, a user-friendly nutrient requirement calculator based on soil test values.
A Soil Constraints and Management Package (SCAMP) that utilises soil data to identify soil constraints to long-term productivity and profitability (Moody et al., 2008).

Development of ‘SafeGauge for Nutrients’ that aims to assess the risk of off-site losses (leaching or run-off) following fertiliser applications (Moody et al., 2008).

Research trials that investigate aspects of nutrient management not fully understood and the nutrient requirements of new farming systems (Wood et al., 2008).

Results and improvements from these activities are fed directly into the nutrient management short-course.

Principles of the N management guidelines used within the SIX EASY STEPS program

The N guidelines in the SIX EASY STEPS program are based on a combination of district yield potential and a soil N mineralisation index. The district yield potential is determined from the best possible yield averaged over all soil types within a district and is defined as the estimated highest average annual district yield (t cane/ha) multiplied by a factor of 1.2 (Schroeder et al., 2007a). This concept recognises differences in the ability of districts and regions to produce cane. The district yield potential for several districts (Wet Tropics, Herbert, Plane Creek, Bundaberg/Isis and Maryborough) is 120 t cane/ha (estimated highest average annual yield of 100 t cane/ha multiplied by 1.2). The district yield potential for the Proserpine and Mackay regions is set at 130 t cane/ha, and two values have been set for the Burdekin region depending on perceived longer-term yields: 150 t cane/ha and 180 t cane/ha.

The district yield potential is used to establish the base N application rate according to an estimate previously developed by Keating et al. (1997). They found that 1.4 kg N/t cane was required up to a cane yield of 100 t/ha and 1 kg N/t/ha thereafter. This is used to set a base-line N application rate of 160 kg N/ha for the Wet Tropics, Herbert, Plane Creek, Bundaberg/Isis and Maryborough districts, 170 kg N/ha for the Proserpine and Mackay districts, and 190 kg N/ha and 220 kg N/ha for the Burdekin region (Table 2).

</tbody>
</table>
With the SIX EASY STEPS approach, inputs are then adjusted according to an N mineralisation index, which classes N inputs (Table 2) according to soil organic carbon (%) values (Schroeder et al., 2005). This produces a range of N application rates for replant (plant cane established shortly after harvest of the final ratoon in the previous crop cycle) and ratoon cane that correspond to these N mineralisation classes within each of the districts (Table 2). As plant cane requires less fertiliser N than replant and ratoon cane, a range of N application rates has also been established for plant cane that follows a bare or grass fallow (Table 2).

When the SIX EASY STEPS N guidelines are considered in terms of N-use efficiency, it has been important to define two terms:

- N-fertiliser utilisation index (kg N/t cane produced) = N applied (kg N/ha) / yield (t cane/ha)
- Fertiliser N-use efficiency factor (t cane/kg N) = yield (t cane/ha) / N applied (kg N/ha)

Management strategies aim to improve N-use efficiency by ensuring that the ‘N fertiliser utilisation index’ is as low as possible, and the ‘fertiliser N-use efficiency’ is as high as possible, without affecting productivity and profitability. The values shown in Table 2 (recommended application rates and district yield potential values) can be used to determine the SIX EASY STEPS target N fertiliser utilisation index (N application rate/district yield potential) and target fertiliser N-use efficiency (district potential yield/N application rate) values that apply to replant / ratoon cane and plant cane in each of the districts (Table 3).

**Table 3** – Target fertiliser N use efficiency and N fertiliser utilisation index values calculated for the N management guidelines in the SIX EASY STEPS program.

| Recommended N: replant / ratoon cane (kg N/ha) | 220 | 210 | 200 | 190 | 180 | | |
| Target N fertiliser utilisation index (kg N / t cane) | 1.22 | 1.17 | 1.11 | 1.06 | 1.00 | | |
| Target fertiliser N use efficiency (t cane/kg N) | 0.82 | 0.86 | 0.90 | 0.95 | 1.00 | | |
| Recommended N: plant cane after a grass/bare fallow | 180 | 170 | 160 | 150 | 140 | | |
| Target N fertiliser utilisation index (kg N / t cane) | 0.83 | 0.78 | 0.72 | 0.67 | 0.61 | | |
| Target fertiliser N use efficiency (t cane/kg N) | 1.20 | 1.29 | 1.38 | 1.50 | 1.64 | | |
The information in Table 3 shows that the target N fertiliser utilisation index value ranges from 1.33 kg N/t cane (for replant / ratatoule cane grown on soils with very low soil organic C in districts with a yield potential of 120 t cane/ha) to 0.61 kg N/t cane (for plant cane grown on soils with 1.6–2.0 % organic C in the higher yield potential (180 t cane/ha) areas of the Burdekin region.

As the SIX EASY STEPS program also recognises the N inputs from other sources (legume fallow crops, mill by-products, residual mineral N remaining after horticultural crops that are grown in rotation with sugarcane, irrigation water, etc), lower N fertiliser utilisation index values and higher fertilisation N-use efficiencies are used to take these into account. Examples of the calculated target values for the efficiency factors after legume fallow crops are shown in Table 4. Where the other sources of N supply enough N to meet the N requirement for sugarcane production, the N fertiliser utilisation index will be zero.

The SIX EASY STEPS program also recognises that, if a sub-district or farm consistently produces yields that are either higher or lower than the district yield potential, the baseline application rate should be adjusted upward or downward by 1 kg N per tonne of cane above the district yield potential. Such adjustments influence both target N-use efficiency factors.

Table 4—Target fertiliser N use efficiency and N fertiliser utilisation index values calculated for the N management guidelines for plant cane following legume fallow crops (Wet Tropics, Plane Creek, Bundaberg/Isis and Maryborough: district yield potential = 120 t cane/ha)

Assessing the value of the SIX EASY STEPS N management guidelines

A combination of small plot experiments and larger-scale on-farm replicated strip-trials has provided the means of assessing the value of the SIX EASY STEPS N management guidelines.

Small plot experiment

Data from a trial conducted in the Tully district of the Wet Tropics were recently used to assess the alternative N management strategies (Table 1) and what each of these means in terms of productivity, profitability and environmental implications (Schroeder et al., 2009a). Cumulative response curves for both cane and sugar yields were produced by summing yields from successive crops within the crop cycle and plotting these yields against cumulative N rates (Schroeder et al., 2009a). These curves were used to calculate industry partial net returns for each of the N management strategies. The N strategies that were evaluated were:

- Grower-developed (a possible grower application rate used in the Tully district).
- Traditional (previous industry guidelines as indicated by Calcino (1994)).
- SIX EASY STEPS (according to the guidelines shown in Table 2).
- N Replacement (1 kg N/t cane in the previous crop (Thorburn et al., 2007)).

The appropriate N inputs and yield data from the trial are shown in Table 5. While the grower-developed, traditional and SIX EASY STEPS approaches produced cumulative yields of 304, 305 and 303 t cane/ha, respectively, over the crop cycle (plant crop to third ratoon), the N Replacement strategy produced 277 t cane/ha over the same period. Based on sugar price (Aus$320/t sugar) and the cost of N (Aus$1.56/kg N) as applicable in June 2009, partial net returns for the N Replacement strategy were Aus$247/ha/year less than that of the SIX EASY STEPS. The grower-developed approach also resulted in Aus$36/ha/year loss in partial net return. The data (Table 5) indicated that yields did not normalise when low nitrogen inputs (such as those advocated by the N Replacement strategy) continued over the crop cycle.

The yield and N input data were used to calculate the N-use efficiency factors for each of these N management strategies (Table 6).

</table>
The calculated N utilisation index values for the SIX EASY STEPS approach and the N Replacement strategy over the crop cycle (1.78 kg N/t cane and 1.16 kg N/t cane, respectively) were lower than that of the grower-developed and traditional approaches (2.27 kg N/t cane and 1.97 kg N/t cane, respectively). The grower-developed strategy would be considered wasteful of N inputs as well as being environmentally unacceptable. In this case the actual N-use efficiency was much lower than that of both the SIX EASY STEPS and the N Replacement strategies.

Although the N Replacement concept appears to be more efficient, the decrease in productivity (cane and sugar per hectare) resulted in losses in profitability compared to the SIX EASY STEPS approach. These results indicate that improvement in N fertiliser-use efficiency cannot be seen in isolation from productivity and profitability on farm. The SIX EASY STEPS approach that considers both these aspects is balanced and therefore more appropriate than systems aimed at either maximum production or being overly environmentally focused.

**Replicated demonstration strip trials**

Four participative replicated demonstration strip trials that were recently established in first ratoon cane crops in the Tully district to compare the productivity and profitability associated with three of the N input strategies identified in Table 1 (Grower-developed versus SIX EASY STEPS versus N Replacement). The N input strategies that were tested included the growers’ usual application rates, the SIX EASY STEPS guidelines (Table 2) and the N Replacement strategy (1 kg N/t cane produced in the previous crop).

An economic assessment of each N input approach was undertaken using the ‘pooled’ data from the four trials by:

- Determining the partial net return per hectare to the grower, where:
  \[
  \text{Grower partial net return} = (\text{gross income calculated from the Tully cane payment formula}) - (\text{cane yield} \times \text{estimated harvesting costs plus levies}) - (\text{fertiliser cost}) \\
  \]

- Calculating the industry (grower and miller) partial net return per hectare, where:
  \[
  \text{Industry partial net return} = (\text{sugar yield} \times \text{price of sugar}) - (\text{fertiliser cost} \times \text{application rate (kg/ha)}) - (\text{cane yield} \times \text{estimated harvesting costs plus levies})
  \]

The results of the statistical analysis and economic assessment of the pooled yield data from the four strip trials are shown in Table 7. Yields associated with the ‘grower’ and SIX EASY STEPS N inputs were not significantly different, but the N Replacement strategy resulted in yields (t cane/ha and t sugar/ha) significantly lower than those obtained from both of these approaches (across the four trial sites).

**Table 7**—Influence of different fertiliser strategies on cane yield, CCS, sugar yield and partial net returns using pooled data from the Tully SIX EASY STEPS calibration strip trials (first ratoon crop harvested 2008).

1Means with the same superscript letter in each column are not significantly different.
2Industry = total partial net return (grower plus miller).

Assumptions: sugar price = Aus$320/tonne, cost of N = Aus$1.56/kg
The grower and industry net returns indicated a decrease in value: Grower > SIX EASY STEPS > N Replacement. However, as the yields associated with the ‘grower’ and SIX EASY STEPS strategies were not significantly different from each other, the net return values were also viewed as being not different. Hence the partial net return values associated with the SIX EASY STEPS approach (grower: Aus$1996 and industry: Aus$3323) and the N Replacement strategy (grower: Aus$1879 and industry: Aus$3109) form a valid comparison. The SIX EASY STEPS approach resulted in a mean grower partial net return of Aus$117/ha and a mean industry partial net return of Aus$214/ha higher than that of the N Replacement.

Discussion and conclusions

The SIX EASY STEPS program is consistent with the defined principles of best practice management. It aims to directly minimise losses of productivity, profitability, applied nutrients and inherent soil fertility.

This is achieved through the SIX EASY STEPS framework that enables growers to tailor their nutrient inputs for their specific circumstances (particular soils, climatic and production conditions, etc). Although this paper deals almost exclusively with N, it was recognised earlier that the SIX EASY STEPS program is aimed at overall nutrient management that encourages sustainable and ‘balanced’ inputs on-farm.

Trial results presented indicate that the SIX EASY STEPS N guidelines are robust and much more in line with the concept of sustainability than the other strategies considered. The fact that these guidelines are based on a combination of district yield potential and a soil mineralisation index enables N inputs to be both district and soil specific.

Despite the use of pre-determined yield potentials within the current SIX EASY STEPS N guidelines, the program has enough flexibility to allow deviations from these values. Already, it is recognised that adjustments can be made for sub-districts or farms that consistently produce yields (over more than 15 years) that are either higher or lower than the district yield potential.

Calculation of the target N-use efficiency factors across the full range of SIX EASY STEPS N guidelines, especially when all possible sources of N within the soil/plant environment were included, indicated that appropriate N efficiencies are being targeted.

This strengthens the SIX EASY STEPS system as an appropriate and fully comprehensive nutrient management package. This was confirmed by the results of the economic analyses performed on data from both small plot experiments and commercially-based replicated strip trials conducted on-farm. Importantly, the economic viability of the SIX EASY STEPS N guidelines was illustrated for both the grower and milling sectors.

In overall terms, it is vital that the most appropriate N inputs are used within the sugarcane production system in Australia. This not only has implications for the environment, especially the Great Barrier Reef, but also for the communities of regional Queensland that are dependent on a sustainable sugar industry. It is our opinion that the SIX EASY STEPS guidelines, especially those that relate to N management, are the only viable option at present.

PALABRAS CLAVE: Caña de Azúcar, Recomendaciones para el Manejo de Nitrógeno, Validación, Validez.

Resumen

ACTUALMENTE la industria azucarera australiana enfrenta una vigilancia sin precedentes sobre su uso de nutrientes, debido a iniciativas para proteger la Gran Barrera de Coral del exceso de nutrientes y sedimentos provocados por las actividades agrícolas a lo largo de la costa de Queensland. Sin embargo, esta acción necesita verse en conjunto con la necesidad de una industria cañera sostenible. Recientemente se ha desarrollado un programa global para el manejo de nutrientes (el programa SEIS PASOS SENCILLOS) para la industria azucarera australiana. Éste reemplaza las recomendaciones generales previas que no diferenciaban entre regiones o tipos de suelo y carecian de precisión. El nuevo sistema fundamenta una producción cañera rentable y sostenible, aumenta la conciencia ambiental y es consistente con la aplicación de mejores prácticas. El artículo resume las estrategias alternativas para el manejo de nitrógeno dentro de la industria azucarera australiana. Describe las mejores prácticas para el manejo de nutrientes y los conceptos que fundamentan el programa SEIS PASOS SENCILLOS, explica los principios usados dentro del programa en cuanto a recomendaciones para el manejo de nitrógeno, y relaciona todo con la
eficiencia en el uso de nitrógeno. Además, se evalúa la validez de SEIS PASOS SENCILLOS para recomendaciones en el manejo de nitrógeno. Los resultados de los experimentos que se presentan indican que las recomendaciones de nitrógeno de SEIS PASOS SENCILLOS son robustas y mucho más en línea con el concepto de sostenibilidad que cualquiera de las otras estrategias consideradas. El cálculo de los factores clave en la eficiencia del uso de nitrógeno a lo largo de los SEIS PASOS SENCILLOS para recomendaciones de nitrógeno, especialmente al incluir todas las posibles fuentes de nitrógeno en el ambiente suelo/planta, refuerza al programa para que se considere como un paquete completo para el manejo de nutrientes. Esto se confirma con los resultados de análisis económicos de datos provenientes de experimentos en parcelas pequeñas y tratamientos en franjas con repeticiones, realizados en campos comerciales.
RECOVERY OF NITROGEN (15N) BY SUGARCANE FROM PREVIOUS CROP RESIDUES AND UREA FERTILISATION UNDER A MINIMUM TILLAGE SYSTEM

KEYWORDS: Green-Cane, 15N Labelled Urea, Sugarcane Trash, Nitrogen Uptake, Mineralisation.

Abstract

RESIDUES of green-harvested sugarcane contribute to nutrient recycling in production systems. Therefore, better understanding of trash decomposition dynamics can help crop fertilisation management. This study was conducted during the 2006–2008 seasons in Jaboticabal, north-eastern Sao Paulo State, Brazil and aimed to evaluate the nitrogen recovery rates from the previous crop residues or from urea applied on sugarcane planting in a minimum tillage system, thus without trash and rhizome incorporation in crop renewal. Previous crop residues consisted of 9 and 3 t/ha of sugarcane trash (dry tops + leaves) and root system (roots + rhizomes) enriched with 1.07 and 0.81% 15N isotope, respectively. These contributed 51 and 33 kg/ha of N. 15N labelled trash laid on the soil surface and buried 15N-root system attempted to simulate the original field residues disposal. The SP81-3250 variety was planted with 80 kg N/ha of a 5.17% 15N-labelled urea. Recovery of sugarcane residues-N (trash-N and root system-N) or urea-N incorporated to the soil at planting were evaluated in distinct plant parts (stem, tops and dry leaves) during three consecutive harvest seasons. Recovery of urea-N was higher in the first harvest season (31% of initial N rate) and its uptake decreased in the second and third to 5% and 4%, respectively. In later harvested seasons, urea-N had probably been turned-over as soil organic matter and/or microbial biomass but remained in the soil N pool and available for plant recovery. Trash-N uptake closely resembled urea-N uptake, and only 13% of its N content was recovered in the first year, followed by 7% and 3% in the second and third seasons. Root system-N recovery was different since the second cut uptake was higher than the first followed by the third, 9% 6% and 2% respectively. Three year cumulative recovery of urea-N, trash-N and root system-N was 39%, 23% and 17%, respectively. Most recovered N was found in stems followed by tops and dry leaves.

Introduction

Brazil is the world’s largest sugarcane producer, totalling 7 million hectares of which more than 50% of harvest is performed without burning in Sao Paulo State (Unica, 2009). Sugarcane under green cane trash blanket (GCTB) has been adopted by many producers worldwide as a conservative crop system, reducing soil erosion and greenhouse gas (GHG) emissions. Likewise, minimum or no-tillage systems also present benefits in cost savings for highly competitive growers (Wood, 1991).

Residues of GCTB contribute to nutrient recycling in production systems; therefore, better understanding of trash decomposition dynamics can help crop fertilisation management. Those crop residues provide annually about 40 to 120 kg/ha of N thereby increasing the amount of organic matter and nutrients in the soil (Trivelin et al., 1996; Wood, 1991; Oliveira et al., 2002).
Nitrogen tracer (\(^{15}\text{N}\)) trials indicate that fertiliser-N recovery by the sugarcane crop varies from 5% to 40% (Basanta et al., 2003; Franco, 2008; Gava et al., 2005; Meier et al., 2006; Trivelin et al., 1996). These low recovery rates might be due to N losses from soil by denitrification and/or ammonia volatilisation, and gaseous losses from leaf canopy of plants (Trivelin et al., 1996) and microbial immobilisation of N in the soil (Gava et al., 2005; Oliveira et al., 2002).

Crop residues mineralisation is dependent on environmental factors such as temperature, soil moisture and aeration. Nevertheless, chemical composition of residues such as C:N ratio, lignin, cellulose, hemicellulose, and polyphenols content also play an important role in trash decomposition and nutrient dynamics (Janzen et al., 1988; Meier et al., 2006; Oliveira et al., 2002).

Sugarcane trash presents on average 390 to 450 g/kg of carbon and 4.6 to 6.5 g/kg of N, thus a C:N ratio about 100. Under these conditions, a strong immobilisation of soil N by microbial biomass and a reduced net N mineralisation for the subsequent growing season after harvested unburned sugarcane is expected, as pointed out by several trials using \(^{15}\text{N}\) tracer (Franco, 2008; Gava et al., 2005; Ng Kee Kwong et al., 1987; Oliveira et al., 2002; Meier et al., 2006).

Nitrogen recovery from crop residues incorporated into the soil varies from 2.4% to 15%. The recovery rate depends basically on residues quality regarding N content, higher than 20 g/kg and a C:N ratio lower than 25. This allows faster mineralisation compared to N immobilisation and enables higher N uptake by plants from those organic sources (Ng Kee Kwong et al., 1987; Janzen et al., 1988; Chapman et al., 1992; Gava et al., 2005).

Most studies have considered only one or two harvest seasons to evaluate the effect of N uptake from fertilisers and crop residues. This study was conducted in north-eastern Sao Paulo State, Brazil and aimed to evaluate nitrogen recovery rates from the previous-crop residues and from urea applied to sugarcane under a minimum tillage system during three consecutive harvest seasons, 2006 to 2008.

Material and methods

Location, trial design and \(^{15}\text{N}\) labelled fertiliser/crop residues

The trial was planted on March 2nd, 2005 in Jaboticabal county, north-eastern Sao Paulo State (Lat 21°17’S, Long 48°12’W) on a clayey Typic Hapludox under minimum tillage system. The previous sugarcane crop, 5th ratoon of RB855536 variety, had been desiccated with herbicide and succeeded by a single subsoiling operation, attempting to preserve previous crop residues on the soil surface.

Soil 0–25 cm layer analysis indicated: 135, 227 and 628 g/kg of total sand, silt and clay, respectively, pH\(_{\text{(CaCl2)}}\) 5.2; OM (g/dm\(^3\)) 31; P (mg/dm\(^3\)) 42 and K, Ca, Mg, and CEC, 3.1, 31, 9, 77.4 (mmolc/dm\(^3\)), respectively.

A randomised block design was adopted with four replicates of twelve rows with 15 m length and spaced 1.5 m apart. Plant-cane fertilisation (N:P\(_2\text{O}_5\):K\(_2\text{O}\)) was 80:120:120 with a planting density of twelve viable buds per metre of SP81-3250 variety. On ratoons, fertilisation was only KCl (150 kg/ha K\(_2\text{O}\)) applied as a row top dressing after each harvest.

In each plot replicate for plant-cane, micro plots comprising 2.0 m length furrows were assembled and a 5.17% \(^{15}\text{N}\) enriched urea was buried as done with ordinary urea in the remaining plot area (Trivelin et al., 1994).

Attempting to simulate past crop residues left on the soil surface, hereafter known as previous crop trash (PCT) and rhizomes (PCR), a small plot of the previous variety (RB855536) was cropped outside this trial, and the plants were labelled by foliar spraying with a 28% \(^{15}\text{N}\) urea solution, according to Faroni et al. (2007). The achieved concentrations of C, N (g/kg) and \(^{15}\text{N}\) (%) on PCT and PCR were 402, 5.7, 1.07% and 334, 6.6, 0.81%, respectively. Thus, C:N ratios on those materials were around 71:1 for PCT and 51:1 for PCR.
Furthermore, dry leaves and rhizomes were harvested out of this plot in order to assemble other $^{15}$N labelled residues micro plots (2.0 x 1.5 m), settled separately in each replication. To simulate the original disposal of crop residues, 9 t/ha of PCT was laid on soil surface and 3 t/ha of PCR was buried into soil as in Franco (2008). Thus, the total N (kg/ha) added by urea, PCT and PCR were 80, 51 and 33, respectively.

Rainfall during the studied seasons was: 1767, 1715 and 1367 mm for plant-cane, first and second ratoons, respectively. Average maximum and minimum temperatures (ºC) in these seasons were 30.4 and 18.0, respectively.

**Harvesting, sampling and statistical analysis**

The trial has been conducted over three consecutive harvest seasons: 18 month plant-cane was harvested on August 10th, 2006 and first and second 12 month ratoons on August 21st, 2007 and 25th July, 2008, respectively. Agro industrial yield data were evaluated but will not be discussed in this paper.

Harvest of urea, PCT and PCR micro plots comprised the collection of cane in 1.0 m of the central and two adjacent rows, in the same contiguous position as described in Trivelin et al. (1994) and performed in several trials (Trivelin et al., 1996; Basanta et al., 2003; Franco, 2008; Gava et al., 2005). All plant parts were harvested separately (stems, dry leaves and tops). Plant parts fresh mass were evaluated directly in the field with a weighing scale and crushed in mechanical forage chopper as in Franco (2008).

Homogenised sub-samples were prepared according to Trivelin et al. (1996) (65ºC drying for 72 h and finely ground on Willey type mill) for determination of total N (%) and $^{15}$N abundance analysis in a mass spectrometer model Hydra 20-20 SerCon Co., UK, coupled to an automatic N analyser ANCA-SGL (Barrie & Prosser, 1996).

Nitrogen recovery from fertiliser and crop residues was calculated using formulae described below (Trivelin et al., 1994; 1996):

$$Ndfs = \frac{(A - 0.367)}{(B - 0.367)} \times NC$$

$$R(\%) = \frac{(Ndfs)}{(NR)} \times 100;$$

where:

- $Ndfs$: N in plant part derived from $^{15}$N source (urea, PCT or PCR);
- $A$ and $B$: $^{15}$N abundances of harvested samples (plant part) and from $^{15}$N source, respectively (0.367% is the natural $^{15}$N abundance);
- $NC$: nitrogen content in each plant part (stem, dry leaves or tops);
- $R$: N recovery from a N source in each sample (plant part);
- $NR$: applied N rate (via fertiliser or crop residues).

ANOVA and F test statistical analyses were performed. Means detected as significant by the F test were compared by the Tukey test at 1 and 5% of probability.

**Results and discussion**

**Nitrogen recovery from planting fertiliser (urea)**

Plant-cane urea-N recovery was higher in the first harvest season, 24.7 kg/ha (31% of applied N) (Table 1). This result is consistent with 28% (22 kg/ha of urea-N) by plant-cane obtained by Franco (2008) who evaluated two other field trials using the same sugarcane variety and planting fertiliser rate (80 kg N-urea/ha). Bologna-Campbell (2007) also used the same N rate in a study with SP80-3280 variety planted in pots and obtained 35% of urea-N utilisation for the whole plant (above ground parts plus roots and rhizomes).

Chapman et al. (1992) also found that 32% of buried urea on planting was present in the first crop, despite the applied rate was two-fold compared with this case (160 kg/ha). Basanta et al. (2003) concluded that 63% (40 kg/ha) of N applied on planting was recovered by plant cane. Note
that those authors utilised a lower N dose (63 kg N/ha) as ammonium sulfate applied 50 days after planting. Korndorfer et al. (1997) found 53% of apparent urea-N recovery applied on plant cane measured using a non-isotopic method (difference method). Those authors emphasised this method usually overestimates real fertiliser-N uptake.

Table 1—Nitrogen (15N) recovery (R%) from fertiliser (Urea) applied at planting, previous crop trash (PCT) and rhizomes (PCR) in 2006, 2007 and 2008 growing seasons.

Slight differences of urea-N accumulation on plant-cane parts were found, compared to literature results. Data shown in this study presented higher uptake by the stems (77%) followed by tops (12%) and dry leaves (11%) (Table 1). Franco (2008) obtained 54% of total urea-N applied on stems, 22% on dry leaves and 24% on tops of plant cane, similar to Basanta et al. (2003) who concluded that 56% of planting fertiliser-N uptake was on stems, 23% dry leaves and 22% on tops. Korndorfer et al. (1997) found that 56% of urea-N uptake remained on stems; 16% on dry leaves and 28% on tops, respectively. These differences could be explained by the higher tonnage obtained in the present work (average 156 t/ha, data not shown) which could lead to higher urea-N accumulation in millable stalks. This could also reflect on N uptake by cane tops in further years since there were no significantly differences in three seasons for this specific plant part (Table 1).

The cumulative urea-N uptake in three seasons (2006 to 2008) reached 31.5 kg/ha (21 in stems, 4.5 dry leaves and 6 on tops). The overall recovery of urea-N applied at planting in three consecutive seasons was 39% of which 66% was found in stems, 14% in dry leaves and 20% in tops (Table 1). After the first year, urea-N had probably been turned-over as soil organic matter and/or microbial biomass but remained in the soil as an available N pool for plant recovery.

These results concord with those of Chapman et al. (1992) who obtained 32% of N recovery from buried urea application in the first year and an average of 5% was recovered by the crop above
ground part on the second cut. In the present results, 5% and 3.5% of urea-N was recovered in the second and third harvest seasons, respectively (Table 1). Basanta et al. (2003) concluded that 77% (49 kg/ha) of planting fertiliser-N (ammonium sulfate) was recovered after three cropping seasons. From that amount, 53% was exported by stems, 24% dry leaves and 23% by cane tops, respectively.

The urea-N uptake by the whole above ground part over time (1st to 3rd cut) was 31%, 5% and 4%, the same pattern obtained by Basanta et al. (2003), 63%, 11%, 4%, for first second and third cuts, respectively.

**Nitrogen recovery from previous crop residues (PCT and PCR)**

Nitrogen recovery from PCT and PCR by plant cane was 13% and 6%, respectively (Table 1). These results are consistent with those of Ng Kee Kwong et al. (1987) who observed up to 14% of trash-N recovery, when this residue remained for eighteen months in field conditions. Bologna-Campbell (2007) found 14% of crop residues-N utilisation by sugarcane after 12 months planting by using a mixture of sugarcane trash (tops + dry leaves) and rhizomes + roots labelled with $^{15}$N incorporated to the soil; 74% of crop residues-N remained in the soil at the end of the 1st season harvested.

PCT-N uptake decreased from the first to third cropping season, 13%, 7% and 3%; respectively. PCT-N amount found in stems was 74%, 11% in dry leaves and 15% in cane tops (Table 1). This distribution agreed with Gava et al. (2005) who found trash-N uptake as 52% in stems, 7% in dry leaves and 29% in cane tops. PCT-N uptake was closely related to urea-N recovery and was remarkably higher in the first cut, decreasing in the second and third harvest seasons (Table 1). This also indicates that the urea-N added to soil under GCTB and minimum tillage system could have enhanced crop residues mineralisation.

In contrast to PCT-N, a larger amount of PCR-N was recovered after the plant-cane cycle, 9% during the second harvest season, followed by 6% on the first and 2% on the third season (Table 1). This could have happened because this residue was previously buried into soil in a minimum tillage system environment, thus with limited aeration capacity leading to lower mineralisation rates in the first year (Janzen et al. 1988). This result differs from those obtained by Chapman et al. (1992) who stated that 4% of the N from a $^{15}$N-labelled crop residue (roots and stubbles) was assimilated by sugarcane after two cropping seasons. They mentioned that sometimes temporary flooding may lead to lower decomposition rates of crop residues and can reduce its N availability to plants.

Unburned cane and in this case, minimum tillage system, can lead sugarcane root system to be more superficial and take advantage of surface nutrients (Meier et al., 2006; Oliveira et al., 2002). PCR-N recovered by crop was 57% in stems, 19% in dry leaves and 23% in tops.

After three cropping seasons, N recovery from PCT and PCR by sugarcane aerial part was 12 and 6 kg/ha, respectively. As those residues contributed initially with 51 and 33 kg N/ha, N uptake was approximately 23% and 17% after three harvests (Table 1). Basanta et al. (2003) obtained 7 kg/ha (5%) of trash-N recovered by sugarcane in two consecutive cropping seasons, of which 51% was in stems, 24% in dry leaves and 29% in tops.

Overall N uptake from PCT and PCR found herein (23% and 17% – Table 1) are larger than ones found by Ng Kee Kwong et al. (1987) and Gava et al. (2005), 14% and 9%, respectively. This could be explained by the lower C:N ratio on residues applied during this work (PCT: 71:1 and PCR: 51:1) compared with those used by authors where C:N ratio was higher than 125:1. Furthermore, higher C:N ratios can decrease mineralisation rates as stressed by Janzen et al. (1988). Another point to consider is the total time of each trial (three seasons in this work against one in the others) and the local environment temperature, an important factor to be considered in this kind of evaluation.
It is also clear that trash composition is dependent on variety characteristics. Meier et al. (2006) used a $^{15}$N-labelled trash from Q166 variety (C:N 105:1) in their research in Queensland, Australia but stated that this ratio usually varies from 70:1 to 120:1. Oliveira et al. (2002) found C:N = 95:1 on recently harvested trashes of two distinct varieties (SP79-1011 and SP80-1842) and two locations in Sao Paulo State, Brazil. Bologna-Campbell (2007) obtained similar values of C:N ratio compared to the present work, 89:1 for trash and 57:1 for root system grown in pots.

Wood (1991) stated that unburned cane management provided 50% of overall urea-N recovery compared to less than 40% in burned cane but emphasised that variety suitability for GCTB crop management is mandatory for successful sugarcane growing.

In general, the amount of N recovered decreased in the order stems>tops>dry leaves. These results are consistent with those of Basanta et al. (2003), Gava et al. (2005) and Ng Kee Kwong et al. (1987) indicating that, despite crop residues-N having slow release and is mainly immobilised in the soil, it can become a complementary source of N for succeeding crops.

**Conclusion**

Nitrogen recovery from urea, PCT and PCR after three harvest seasons was 39%, 23% and 17%, respectively, indicating that N from crop residues is an important long-term source of nitrogen to sugarcane.

The larger portions of recovered nitrogen from urea and crop residues were found on stems followed by tops and dry leaves.

MOTS CLES. Canne Récoltée en Vert, Urée Marquée $^{15}$N, Paillis de Canne à Sucre, Prélèvement d’Azote, Minéralisation.

Résumé

Les résidus de canne coupée en vert contribuent au recyclage des éléments minéraux dans les systèmes de production. Une meilleure connaissance de la dynamique de décomposition du paillis peut servir lors de la gestion de la fertilisation. Une étude fut réalisée pendant les saisons 2006-2008 à Jaboticabal, au Nord-Est de l’Etat de Sao Paolo, Brésil. Cette étude avait pour but d’évaluer les taux de récupération d’azote provenant des résidus de la récolte précédente ou de l’urée appliquée lors de la plantation de canne dans un système de type travail du sol minimum. Sans incorporation du paillis et des souches lors du renouvellement de la culture. Les résidus de la culture précédente étaient constitués de 9 et 3 T/ha de paillis de canne (feuilles et sommets secs) et du système souterrain (racines et rhizomes); enrichis respectivement avec 1.07 et 0.81 % d’isotope de $^{15}$N Ceci correspondait à 51 kg/Ha de N marqué avec $^{15}$N dans le mulch laissé en surface et à et 33 kg/Ha de système racinaire marqué avec $^{15}$N et enfoui pour représenter le système initial de résidus. La variété SP81-3250 fut plantée avec 80 kg/Ha d’azote d’urée marquée à 5.17%. La mobilisation de l’azote des résidus (paillis et parties racinaires) ou de l’azote de l’urée appliquée lors de la plantation de canne dans un système de type travail du sol minimum sans incorporation du paillis et des souches lors du renouvellement de la culture. Les résidus de la culture précédente étaient constitués de 9 et 3 T/ha de paillis de canne (feuilles et sommets secs) et du système souterrain (racines et rhizomes); enrichis respectivement avec 1.07 et 0.81 % d’isotope de $^{15}$N Ceci correspondait à 51 kg/Ha de N marqué avec $^{15}$N dans le mulch laissé en surface et à et 33 kg/Ha de système racinaire marqué avec $^{15}$N et enfoui pour représenter le système initial de résidus. Palabras clave: Caña en Verde, Urea Marcada con 15N, Trash de Caña de Azúcar, Absorción de Nitrógeno, Mineralización.

Resumen

En los sistemas de producción, los residuos de caña cosechada en verde contribuyen al reciclaje de nutrientes. Por ello una mejor comprensión de la dinámica de descomposición del trash puede ayudar en el manejo de la fertilización del cultivo. Este estudio se condujo durante las zafra 2006-2008 en Jaboticabal, en el noreste del estado de Sao Paulo, en Brasil. El objetivo era evaluar los índices de recuperación de nitrógeno de los residuos de cosechas previas o de urea aplicada a plantaciones de caña de azúcar bajo un sistema de labranza mínima, es decir, sin incorporación de trash y rizomas en la renovación del cultivo. Los residuos de cosechas anteriores consistieron en 9 y 3 t/ha de trash de caña de azúcar (cogollos secos + hojas) y sistemas radiculares (raíces + rizomas) enriquecidos con 1.07 y 0.81% del isótopo 15N, respectivamente. Esto aportó 51 y 33 kg/ha de N. Para simular los residuos reales de que se dispone en el campo, se colocó el trash marcado con 15N sobre el surco y los sistemas radiculares se enterraron. La variedad SP81-3250 se plantó con 80 kg N/ha de urea marcada con 5.17% de 15N. La recuperación de nitrógeno proveniente de residuos (trash y raíces) o de urea incorporada al suelo al momento de la siembra, se evaluó en diversas partes de la planta (tallos, cogollos y hojas secas) durante tres zafra consecutivas. La recuperación de N de urea fue mayor en la primera cosecha (31% del índice de N inicial) y su absorción disminuyó en la segunda y tercera cosecha a 5 y 4%, respectivamente. Probablemente el N de la urea se reincorporó al suelo como materia orgánica o biomasa microbiana en las zafra posteriores, pero permaneció en el suelo disponible para ser recuperado por la planta. La absorción del N del trash fue similar a la del N de urea y solamente el 13% de su contenido de N se recuperó el primer año, seguido de 7 y 3% en la segunda y tercera cosecha. La recuperación del N de los sistemas radiculares fue diferente, dado que la absorción durante la segunda cosecha fue mayor que la de la primera, seguida por la tercera, con 9, 6 y 2% respectivamente. La recuperación acumulada en tres años de N de urea, trash y sistemas radiculares fue 39, 23 y 17%, respectivamente. La mayor parte del N recuperado se encontró en los tallos, seguidos por los cogollos y hojas secas.

dans le pool azoté; disponible pour la mobilisation par la plante. La mobilisation de l’azote du paillis fut proche de celle de l’azote de l’urée, et seulement 13% de sa teneur en azote fut récupéré la première année, puis 7 et 3% les deux années suivantes. La mobilisation de l’azote du système racinaire fut différente puisque la mobilisation de la seconde récolte fut plus élevée que celle de la première et de la troisième à raison de 9, 6 et 2% respectivement. Les mobilisations cumulées sur 3 ans de l’azote de l’urée, du paillis et du système racinaire furent de 39, 23 et 17%, respectivement. La plus grande partie de l’azote récupéré fut mobilisée dans la tige, suivie des sommets et des feuilles.
ACIDITY NEUTRALISATION ASSESSMENT AND REMEDIATION OF A CONSTRUCTED WETLAND IN SUGARCANE LAND

KEYWORDS: Acidity Remediation, Constructed Wetland, Rehabilitation for Sugarcane.

Abstract

A CONSTRUCTED wetland of six level-terraced bays has been trialled for treating acidic sugarcane land drainage arising principally from the oxidation of acid sulfate soils. A concern has been that the cane land may have been permanently degraded for future cane production due to the accumulation of acidic metal contaminants (especially iron and aluminium) stemming from this remediation technique. The site is now being remediated so that it can be returned to cane production. Following initial measurements to establish the water quality and sediment characteristics in the wetland, assessment was made of the required acidity neutralisation by liming, and these results were compared with best management practices for acid sulfate soil drains of New South Wales cane areas. Lime application and its incorporation were accompanied by removal of constructed banks and re-levelling of the cane block. The ability of the constructed wetland to neutralise acidity has been reported previously. Further assessment of water quality following rainfall and acid drainage shows the inherent neutralising capability of constructed wetlands, as determined by changes to pH, electrical conductivity, dissolved oxygen, and metal concentrations. Total acidity of surface soils (0–50 mm) was measured as being comparable with drain sediment in acid sulfate soils. Lime application, its incorporation, and re-levelling of the wetland site are within the scope of standard farmland practices. This approximately 1.6 ha constructed wetland surface was only capable of treating ~10% of the total acidity discharge from the 100 ha cane farm. The adoption of this as standard practice in acidic sugarcane drainage treatment is therefore impracticable. However, the principles shown here have potential for application in management of vegetated drains. Results show that the land used for the constructed wetland has not been permanently damaged by this trialled acidity remediation device.

Introduction

Acid sulfate soils (ASS) underlie more than 50% of the estuary floodplains used for sugarcane production in New South Wales, Australia. The sub-tropical high rainfall of these lands requires major surface drainage systems with the soils supplying significant acidity to the drainage water.

Robert Quirk operates one farm (100 ha) on ASS, and this site over the past 20 years has been the subject of much research and trialling of best management practices to reduce acidity discharge. Dr Rosalind Green completed most of her doctoral studies on the Quirk farm and its

drainage system, trialling a number of potential acidity management techniques. An important outcome of Green’s research was that, although protonic acidity ($H_3O^+$, as indicated by pH) is an important component of the drain water acidity, the main transported acidity component (>70%) is in the dissolved metals, particularly Aluminium (Al) and Iron (Fe) (see Figure 1).

These dissolved metals hydrolyse and form acidity when they precipitate, particularly in downstream waters (simplified in Equ. 1 and 2).

$$\text{Al}^{3+} + 3\text{H}_2\text{O} \rightarrow \text{Al(OH)}_3^{(s)} + 3\text{H}^+ \quad (1)$$

$$\text{Fe}^{3+} + 2\text{H}_2\text{O} \rightarrow \text{FeOOH} + 3\text{H}^+ \quad (2)$$

Managing such acidity from sulfide minerals and their oxidation products is also a major environmental issue with many mine sites. One management technique used to reduce acid mine drainage (AMD) is with constructed wetlands.

Therefore, using funds from the Australian Sugar Research and Development Corporation, a wetland of 6-terraced bays (approx. 2 ha of land with 1.6 ha of wetland surface) was constructed in 2003/4 adjacent to the drainage outlet from the 100 ha Quirk farm. A proportion (about 10%) of the drainage discharge from the farm was pumped into the uppermost bay from which it gravitated back into the farm’s outlet drain.

Characteristics and performance of this wetland have previously been reported in Quirk et al. (2009). The wetland has completed its proposed tasks and is now being returned to its former cane production.

Two major issues of concern for the NSW sugar industry are: firstly, whether the precipitation of the acidity in the wetland would permanently damage the land for future cane production, and secondly, whether such a management technique might in the future be forced upon the industry.
April 2009 wetland operation and modifications

A major problem with operation and monitoring of water quality performance in the wetland has been the need to pump water into it from the farm’s outlet drain after an appropriate amount of rain that promoted an acidity discharge event. Rainfall was often insufficient to retain water over the wetland surface, with sediments and any precipitated metals frequently drying out. At other times flooding from the adjacent Tweed River inundated the area under more than 1 m of floodwater. During periods of low rainfall, the farm’s drain water was both too little and became too saline (electrical conductivity, EC > 3 dS/m) to allow pumping into the wetland. Controlled leakage into the farm’s drain system is enabled from the adjacent semi-tidal McLeod’s Creek (EC up to 20 dS/m) so that drain-bottom sediments do not dry out and oxidise. A large capacity electrical pump at the farm drain’s outlet maintains the drain system water level sufficiently low to provide small rain event runoff storage but below that which would cause any lateral transfer of saline water under the cane crop. Generally, a rain event of about 35 mm is sufficient to fill the farm’s drain system and initiate the automatic pump.

At the end of March 2009 about 120 mm of rain occurred followed by a further 300 mm during the first week of April (see Figure 2). An intensive final monitoring program between April 7 and 24 was therefore undertaken that included shifting the wetland inlet position from Bay #1 to Bay #3. Bays #1 and #2 were then allowed to commence drying and enable vegetation and sediment sampling as a prelude to trialling acidity neutralisation and wetland rehabilitation for cane production.

Water quality monitoring was completed across the wetland during the April study period. Initially, water quality in all wetland bays was measured (pH, EC, dissolved oxygen-DO or redox potential) but on April 10th the water inlet was transferred from Bay #1 into Bay #3 as mentioned above (see Figures 3 and 4). The effect of the initial large rainfall event is seen with the input water and down through the wetland, in values of high pH and low EC. The initiation and progress of acidic inputs through the wetland is seen in Figure 3.
Towards the end of the study period, the input of less acidic (higher pH) and more brackish drain water (higher EC) can be seen.

Clearly, although acidic water was input continuously at about 100 L/min (there were some brief occasions when the pump stopped), as previously shown in Quirk et al. (2009), the wetland neutralised this acidity in the first one or two bays so that little of this acidity load exited from the wetland.

Red-brown iron precipitates on the wetland vegetation were obvious, particularly nearer the inlet points where initially reduced ferrous iron oxidised to ferric oxy-hydroxides (see Equ. 2).

The reduction of incoming dissolved sulfate to metal sulfide was seen in formation of black precipitates and objectionable odours, particularly after rain ceased and DO decreased over time.
Wetland vegetation sampling

Wetland vegetation was established by natural recruitment from apparently waterborne seeds. The main two species were couch grass (Cynodon dactylon) and common spike rush (probably Eleocharis palustris).

Both of these perennial, strongly rhizomatous species are native to Australia, although widespread elsewhere in the tropics and sub-tropics. A number of larger and woodier weed species established in the wetland over time, particularly on the wetland bay and perimeter banks. However, these weeds were controlled by weedicide wicking and spot spraying. The couch grass established best on the flat area of each bay while the Eleocharis tended to establish in the deeper water of the borrow-pits formed during bank construction (see Figure 5).
Total plant dry biomass samples of each of the two main species were taken from Bays #1 and #2. Three samples of each species were extracted using a spade, separating the root and shoot portions, bulking the sub-samples together, and oven-drying (85°C) and weighing. The total biomass of Couch was 3.17 kg/m² (about 32 t/ha, with approx. 60% shoot and 40% root); Eleocharis was 2.55 kg/m² (about 25 t/ha, with approx. 50% shoot and 50% root). These biomass yields are after more than 3 years growth; small by comparison to sugarcane and rather small by comparison to one-year irrigated pasture yields in Victoria, Australia (19–31 t/ha, shoot only; from Blaikie et al., 2002).

Wetland soil samples and contained acidity measurement

Three surface soil samples (0–50 mm) were taken by core from each of Bays #1 and #2 after diversion of the water flow. Each sample was bulked from 3 sub-samples. The samples were dried, sieved and analysed at the Tweed Laboratory (Tweed Shire Council) using the standard acid sulfate soil analytical methods of Ahern et al. (2004). The measured pH (pH_{KCl}) and total existing acidity measured by titrating to end-point pH 5.5 in a 1M KCl soil extract (‘TAA’), and the existing plus potential acidity with another such titrated extract, but additionally after oxidation with 30% hydrogen peroxide (‘TPA’), are shown in Table 1. The peroxide treatment in TPA is intended to oxidise any sulfide minerals in the sample.

Table 1—Wetland surface soil (0–50 mm) acidity analyses. Values of TAA and TPA in mol H⁺/t dry soil.

</tbody>
</table>

The overall mean TPA of 139 mol H⁺/t across Bays #1 and #2 equates to approx. 7 kg H₂SO₄/t soil. Assuming this represents the surface 0–50 mm of the total 1.6 ha of the wetland surface, and further that the soil bulk density is 1 t/m³, the measured acidity is the equivalent of approx. 5.6 tonnes of H₂SO₄ in the 1.6 ha. Each tonne of H₂SO₄ requires approx. 1 tonne of lime (CaCO₃) for acidity neutralisation. Using the common factor of safety of 1.5, neutralisation of the surface soil acidity, mostly sourced from inputs to the wetland, therefore, would require about 8.5
tonnes of lime (about 5.3 t/ha). This approximates the rate of lime normally applied by Robert Quirk (5 t/ha) with a plant cane crop to satisfy the NSW cane industry’s Code of Best Management Practices (CBMP) for managing acid sulfate soils. Of course, the measured surface soil acidity was from those bays where most metal-sourced acidity would have been precipitated.

**Application of constructed wetlands for acidity amelioration in sugarcane**

It is clear from these results that, having limited the input of salt to the wetland, the inputs of acidity from the farm’s drain water has not permanently damaged the soil and the land can easily be rehabilitated for cane production after adequate lime application, removal of terrace and perimeter bank by in-filling their adjacent borrow-pits, and re-establishing the laser-levelled drainage regime. The amount of acidity accumulated in the wetland over the 3 to 4 years of its intermittent operation probably had a significantly smaller effect than that of the land adjacent to cane field drains when they are cleaned and the drain sediments limed, spread, and incorporated into the cane field, as per the industry’s CBMP.

This wetland already occupied about 2% of the farm’s land area and only treated about 10% of the acid water discharge. On this basis, it might require a constructed wetland occupying up to 20% of a cane farm to treat all of the acidity discharge. Such a possible management tool is completely impracticable. However, there are still useful lessons that can be gained from this experiment, but these would require some shift in understanding and operation by cane farmers.

It is clear that acid water passing through vegetation stands has some of its acidity removed. Most drains in NSW cane lands have various vegetation growth, often including the main species (Couch and Eleocharis) identified in this wetland. In some instances, the water depth in the drain is too great for these species but there is a move being encouraged for farmers to use shallower drains.

On many occasions, farmers see the presence of any in-drain plant growth as deleterious to the passage of drainage water. Nevertheless, the drains are mostly required to remove water quickly under fairly high flow conditions.

At these times, the useful plant species we have identified are drowned-out and would cause little obstruction to flow. In the latter phase of a flood hydrograph, the flow rates are less and it is at this time that acidity discharge is greatest so the presence of in-drain plants would reduce acidity discharge. Any metal-sourced acidity precipitates would periodically be neutralised by liming during drain cleaning in accordance with industry’s CBMP.

MOTS-CLÉS: Assainissement d'Acidité, Marais Artificiels,
Réhabilitation de la Canne à Sucre.

Résumé

Un marais artificiel de six niveaux en terrasses a été testé pour le traitement des drainages acides des terres de canne à sucre résultant principalement de l'oxydation des sols acides sulfatés. Une préoccupation a été que ces terres de canne ont été définitivement dégradées en raison de l'accumulation des contaminants métalliques acides (en particulier le fer et l'aluminium) découlant de cette technique d'assainissement. Le site a été maintenant assaini pour qu'il puisse être remis sous production cannière. Suite aux premières analyses pour établir la qualité de l'eau et les caractéristiques des sédiments dans le marais, la neutralisation de l'acidité existante par le chaulage a été évaluée, et les résultats ont été comparés avec les meilleures pratiques de gestion des sols sulfatés acides cultivés en canne dans la Nouvelle-Galles du Sud. L'application de chaux et son incorporation ont été accompagnées par l'élimination des marais construits et par un nivellement du bloc de canne. La capacité du marais artificiel pour neutraliser l'acidité ayant été démontrée précédemment, une évaluation plus approfondie de la qualité de l'eau après les pluies, et de drainage acide montre maintenant la capacité de neutralisation inhérente des zones humides artificielles, telles que indiquées par les changements de pH, de la conductivité, d’oxygène dissous, et par les concentrations des métaux. L'acidité totale des sols de surface (0–50 mm) était comparable à celle des sédiments dans l'eau de drainage des sols acides sulfatés. L’application de chaux, son incorporation, et le re-nivellement de la zone humide sont à la portée des pratiques agricoles standard. Ce marais d’environ 1.6 ha de surface a été capable de traiter seulement environ 10% de la décharge d'acidité totale provenant de 100 ha de canne. L'adoption de cette pratique comme un standard pour le traitement du drainage acide de canne à sucre n'est donc pas possible. Toutefois, les principes présentés ici ont un potentiel d'application dans la gestion de la végétation des drains. Les résultats montrent que les terres utilisées pour la construction des marais n'ont pas été endommagées de façon permanente par ce dispositif d'assainissement de l'acidité.
EVALUACIÓN DE NEUTRALIZACIÓN ÁCIDA Y REMEDIACIÓN DE UN HUMEDAL DE UNA PLANTACIÓN DE CAÑA DE AZÚCAR

PALABRAS CLAVE: Acidez, Remediación, Humedal, Rehabilitación para Caña de Azúcar.

Resumen

SE CONSTRUYÓ un humedal de seis niveles en terrazas para drenaje de tierras plantadas con caña de azúcar, acidificadas principalmente por la oxidación de suelos con sulfatos ácidos. Surgió preocupación por degradación permanente del terreno, a causa de esta técnica de remediación, para la producción futura de caña de azúcar por la acumulación de contaminantes de metales ácidos (especialmente hierro y aluminio). Actualmente el lugar se encuentra bajo remediación para devolverlo a la producción de caña. Luego de mediciones iniciales para establecer la calidad del agua y las características de los sedimentos en el humedal, se evaluó el requerimiento de cal para la neutralización de la acidez y estos resultados se compararon con las mejores prácticas de manejo del drenaje de suelos con sulfatos ácidos del área cañera de Nueva Gales del Sur. Además de la aplicación de cal y su incorporación, se eliminaron los montículos formados y se niveló el lote. Previamente se ha reportado la capacidad de los humedales para neutralizar la acidez. Una evaluación más profunda de la calidad del agua después de la lluvia y del drenaje de ácidos, muestra la capacidad de neutralización de los humedales, lo cual se observa en cambios de pH, conductividad eléctrica, oxígeno disuelto y concentración de metales. La acidez total de la superficie de los suelos (0–50 mm) es comparable con el sedimento del drenaje de suelos con sulfatos ácidos. La aplicación de cal, su incorporación y la nivelación del humedal están contempladas entre las prácticas agrícolas estándar. En este caso, la superficie del humedal, de aproximadamente 1.6 ha, tuvo capacidad para tratar únicamente alrededor del 10% de la descarga ácida total de las 100 ha de la finca cañera. La adopción de ésta como una práctica estándar en el drenaje de ácidos es, por tanto, impráctica. Sin embargo, los principios mostrados en el presente trabajo tienen potencial aplicación en el manejo de drenaje de suelos anegados. Los resultados muestran que los terrenos utilizados no presentan degradación permanente a causa de la construcción de los humedales.
EFFECT OF HARVEST METHOD ON MICROCLIMATE AND SUGARCANE YIELD IN FLORIDA AND COSTA RICA

KEYWORDS: Green Cane, Burning, Soil Temperature, Crop Residue, Tiller Population.

Abstract

THERE IS worldwide pressure on sugarcane industries to adopt ‘green cane’ harvesting systems that do not involve burning. The objective of this study was to compare the effect of sugarcane harvest methods on cane productivity and microclimate in Florida, U.S.A. and Costa Rica. The treatments included 1) burnt cane, 2) green cane, and 3) green cane with residue management. These treatments were implemented at three sites: A) Everglades Research and Education Center (EREC), Belle Glade, Florida on a muck Histosol with high organic matter, B) Hilliard Brothers Farms, Florida on an Entisol with sandy texture, and C) Azucarera El Viejo mill in Guanacaste, Costa Rica on a clay loam Inceptisol. The green cane residue provided a buffering effect on soil temperatures (15–cm depth) at the Florida muck site. There was a trend for higher biomass yields in burnt cane when harvested early (Nov – early Jan), and a significant cumulative 3-year difference of 22 t/ha of cane favouring burnt vs. green cane treatments. However, cane yields were not different when harvested late in the season (mid-February – March). On the Florida sand site, a decline in tiller population, particularly in green cane, was linked to frost events in February, 2006. Air temperatures at 10-cm aboveground were lower in green cane during frosts, which led to significantly lower tiller population in green cane in the first ratoon crop. Cane biomass yields on sand followed similar trends to those on the muck soil with burnt cane recording higher yields when harvested early but not significantly different when harvested late. At the Inceptisol site in Costa Rica, trash content, biomass and sucrose yields were not significantly different in green vs. burnt cane in the plant cane and first ratoon crops. In Costa Rica, cane residues reduced maximum soil temperatures by 5–10°C for 3 months from harvest to canopy closure. Our results indicate that green cane residues have a significant effect on microclimate and that green cane harvest in Florida would be better suited for late rather than early harvest time periods.

Introduction

In burnt sugarcane systems, the crop is harvested annually in a process that utilises controlled fires prior to harvest to remove excess, adhering leaves on the standing stalks. The juices
of the sugarcane stalk contain the majority of sugar in the plant, whereas the topmost growing point and leaves (both green and senesced) have much lower sucrose contents. Furthermore, as much as 25 to 30 percent of the above-ground biomass in sugarcane is present as leaves and tops (commonly referred to by sugarcane growers as the cane trash) and is undesirable from the standpoint of processing for sugar and molasses. Pre-harvest burning destroys the trash, and increases the efficiency and profitability of the harvesting process (Meyer et al., 2005).

There are sound reasons based on conservation and agricultural science to effectively utilise crop residues by returning them to the soil if feasible. Important among these are the conservation and recycling of nutrients and organic matter, and the reduction of soil erosion and runoff in agricultural systems (Dominy et al., 2002).

As a result, there are incentives to experiment with alternative systems of harvesting unburned sugarcane which may show potential environmental and agronomic benefits (Kingston et al., 2005). Some of the potential benefits include: 1) improved air quality, 2) greenhouse gas reductions, 3) rainfall conservation (Morandini et al., 2005), 4) reduced soil erosion, herbicide usage and runoff (Makepeace and Williams, 1988; Prove et al., 1986), and 5) improved soil quality and nutrient recycling (Barzegar et al., 2000; Graham et al., 2002).

In green cane harvest systems, the non-commercial residues are conserved as surface mulches. Despite this benefit, there are major agricultural concerns with the green cane system because, under specific conditions, it has been shown to reduce sugarcane biomass and sugar yields due to excessive soil wetness, lower soil temperatures (Oliviera et al., 2001), slower ratoon crop regrowth rates, and possible allelopathic effects (Cock et al., 1997; Kingston et al., 2005). Heavy crop residues left on the fields may facilitate higher pathogen and pest pressures (Liu and Allsopp, 1996).

Additionally, trash residues generally impede effective cultivation. As a consequence, many sugarcane growers disk green cane residues into the soil following harvest. Modifying harvest practices at this scale could significantly impact the economics of producing and harvesting the sugarcane crop, as well as the entire agro-ecosystem of sugarcane fields.

However, agricultural, environmental, and social pressures are continuing to push sugarcane farming operations towards higher adoption of green cane harvesting systems, and many of the potential limitations may be solved or minimised through a multidisciplinary research team approach.

The Costa Rican sugarcane industry differs from the Florida industry in that the number of mills is greater (16 vs. 4) whereas the amount of sugar produced is smaller (380 000 vs. 1 520 000 tonnes in 2006/2007). The Costa Rican industry also is widely dispersed throughout the country while the Florida industry is concentrated south of Lake Okeechobee.

However, both industries are facing threats from increased urbanisation and environmental regulation that may push them towards greater implementation of green cane harvesting. Thus, it is important to generate sound scientific data on the benefits and disadvantages of green cane for both industries.

The objectives of this study were to determine the effect of different harvest management strategies (burnt cane, green cane, and green cane with residue management) in Florida and Costa Rica on sugarcane growth, yield and microclimate. An additional goal was to determine the effect of early vs. late harvest dates in Florida on sugarcane growth and yield under different harvest management.

Materials and methods

Harvest management experiments were established at 3 locations (Table 1): Everglades Research and Education Center (EREC) in Belle Glade, Florida; Hilliard Brothers Farms in

Clewiston, Florida; and Azucarera El Viejo in Guanacaste, Costa Rica. The EREC and Hilliard Brothers sites were harvested both early and late in the season whereas the El Viejo site was harvested once per season. All sites imposed different harvest management treatments including burning, green cane, and green cane with harvest residue management. The residue management treatments differed by location due to grower preference, and included raking from the crop row (EREC and Hilliard Brothers), disking between rows (Hilliard Brothers), and complete residue removal from the field (El Viejo). Due to different burn regulations between sites, the burnt treatment was implemented during daylight hours at EREC and Hilliard Brothers, whereas burns were conducted at night at El Viejo.

Table 1—Soil type, cultivar, planting and harvest dates for the 3 sites included in the study. PC, 1R and 2R refer to plant cane, first ratoon and second ratoon crops, respectively.

Measurements at all sites included crop residue (‘trash’) dry weights taken immediately after harvest, tiller population counts at monthly intervals, and whole-plot sugarcane biomass weights.

Plot sizes at all locations were at least 12 m wide x 300 m long to allow for adequate burning and also for efficient commercial-scale mechanical harvest and transport, as well as uniform trash deposition in the green cane treatments.

Cane yields were calculated from trailer or rail car weights recorded at the mill. Sucrose yields were calculated by established methods (Gilbert et al., 2006). Soil temperatures were recorded at 15-minute intervals at 15-cm depth within the row in Florida and at 2 and 10 cm in Costa Rica throughout the growing season. In addition, air temperature at 10-cm height above the row was recorded at 15-minute intervals from January–May at the two Florida locations.

Results and discussion

Sugarcane harvest management had a highly significant effect on crop residue deposited on the field (Table 2). Burning in standing cane resulted in 2.0–3.4 t/ha of residue whereas green cane harvest averaged 10.2–18.1 t/ha of residue remaining in the field.

The amount of residue declined in the ratoon crops at all locations, consistent with decreasing total crop biomass in the ratoons compared to the plant cane crops. There was a significant increase in residue production during late harvest at EREC but no significant difference in residue production due to harvest date at Hilliard Brothers (Table 2).

The residue levels obtained in the green cane treatments were similar to the 7–16 t/ha recorded in Argentina (Romero et al., 2007) and 7–12 t/ha obtained in Australia (Robertson and
Thorburn, 2007), but lower than reported in Columbia (Cock et al., 1997) and greater than estimated in Louisiana (Johnson et al., 2007).

Table 2—Crop residue dry weights at three sites. Data presented are mean values for harvest management treatment, crop class and date of harvest.

Soil temperature (15-cm depth) was significantly affected by harvest management at the EREC site. During cool periods early in the growing season, the presence of green cane residue led to higher minimum soil temperatures (Figure 1A), whereas, later in the season as air temperatures increased, the green cane plots recorded lower maximum soil temperatures (Figure 1B). Thus, the green cane systems led to a buffering of soil temperatures on both a diurnal and a seasonal basis. Leaf area indices were higher for the burnt treatment on muck, particularly when harvested early, which could have been due to lower soil temperatures early in the season leading to delayed emergence and growth. The buffering of soil temperature in green cane in our study concurs with soil temperature data reported from Louisiana (Viator et al., 2005), Argentina (Morandini et al., 2005) and Brazil (Oliviera et al., 2001).

![Fig. 1—Soil temperature (averaged over 15-min periods) at 15-cm depth as affected by harvest management at the EREC site during A) Early-season: January 7–13, 2005 and B) Late-season: March 11–17, 2005.](image-url)
Burnt cane treatments recorded higher cane yields (cane t/ha; TCH) than the green cane or raked treatments when harvested early at EREC; however, there were no significant yield differences between harvest management treatments when harvested late (Figure 2). Green cane harvest can be either beneficial or detrimental to sugarcane yield. Sugarcane yield increases under green cane have been documented in Brazil (Ball-Coelho et al., 1993) and Mexico (Toledo et al., 2005), whereas yield losses have been reported from Louisiana (Viator et al., 2008). In general, green cane harvest appears to be most detrimental to cane yield in cool and wet environments (Kingston et al., 2005).

Air temperatures during two freeze events in Feb, 2006 at the Hilliard Brothers site are presented in Figure 3. During cold nights, when air temperature declined below 5°C, the green cane treatments consistently recorded air temperatures that were 2–3°C lower than air temperatures in the burnt cane treatments. Lower air temperatures for a longer duration can have significant effects on plant growth if they cause freezing of plant tissue. We should note that the burnt cane treatments also recorded below-freezing temperatures on February 14, during an extremely cold freeze event. However, under the milder conditions recorded on February 13, sugarcane in the green cane plots would have been frozen whereas burnt cane would not.
The lower minimum air temperatures recorded in green cane are most likely due to trash reflectance leading to lower soil heat flux during the day, and thus less re-radiation of heat from the soil at night in the green cane treatments. This hypothesis would be supported by the higher maximum daytime temperature recorded in green cane for Feb 13 and 14 (Figure 3). To our knowledge, this is the first report of the effect of green cane residue on air temperatures within sugarcane fields.

The freeze events recorded in February, 2006 at the Hilliard Brothers site had a significant effect on tiller populations (Figure 4). Tiller populations in all treatments declined following the freezes, but the green and between-row disk ing treatments were most severely affected and took the longest to recover. These tiller population data can be explained by the air temperatures which reflect increased number and severity of freeze events when residue was allowed to remain within the row early in the growing season.

![Fig. 4—Tiller population for the different harvest management treatment for the first ratoon crop at the Hilliard Brothers site.](image)

The freeze events recorded in the first ratoon crop led to significantly higher cane (TCH) and sucrose (TSH) yields in burnt cane compared to the other harvest management treatments at the Hilliard Brothers site. However, 3-year cumulative yields across plant cane through to second ratoon crops were not significantly different (Table 3).

There was no significant effect on cane yields from harvest management treatments for plant cane or first ratoon at El Viejo, Costa Rica (Figure 5A), although there was a trend ($P=0.09$) towards higher sucrose yields in the first ratoon crop in burnt cane (Figure 5B). Overall, yields were lower across treatments in the first ratoon crop primarily due to flooding of the fields in October, 2008.
Fig. 5—Cane A) and sucrose B) yield for different harvest management treatments for the plant cane (PC) and first ratoon (1R) crops at the El Viejo, Costa Rica site.

The presence of crop residues also buffered soil temperature at the El Viejo, Costa Rica site. From harvest in March to canopy closure in July, crop residue reduced maximum soil temperatures by 5–10°C at 2-cm depth (Figure 6A) and by 2–5°C at 10-cm depth (Figure 6B).

Fig. 6—Daily maximum soil temperatures for different harvest management treatments at 2 (A) and 10-cm depth (B) at the El Viejo, Costa Rica site.

Conclusions

Green cane harvest buffered soil temperatures in 3 different soil types (Histosol, Entisol and Inceptisol), and also led to lower air temperatures during freeze events in Florida, indicating significant effect of harvest methods on microclimate. These microclimate effects led to significant reductions in sugarcane tiller populations and plant growth in green v. burnt cane following freeze events in Florida. Our results indicated a yield penalty in green cane systems in Florida when harvested early in the season; thus, green cane harvest should be recommended for later harvest periods. In Costa Rica, there were no significant differences in sugarcane growth and yield in green v. burnt cane in the plant cane and first ratoon crop.

Résumé

Dans le monde entier, les industries de canne à sucre sont contraintes d'adopter les systèmes de récolte en canne verte qui évitent de brûler la canne. L’objectif de cette étude était de comparer les effets des différentes méthodes de récolte sur la productivité et le microclimat de canne en Floride et au Costa Rica. Les traitements incluaient 1) la canne brûlée, 2) la canne 2 verte et 3) la canne verte avec gestion des résidus. Ces traitements ont été appliqués sur 3 sites : A) au Centre de Recherche et de Formation des Everglades (EREC), Belle Glade, Floride sur un Histosol noir riche en matière organique, B) sur les exploitations Hilliard Brothers, Belle Glade, Floride sur un Entisol à texture sableuse, et C) sur l’exploitation de l’usine sucrière EL Viejo, à Guanacaste, Costa Rica sur un Inceptisol argilolimoneux. Les résidus de canne récoltée en vert ont provoqué un effet tampon sur les températures du sol (à 15 cm de profondeur) sur le sol noir organique de Floride. Les cannes brûlées récoltées en début de campagne (Nov.- début Janvier) produisent généralement des rendements plus élevés, avec une différence significative de 22T/ha en cumulé sur 3 ans par rapport à la canne récoltée en vert. Cependant, les rendements ne furent pas différents sur les récoltes de fin de campagne (mi-février–mars). Sur le site sableux de Floride, la diminution de la population de tiges, en particulier sur canne récoltée en vert, fut causée par les gelées de Février 2006. Les températures de l'air à 10 centimètres au dessus de la surface furent inférieures en canne verte durant les gels, ce qui a diminué significativement la population de tiges en canne verte lors de la récolte de la première repousse. Les rendements canne sur sol sableux ont suivi des tendances similaires à ceux sur le sol noir organique avec des rendements plus élevés en canne brûlée pour les récoltes de début de campagne et pas de différence pour les récoltes de fin de campagne. Sur l’Inceptisol du Costa Rica, les teneurs en résidus, les rendements canne et sucre ne furent pas différents entre canne verte et brûlée en canne plantée et repousse. Au Costa Rica, les résidus de récoltes réduisirent les températures maxima du sol de 5 à 10°C pendant 3 mois, de la récolte à la fermeture du couvert. Ces résultats montrent que les résidus de canne verte ont un effet significatif sur le microclimat et que la récolte de la canne en vert en Floride serait plus adaptée en fin plutôt qu’en début de campagne.
EFECTO DEL METODO DE COSECHA SOBRE EL MICROCLIMA Y LA PRODUCTIVIDAD DE LA CAÑA DE AZÚCAR EN LA FLORIDA Y COSTA RICA

PALABRAS CLAVE: Caña Verde, Quema, Temperatura del Suelo, Residuos de Cosecha, Población de Tallos.

Resumen

Hay presión sobre la industria azucarera mundial para que se adopten sistemas de cosecha de “caña verde” que no involucren quemado. El objetivo de este estudio fue comparar el efecto de los métodos de cosecha de caña de azúcar de caña sobre la productividad y el microclima en Florida, EE.UU. y Costa Rica. Los tratamientos incluyeron 1) caña quemada, 2) caña verde, y 3) la caña verde con manejo de residuos. Estos tratamientos se establecieron en tres lugares: A) En Everglades Research and Education Center (EREC), Belle Glade, Florida en un Histosol, B) En Hilliard Brothers Farms, Florida, en un Entisol con textura arenosa, y C) Azucarera El Molino Viejo, en Guanacaste, Costa Rica en un Inceptisol franco-arcilloso. El residuo de la caña verde proporcionó un efecto amortiguador de las temperaturas del suelo (15 cm de profundidad) en el suelo pesado de la Florida. Hubo una tendencia a mayor rendimiento de biomasa en la caña quemada con cosecha temprana (noviembre–principios de enero), y una diferencia significativa de 22 t/ha en el acumulado de 3 años favoreciendo los tratamientos de caña quemada vs los de caña verde. Sin embargo, los rendimientos de caña no fueron diferentes cuando se cosechó al final de la temporada (mitad de febrero-marzo). En el sitio arenoso de la Florida, la disminución de la población de tallos, particularmente en caña verde, estuvo ligada a heladas que se presentaron en febrero de 2006. Las temperaturas del aire a 10-cm sobre el suelo durante las heladas fueron más bajas en caña verde que en caña quemada, lo que condujo a una significativamente menor población de tallos durante la primera soca de la caña verde. El rendimiento de biomasa de la caña en el suelo arenoso siguió tendencias similares a las de la caña quemada en el suelo pesado registrando mayor rendimiento con cosecha temprana, pero sin diferencias significativas cuando se realizó la cosecha tardía. En el suelo Inceptisol en Costa Rica, el contenido de los residuos, la biomasa y los rendimientos de sacarosa no fueron significativamente diferentes en caña verde vs. quemada en la platilla y la primera soca. En Costa Rica, los residuos de caña redujeron las temperaturas máximas del suelo de 5-10 ºC durante el periodo de 3 meses que va desde la cosecha hasta el cierre del dosel. Nuestros resultados indican que los residuos de la caña verde tienen un efecto significativo en el microclima y que la cosecha de caña verde en la Florida sería más adecuada para cosecha tardía que temprana.
AGROCLIMATIC ZONING AND CLIMATIC RISKS FOR SUGARCANE IN MEXICO—A PRELIMINARY STUDY CONSIDERING CLIMATE CHANGE SCENARIOS

By

São Paulo State Agriculture and Food Secretariat, Brazil, Agronomic Institute

brunini@iac.sp.gov.br

KEYWORDS: Sugarcane, Crop Zoning, Climate Risks, Climate Change.

Abstract

In the existing scenario of current agricultural management systems and climatic standards, a new source of uncertainties must be taken into account, namely, the temperature scenarios and water availability resulting from climate changes. In this aspect, agricultural zoning, supported by the climatic and edaphological potential of a region, and the climate scenarios, along with the associated risks, have become highly relevant. This paper considers an example of the sugarcane crop in Mexico, indicating possible potential areas for crop development, and what are the climatic risks during plant growth, based on crop zoning criteria, as well as the impact of global warming in future scenarios. The agroclimatic scope and the edaphological and climatic zoning were defined through the quantification of physical resources and the water balance parameters of different regions, indicating the relationship between energy availability, water supply and crop water demand. The study further determined the influence of climate changes in the quantification of the water balance for the regions and the effects of this anomaly in sugarcane development. The study was based on meteorological data from historic series from Mexican research institutes and from the National Meteorological Service of Mexico, accessible via the Web. The available products are: a) monthly and annual air temperature; b) monthly and annual total rainfall, c) monthly and fortnightly values of water deficit and surplus; d) drought probability at monthly and fortnightly level and maps of frost. As a result, maps of agroclimatic suitability for the various regions in Mexico were produced with the current climate standards as well as considering the increase in meteorological adversities and the change in the scenarios due to global warming. Climatic risks associated with high or low temperatures and the probability of drought events are shown for both agrometeorological and meteorological factors, with an indication of the regions that are more suitable for the development of this crop.

Introduction

In the established scenarios based on the current agricultural management systems and the climate patterns that affect development of the sugarcane crop, a new source of uncertainty must be taken into account—the temperature and water availability scenarios resulting from climate changes and/or global warming.

Despite abundant discussion and a multitude of studies indicating future scenarios related to global warming and the current modifications resulting from those possible changes, or even the anomalies due to seasonal climate variability, very little is known as a fact, especially how crops respond to a new thermal regime, the physiological and metabolic adaptations, and the consequent modifications to which crops will be subject. Therefore, it is the responsibility of different agencies...
to propose adaptation measures in order to reduce the negative effects of climate adversities. An important procedure is the establishment of public policies for agricultural development based on climatic characteristics. In that sense, agricultural zoning followed by Agro-ecological Zoning, based on the climatic and edaphic potential of a region and its associated risks, are highly relevant. It is also important to mention that the agro-ecological zoning might provide complementary information about the climatic risk in certain phases of the crop such as: high or low temperatures, drought or excess rainfall, thus indicating the climatic risk and the feasibility of success and production.

In spite of its remarkable adjustment to climatic conditions, the sugarcane plant finds its best conditions when there is a hot and humid period, with high solar radiation in the growth phase, followed by a dry period, sunny and cooler, in the maturation and harvest phases. The main factors that determine the success of the crop and its economic use are air temperature and rainfall. Studies from Bacchi and Souza (1978) indicated that, in irrigated crops, growth stopped or was irrelevant for an air temperature below 18ºC whereas, for non-irrigated crops, this temperature was 19ºC. This crop reasonably endures high temperatures of 34/35ºC for a few hours. However, steady values above 38/40ºC may affect its development through the inhibitory effect of physiological activities such as the opening of stomata and CO₂ exchange. An aspect that is still important is flowering, as it may compromise productivity. During the flowering inductive period, both the water supply and temperature regimes are critical. Minimal air temperatures (at night) below 18ºC and maximum temperatures (daytime) above 30/32ºC affect flowering negatively, that is to say, inhibit it (Pereira et al., 1983). After floral induction, the forming of new internodes ceases and the pith process of the basic tissue may start. For most varieties after flowering induction, as long as climatic conditions are suitable, the emission of panicles happens between 7 and 10 weeks. In a such a case, there is an inversion in the process of sucrose production which is directed towards panicle emission and final sugar content is reduced.

This study aims to indicate, in a preliminary form, the potential for agricultural use of the sugarcane crop in the Republic of Mexico and the climate factors that influence this potential. Additionally, a simulation of the effect of global warming on the agricultural suitability of the crop is also presented.

**Materials and methods**

The study of agricultural zoning or agro climatic suitability, followed by agro environmental zoning, comprises the determination, within a certain defined area, of the potential of agricultural use of crops in relation to their climate demands and of how much support the climate can offer in terms of temperature and water supply. It also includes evaluation of climatic risks associated with frost, water deficit, drought or high temperatures. The climate is generally the first element taken into account as it is considered a stability factor, although seasonal variations and climate variability must also be considered.

The methodology used for the definition of the appropriate areas for growth and production of sugarcane is based on studies of climate zoning of crops such as: Camargo and Ortolani (1964), Alfonsi et al. (1995), Brunini et al. (2008a); Brunini et al. (2008b); and Brunini et al, (2009). Despite being relatively work intensive, this methodology is efficient for qualitative climate comparison between the several regions of the globe to study agricultural zoning. Also, a better degree of refinement is reached when this methodology and the climate indexes are compared with indexes of crops in order to obtain the bioclimatic indexes for the referred crop. The widely known and widely used methodology in this type of agroclimatic zoning is the following:

1. Data collection and preparation of basic climatic charts representative of the region (average air temperature; annual and coldest month; and potential evapotranspiration, among others).
2. Calculation of Water Balance for the determination of the following parameters: actual evapotranspiration; water deficit and surplus based on water balance parameters according to Thornthwaite and Mather, (1955).

3. Survey of climate demands of the crop–values estimated based on climate-sugarcane qualification (Brunini, 1997 a; Brunini, 1997b);

4. Comparison of these data obtained in item 3 with the data provided in items 1 and 2 and layout of agroclimatic maps for the referred crops.

After all the processes (1 to 4), a region may be classified for the growth of a plant, in one of three following categories.

- Adequate: when macroclimate conditions are normally favourable for commercial use;
- Restricted: when climate conditions present restrictions which frequently undermine certain phases of the crop. There might be some limitation, not too severe, in terms of temperature and/or water supply;
- Inadequate: when climatic characteristics are not adequate for commercial use. In this case, there are serious limitations in terms of temperature and water supply.

**Meteorological parameters and water balance**

The source of meteorological data for the execution of the studies was the existing climatic basis made available by the National Meteorological Service of Mexico, according to access and collection of information via the WEB in March, 2009 (http://smn.cna.gob.mx).

The basic information obtained was the average monthly air temperature in ºC, average monthly rainfall in mm, along with the geographic coordinates for later georeferencing.

In that preliminary phase of the study, 333 locations, scattered across the entire territory, were analysed.

The water balance for quantification and estimate of water availability in the soil and to indicate water deficit and surplus was developed using the methodology proposed by Thornthwaite and Mather (1955) using the software developed by Brunini and Caputi (2001).

In this case, the average monthly values of air temperature and rainfall were entered in the software and the corresponding water balance parameters were created to obtain the following indices:

a) total annual water deficit (mm);

b) water deficit of the crop’s growth season (mm);

c) annual potential evapotranspiration (mm);

d) total annual water surplus (mm).

The scenario of climatic behaviour and water balance in terms of prospects established by IPCC was evaluated taking into account an average annual warming of 2ºC, considering the effect of such an increase in the period of water deficit, in other words, during the dry season, and its intensity (Assad and Pinto, 2008).

With the new scenario of air temperature, these new values are again inserted into the original data set and new water balances are created considering this increase in air temperature. Water balance has the precision as defined in methodology described by Brunini and Caputi (2001) and the major point is to use soil water holding capacity appropriate for the study.

After the development of the agroclimatic charts and the definition of crop demands in terms of temperature and water supply and the combination of these factors, the agroclimatic zoning was
established. Its climatic adaptation regions were those indicated in Table 1 (Brunini et al., 2007; Brunini et al., 2008b; Brunini, 2008; Brunini et al. 2009).

The characteristics used to quantify crop development and weather variables are used for general crop zoning and they are widely used. For sugarcane, the parameters were defined based on the work carried out by Brunini et al. (2007), Brunini et al. (2009), and Camargo and Ortolani (1964).

**Results and discussion**

Based on weather parameters and crop response, the study was sub-divided into 2 major topics, one considering the actual climate scenario and an analysis considering global warming, based on a temperature increase of about 2ºC.

**Actual climate scenario**

Theme climatic maps were developed based on climatic information of the locations; they refer to temperature and water availability for Mexico, according to Figures 1 and 2. The maps were developed with the use of the ArcGis program and the information and data made available in shapefile form, which may be converted to Excel spreadsheets.

![Fig. 1—Average annual air temperature for the Republic of Mexico (preliminary analysis).](image-url)
The edaphological and climatic suitability map of the crop, with the different conditions of adaptation and soil type, was based on the crossing of information from these maps. This information is presented in Figure 3. Basic suitability information for each location and the indication of suitable or unsuitable areas generated the restrictive factors which are specified for each location in each growing stage of the crop, allowing the evaluation of the degree of risk and the most restrictive factor. The basic characteristic for obtaining the results in Figure 3 was the crossing of temperature and water deficit suitability. After this initial process, the information was then compared to the parameters of water balance during the crop growth season, which occurs from September to May, when the climatic restrictions related to water deficit or surplus and effects of temperature in the cycle and productivity are extremely important.
Figure 4 presents the climatic availability conditions in the crop growth season. The climatic restriction is seen in various regions, although in a great part of the regions considered adequate, based on annual climate factor, this situation is reinforced by this more restricted analysis, both in terms of temperature and water availability.

**Fig. 4a**—Preliminary indication of edaphological and climatic suitability for sugarcane crops in the Republic of Mexico, during the crop growth season (temperature restriction).

**Fig. 4b**—Preliminary indication of edaphological and climatic suitability for sugarcane crops in the Republic of Mexico, during the crop growth season (water availability restrictions).

**Climatic changes and crop adaptation**

The aspects of climate change and global warming cannot be viewed based only on a single climatic characteristic, whether it is temperature or rainfall. The processes involved in changes in...
the crop’s response to environmental stress do not depend only on the interaction of plant and environment, but also on the crop’s adaptation processes and metabolic adjustments to the new climatic levels.

Thus, in this study, a simple analogy between a possible global warming scenario is presented considering an average air temperature increase of 2ºC. This anomaly was incorporated in the monthly water balances, and the results of water deficit and surplus were then associated.

Figure 5 presents the comparison of results in terms of water balance when an average of 2ºC was added to the average air temperature for some locations, although the analogy was performed for the 333 locations. It is possible to note that the dry period for the different locations, in other words, its beginning and its end, is practically the same, but the drought intensity, as represented by the total annual water deficit, increases.

These results lead to two different considerations; a) duration of the drought period: in the aspect of annual range of drought period duration, the crop would not be totally affected, indicating that there would be conditions for development and agricultural use; b) intensity of drought: in this case, the varieties would be more exposed to stronger water stress, which could lead to reduction of productivity in sugar, and indicate a greater need for irrigation; and that, in addition to water stress, the low availability of water in the soil would increase the flow of sensitive heat (warming of the air, exposing crops to double stress).

A new scenario indicated by annual water deficit, as shown in Table 2, would be available based on the ratio between the beginning and the end of the drought period, and the intensity of the drought.

Fig. 5—Comparison of the monthly water balance terms for some locations in the Republic of Mexico, for current scenarios and with a 2ºC air temperature increase.
Table 2—Scenario of water deficit climatic characteristics, with a 2°C average air temperature increase, and behaviour of sugarcane crop.

This is also reflected by the climatic availability map, concerning growth and stabilisation period of the crop, normally from September to May. The representative maps of annual temperature availability (average temperature) and annual water deficit were redone based on these analyses, as presented in Figures 6 and 7.

Fig. 6—Estimate of average annual air temperature for the Republic of Mexico, with a 2°C linear average air temperature increase (preliminary analysis).

Fig. 7—Estimate of average annual water deficit for the Republic of Mexico with a 2°C linear average air temperature increase (preliminary analysis).
In addition to that, an analysis for the growth period and complete establishment of the crop was made, also with the scenario of a 2°C linear average air temperature increase. The confrontation of these data presents a new dynamic of agricultural use of that crop in Mexico, as shown in the map in Figure 8. These analyses, when compared to water deficit characteristics in the growth season (Figure 9), indicate that a better varietal management and choice of varieties that are more adapted to longer periods of water stress and high night time temperatures should be used.

It is important to mention that these studies are preliminary and that a wider range of data and locations, as well as deeper evaluation of the global warming scenarios, should be incorporated. Moreover, the study of the climatic scenario was based only on warming, with no modification of rainfall pattern.

Fig. 8—Indication of edaphological and climatic suitability for sugarcane crop in the Republic of Mexico, with a 2°C linear average air temperature increase (preliminary analysis)

Fig. 9a—Preliminary indication of edaphological and climatic suitability for sugarcane crop in the Republic of Mexico, during crop growth season, with a 2°C linear increase in the average air temperature (preliminary analysis—temperature restriction).
A previous study made by Brunini et al. (2008a), when comparing recharge of aquifers determined by the difference between rainfall and potential evapotranspiration, indicates that, if the warming is accompanied by an increase in monthly rainfall of at least 20%, there will be a reduction in the total of estimated water deficit, and greater aquifer recharge.

**Conclusions**

The results analysed indicate that, in terms of edaphological and climatic aspects, the Republic of Mexico presents plentiful conditions for the commercial use of the sugarcane crop.

With the incorporation of the global warming factor, of up to 2ºC, the areas indicated as fully adequate for the development of the crop undergo modification in the water restriction aspect and some areas become restrictive due to the high values of average air temperature, above 26ºC, although it does not make commercial use impractical.

Furthermore, the climatic modification study was developed based only on the increase of average annual temperature, not taking into account factors such as: rainfall distribution and total rainfall, increase and/or decrease of frost, and increase in likelihood of drought risks, which may change the scenario presented.

Résumé
DANS LES SYSTEMES de culture et climats existants, une nouvelle source d’incertitude doit être prise en compte: les scénarios de température et de disponibilité en eau résultants du changements climatiques. A ce niveau, le zonage agricole, établi à partir du potentiel climatique et édaphique d’une région, des scénarios climatiques et des risques associés, devient indispensable. Ce papier prend en compte un exemple de culture de canne à sucre au Mexique, précise les surfaces de développement possibles de la culture et indique les risques climatiques durant la croissance sur les critères de zonage, ainsi que l’impact du réchauffement climatique dans les futurs scénarios. Le domaine d’application agroclimatique et le zonage édaphique et climatique ont été définis en quantifiant les ressources physiques et les paramètres du bilan hydrique de différentes régions, et en indiquant les relations entre disponibilité en énergie, fourniture en eau et besoin en eau de la culture. De plus, l’étude a déterminé l’influence des changements climatiques sur la quantification du bilan hydrique de ces régions et les effets de ces changements sur le développement de la canne. L’étude a été basée sur des séries historiques de données climatiques accessibles sur le web, provenant des instituts de recherche Mexicains et du département météorologique national de Mexico. Les produits disponibles sont: a) la température de l’air mensuelle et annuelle, b) la pluviométrie totale mensuelle et annuelle, c) les valeurs mensuelles et bimensuelles des déficits et excès d’eau, d) la probabilité mensuelle et bimensuelle de sécheresse ainsi que des cartes de gel. Ainsi, des cartes d’aptabilité agroclimatique des diverses régions du Mexique ont été réalisées en prenant en compte les conditions climatiques actuelles, l’augmentation de conditions climatiques défavorables et les changements de scénarios dus au réchauffement climatique. Les risques climatiques associés aux températures élevées ou basses et la probabilité de sécheresses sont indiqués à la fois pour les facteurs météorologiques et agro météorologiques. Les régions les plus adaptées au développement de cette culture sont également présentées.
ZONIFICACIÓN AGROCLIMÁTICO Y RIESGOS CLIMÁTICOS PARA LA CAÑA DE AZÚCAR EN MÉJICO- UN ESTUDIO PRELIMINAR CONSIDERANDO LAS PERSPECTIVAS DE CAMBIO CLIMÁTICO

Por

São Paulo State Agriculture and Food Secretariat, Brazil, Agronomic Institute

PALABRAS CLAVES: Caña de Azúcar, Zonificación de Cultivos, Riesgos Climáticos, Cambio Climático.

Resumen

EN LA PERSPECTIVA existente de los actuales sistemas de manejo agrícola y estándares climáticos se debe considerar una nueva fuente de incertidumbre a saber: los escenarios térmicos y la disponibilidad de agua como consecuencia de los cambios climáticos. En este aspecto, la zonificación agrícola, basada en el potencial climático- edafológico de una región, y las perspectivas climáticas, junto con los riesgos asociados, resultan altamente relevantes. Este trabajo contempla un ejemplo para el cultivo de caña de azúcar en Méjico, indicando posibles áreas potenciales para el desarrollo del cultivo, y cuales son los riesgos climáticos durante el crecimiento de la planta, basado en criterios de zonificación del cultivo, y también considera el impacto del calentamiento global en las perspectivas futuras. El ámbito agro climático y la zonificación climático-edafológica se definieron mediante la cuantificación de recursos físicos y de parámetros del balance hídrico de diferentes regiones, indicando la relación entre la energía disponible, el suministro hídrico y la demanda de agua del cultivo. Además, el estudio determinó la influencia de los cambios climáticos en la cuantificación del balance hídrico por regiones y los efectos de esta anomalía en el desarrollo de la caña de azúcar. El trabajo se basó en series históricas de datos meteorológicos obtenidos de institutos de investigación de Méjico y del Servicio Meteorológico Nacional de Méjico, accesibles en la Web. Los datos disponibles son: a) temperatura del aire mensual y anual; b) precipitaciones totales mensuales y anuales; c) valores mensuales y quincenales de déficit y excedentes hídricos; d) probabilidad mensual y quincenal de sequías y mapas de heladas. Como resultado se obtuvieron mapas agroclimáticos apropiados para varias regiones en Méjico, considerando los estándares climáticos actuales y también el incremento de las adversidades meteorológicas y el cambio en las perspectivas debido al calentamiento global. Los riesgos climáticos asociados con altas o bajas temperaturas y la probabilidad de sequías fueron demostrados para factores agrometeorológicos y meteorológicos, con una indicación de las regiones que son más adecuadas para el desarrollo de este cultivo.
IMPACT OF HIGH RATES OF COAL FLYASH ON SOME PERTINENT SOIL CHARACTERISTICS AND SUGARCANE YIELD IN MAURITIUS

KEYWORDS: Wastes, Cogeneration, Nutrients, Heavy Metals, Uptake.

Abstract

The combustion of coal for cogeneration of electricity by the sugarcane industry in Mauritius generates annually some 20 000 tonnes of ash that need to be disposed of in an environmentally sound manner. As large scale application of ash has been reported to impart agronomic benefits but data under conditions prevailing in Mauritius are lacking, the impact of disposing 50 to 100 t/ha coal flyash in sugarcane fields on soil quality and on sugarcane production was studied in field trials at Belle Rive (>3500 mm/y rainfall), Union Park (>3000 mm/y rainfall), Pamplemousses (>1500 mm/y rainfall) and Médine (900 mm/y rainfall). Though coal ash did not affect soil pH, soil salinity and even soil exchangeable bases, its application at 100 t/ha, when compared to mineral fertilizers, resulted in a reduction of sugar yield at three sites by an average of 1.18 t sugar/ha. At the lower rate of 50 t/ha coal ash, in spite of a significant yield decrease observed at Belle Rive, sugarcane production at Pamplemousses, Union Park and Médine was not significantly different from the control. The N and K uptake by sugarcane was not influenced by the coal ash, though P uptake was enhanced on account of the supplementary P provided in the ash. Additionally, because of its low heavy metal content, coal ash did not increase the heavy metal uptake by the sugarcane plant. In view of the adverse effects observed on sugarcane production, the disposal of rates of coal ash as high as 100 t/ha in sugarcane lands should not be contemplated.

Introduction

In Mauritius, sugarcane is cultivated on some 69 000 ha which represents 85% of the arable land in the country.

The average annual production of five million tonnes cane is currently processed by seven sugar mills to produce on average 500 000 tonnes sugar and 1.5 million tonnes of bagasse.

Through the combustion of bagasse during the crop season, and that of 440 000 tonnes coal during the intercrop season, the sugarcane industry exports some 1300 GWh of electricity to the national grid, representing around 60% of the country’s need. However, cogeneration with coal generates around 20 000 tonnes coal ashes which have to be disposed of judiciously.

Various means of disposal of the ash exist. For example, ash is useful as a construction material or it can be used to decontaminate effluents, but the application of coal ash to agricultural land is believed to represent the most sensible option from both the economic and environment points of view.

Coal ash is in fact a finely divided, amorphous ferro-alumino silicate material, containing all the essential elements that occur naturally in soil except humus and nitrogen (Sear et al., 2003).

It has a pH around 9–10 and possesses certain physical and chemical properties that can be useful, for example, to neutralise soil acidity (Stevens and Dunn, 2004).

Ash has thus been used as a soil amendment (Adriano et al., 2002) and as a source of plant nutrients (Wong and Wong, 1986). Studies on the effects of coal ash on sugarcane yield, however,
remain scanty. Since 20 000 tonnes of coal ash need to be disposed of every year by the sugarcane industry in Mauritius, a study was initiated to assess (i) their impact on soil chemical properties and (ii) their effect on sugarcane yield when high rates are applied.

Materials and methods

Field experiments

Field trials were laid down in four different agro climatic regions of Mauritius, namely at Belle Rive on a Dystropeptic Gibbsiorthox receiving more than 3500 mm of rain per year, at Union Park on a Lithic Humitropept with an annual rainfall of 3300 mm, at Pamplemousses on an Oxic Humitropept receiving 1500 mm rain per year and at Médine, on an Ustic Eutropept with less than 1000 mm rain per year. Some relevant characteristics of the soils at the four experimental sites are shown in Table 1.

Coal ash was applied before planting at two rates (50 and 100 t/ha on a fresh weight basis, 66.42% dry matter). The control treatment received only N and K fertilizers at rates recommended for sugarcane (145 kg N/ha and 190 kg K₂O/ha).

No P fertilisation was applied as soil tests indicated sufficiency in P at all four sites. The N level in the two coal ash treatments was adjusted to the recommended rate of 145 kg N/ha using urea.

All treatments were replicated four times in a randomised complete block design at each experimental site and each treatment plot consisted of four 10 metre rows of sugarcane spaced 1.5 m apart.

Sugarcane was planted at the four sites using three bud cuttings and the resulting plant cane crop was harvested 12 months later in July 2006. The first and second ratoons were harvested in the month of August 2007 and 2008 respectively.

At harvest every year, the cane stalks from the two central rows of each plot were weighed to obtain the cane yields and then sampled for determination of sucrose content with an automatic saccharimeter.

The uptake of NPK and heavy metals (Cu, Zn, Ni, Mn, Pb, and Hg) in the different parts of the cane plant (stalk, top and trash) were measured for the plant cane crop. The NPK in the different plant parts was determined according to the method described by McDonald (1978) while heavy metals were analysed as outlined by Novozamsky et al. (1986).
Results and discussion

Elemental composition of coal ash

The mean elemental composition of the coal flyash collected every three months over a period of three years at three different power stations is shown in Table 2.

As expected, as shown by the range of values obtained, a great variability existed in the elemental characteristics of the coal ash. As reported by Adriano et al, (1980), the chemical composition of ash depends on the source of coal, combustion conditions in the power station and the type of emission control devices used.

Coal ash has an alkaline pH ranging between 7.5 and 11.5 and contains significant amounts of P and K which are essential plant nutrients. The exchangeable calcium which may be as high as 66.1 cmol+/kg in coal ash is responsible for its alkaline nature.

The concentrations of heavy metals obtained in coal ash are, on the other hand, generally much lower than the United States Environmental Protection Agency (USEPA) ceiling limits for wastes (Zn: 420 mg/kg, Ni: 7500 mg/kg, Cu: 4300 mg/kg, Pb: 840 mg/kg, Cd: 85 mg/kg and Hg: 57 mg/kg), (USEPA, 1992).

Specifically the elemental composition of coal ash applied at planting was 1.1 g N/kg, 2.7 g P/kg and 2.2 g K/kg. The composition of coal ash analysed in this study in fact concurs with that reported by Carlson and Adriano (1993) who found that ash in general is quite high in plant nutrients except for N which is lost by volatilisation during combustion.

Coal ash used in this study has also been found to have non-detectable levels of polyaromatic hydrocarbons and polychlorinated biphenyls (GC MSD detection limits 0.02 mg/kg), probably due to the high combustion temperatures which had caused these organic compounds to be degraded. However, as reviewed by Reijnders (2005), coal ashes can also contain quite significant amounts of persistent organic compounds.

**Effect of coal ash on soil pH**

The results obtained in this study showed no major changes in soil pH even after the addition of 100 t/ha coal ash (Table 3). The inherent buffering capacity of soils has probably resisted the changes in pH. In view of the high rates of coal flyash that would be needed to raise significantly the soil pH, coal ash would therefore not be economically viable as an amendment to correct soil acidity in the soils of Mauritius. This finding is in agreement with that reported by Sikka and Kansal (1994) who have also observed no change in soil pH following application of high rates of flyash.

In fact as explained by Cline *et al.*, (2000), the poor liming effect of coal ash is due in part to the low amount of mineralogical lime since a significant portion of its CaO is present in the vitreous components of the ash and is generally released very slowly.

**Effect of coal ash on soil electrical conductivity**

Soil salinity, as reflected by soil electrical conductivity, increased substantially one month after the application of 100 t/ha coal ash (Table 4). But after 12 and even 24 months, the soil electrical conductivity had returned close to its original value of 81.2 µS/cm. Even with the increase in electrical conductivity of the soil observed after one month, the electrical conductivity remained much lower than the maximum value of 1700 µS/cm that sugarcane can tolerate (Rhoades and Loveday, 1990).

It has been reported that the decrease in soil electrical conductivity with time is the result of weathering processes of the coal ash such as hydration and carbonation which play important roles in transforming the primary minerals in coal ash such as CaO and MgO into less reactive secondary mineralogical products that contribute little towards raising soil salinity (Adriano *et al.*, 1980).

Effect of coal ash on soil exchangeable bases

Based on its K content, the application of 100 t/ha of coal ash supplied 220 kg K/ha or 265 kg K$_2$O/ha as opposed to 190 kg K$_2$O/ha in the control treatment where only mineral fertilizers were used. This higher rate of K from coal ash had been insufficient to significantly raise the exchangeable K in the soils. Indeed, soil exchangeable K one month after application of 100 t/ha at all sites was similar to that obtained when 320 kg muriate of potash was used. Likewise, the amounts of Na (17 kg Na/ha) and Mg (97 kg Mg/ha) added to the soil by coal ash applied at 100 t/ha did not significantly increase exchangeable Na and Mg in soil as compared to mineral fertilizers. On the other hand, the addition of 654 kg Ca/ha that the soils received from 100 t/ha coal ash did raise soil exchangeable Ca in the soil (Table 5), particularly one month after application, but this increase still remained within the limits of the standard error (SE).

Cane and sugar yields

Cane and sugar yields in the study followed the same pattern as shown in Figure 1. The addition of coal ash at 100 t/ha decreased cane and sugar yields when compared to the control treatment except at the experimental site of Médine, where no significant difference was found among the treatments.

The application of 50 t/ha of coal ash on the other hand did not in general result in lower yields when compared with mineral fertilizers. At Union Park, a significant increase in sugar yield was even obtained with this lower rate of coal ash. However, certain soils such as at Belle Rive would not tolerate the application of as low as 50 t/ha coal ash as evidenced by the decrease in cane and sugar yields obtained.

The findings of the present study confirmed that, with ash at high dosage, such conclusions as those reported by Siddiqui and Singh (2005) that ash would increase yields of crops such as wheat, barley, soybeans and rice, because of the rich content of essential plant nutrients it contains, would not necessarily be true.

In the present study, though the coal ash applied contained appreciable amounts of plant nutrients in particular P (Table 2), a negative impact was observed on sugarcane yield at 100 t/ha. This detrimental effect of coal ash on yield cannot be attributed to a single factor, but rather to a combination of many factors both in the soil and plant systems. In fact, Jala and Goyal (2006) concluded that in general crop response to coal ash is influenced by the physical and chemical characteristics of the soil and also by the crop itself.

Detrimental effects of high rates of coal ash when observed on plant growth were attributed by Singh and Yunus (2000) to a shift in the chemical conditions of the soil due to the highly alkaline pH and the high levels of soluble elements released from the coal ash.

As shown by the pH and electrical conductivity data in Tables 3 and 4, there was no major increase in soil pH and electrical conductivity 12 months after the application of 100 t/ha of coal ash. This implied that, if the detrimental effect of 100 t/ha of coal ash on sugarcane yields as shown in Figure 1 were indeed caused by a change in the chemical environment of the soil, that change cannot be attributed to the high levels of soluble elements in the coal ash.
NPK uptake

There was no significant difference in the uptake of N and K by the cane plant when coal ash at 100 t/ha was compared with mineral fertilizers. The lack of any difference in N uptake was expected as the amount of N applied was the same for all treatments.

The data nevertheless showed that N in the coal ash was just as available as the N in the mineral fertilizers.

The absence of any difference in K uptake on the other hand confirmed that the additional 75 kg K₂O/ha supplied by the 100 t/ha coal ash has been so diluted in the large volume of soil constituting one hectare, that with no significant difference in soil exchangeable K discerned as reported above, no difference in K availability could be perceived by the sugarcane crop when compared to mineral fertilizers.
In general, P uptake was higher with coal ash at 100 and even at 50 t/ha. This was to be expected because no mineral P was added to the control treatment while coal ash at 100 t/ha supplied an additional 270 kg P/ha.

Moreover, as reported by Lee et al. (2008) silicate released from coal ash enhanced the availability of soil phosphate by displacing P from ligand exchange sites thus rendering P more available to be taken up by sugarcane plants.

Furthermore, it has also been reported by the same authors that phosphate sorption decreased in the presence of silicate which caused P to remain in a more available state. The higher availability of the P as translated by the increased uptake of P with coal ash by sugarcane was, however, not reflected in sugarcane yield (Figure 1) indicating that P was not a limiting nutrient to growth.

**Heavy metal uptake**

There was no significant difference in the uptake of the different heavy metals by the plant cane at the four different sites. The concentrations of heavy metals (Cu, Zn, Ni, Mn, Pb and Hg) in the aboveground parts of the cane crop (stalk, top and trash), 12 months after the application of coal ash at 50 and 100 t/ha, remained low and were not significantly different from the concentrations found in the sugarcane plants that received only mineral fertilizer.

This lack of difference in uptake can be explained by the fact that these heavy metals are large cations which are not very mobile in soil. Other studies have attributed the low uptake of heavy metals by crops as being due to a reduced mobility of heavy metals in an alkaline medium brought about in the vicinity by the ash and by an increase in the sorption of these heavy metals in soil (Ram et al., 2007).

**Conclusion**

Though high rates of coal ash will have little impact on the soil chemical properties as reflected by soil pH, soil salinity and soil exchangeable bases, the present study showed that disposal of coal ash at rates of 100 t/ha should not be entertained in soils under sugarcane in Mauritius. Though the heavy metals present in the coal ash will pose little concern since their
uptake by sugarcane will be little affected, the shift in the chemical conditions in the soil brought about by ash will in general lead to a decline in sugarcane production in Mauritius.

Résumé
LA COMBUSTION de charbon pour produire l'électricité par l'industrie sucrière à Maurice génère annuellement quelque 20 000 tonnes de cendres qui doivent être éliminées d'une manière écologiquement rationnelle. Il a été rapporté que l'application à grande échelle de cendres présente des avantages agronomiques; cependant les données dans des conditions prévalant à Maurice n'étant pas disponibles, l'impact de l'élimination de 50 à 100 t/ha de cendres de charbon dans les champs de canne à sucre sur la qualité des sols et le rendement de la canne à sucre a été étudié dans des essais implantés dans quatre sites aux conditions agroclimatiques différentes, notamment à Belle-Rive (>3500 mm de pluie/an), Union Park (>3000 mm de pluie/an), Pamplemousses (> 1500 mm de pluie/an et Médine (pluie 900 mm de pluie/an). Bien que la cendre de charbon n'a pas eu d'incidence sur le pH, la salinité et même les bases échangeables du sol, son application à 100 t/ha par rapport aux engrais minéraux, a entraîné une réduction du rendement en sucre d'environ 1.18 t/ha dans trois des essais. Au taux inférieur de 50 t/ha de cendre de charbon, en dépit d'une baisse significative des rendements observés à Belle Rive, la production de canne à Pamplemousses, Union Park et Médine n'a pas été significativement différente de celle du contrôle. L’absorption de N et de K par la canne à sucre n'a pas été influencée par la cendre de charbon, bien que celle de P a été renforcée en raison d’un apport supplémentaire de P provenant des cendres de charbon. De plus en raison de sa faible teneur en métaux lourds, la cendre de charbon n'a pas augmenté l'absorption de métaux lourds par la canne à sucre. Compte tenu des effets indésirables observés sur la production de canne à sucre, l'élimination de la cendre de charbon à des taux aussi élevés que 100 t/ha dans les champs de canne à sucre ne devrait pas être envisagé.
IMPACTO DE ALTAS CANTIDADES DE MATERIAL PARTICULADO DE CHIMENEAS EN ALGUNAS CARACTERÍSTICAS DEL SUELO Y EN LOS RENDIMIENTOS DE LA CAÑA DE AZÚCAR EN MAURITIUS

Resumen

LA COMBUSTIÓN de carbón para la cogeneración de electricidad por parte de la industria azucarera en Mauricio genera anualmente unas 20 000 toneladas de material particulado de chimeneas que deben ser eliminados de manera ambientalmente racional. Se han reportado beneficios agronómicos de la aplicación a gran escala de ceniza, pero la información para las condiciones que prevalecen en Mauricio es escasa. El impacto de la aplicación de 50 a 100 t/ha de material particulado sobre la calidad del suelo y en la producción de caña de azúcar, ha sido evaluado en ensayos a campo realizados en Belle Rive (lluvia>3500 mm/año), Union Park (lluvia>3000 mm/año), Pamplemousses (lluvia>1500 mm/año) y Médine (900 mm de lluvia mm/año). A pesar de que las cenizas de carbón no afecta el pH del suelo, la salinidad del suelo, ni las bases intercambiables, aplicaciones de 100 t/ha, en comparación a aplicaciones de abonos minerales, se tradujo en una reducción promedio del rendimiento de azúcar, de 1.18 t/ha, en tres sitios. La dosis más baja de 50 t/ha de cenizas produjo un descenso significativo de los rendimientos en Belle Rive, mientras que la producción de caña de azúcar en Pamplemousses, Union Park y Médine no fue significativamente diferente del testigo. La absorción de N y K por parte de la caña de azúcar no se vio afectada por el material particulado, a pesar de que la absorción de P fue mayor a causa de los P complementarios provistos por la ceniza. Además, debido a su bajo contenido de metales pesados, el material particulado no aumentó la captación de metales pesados por parte de la planta de caña de azúcar. En vista de los efectos adversos observados en la producción de caña de azúcar, la disposición de cantidades de cenizas de carbón, tan altas como 100 t/ha no deben ser contempladas en campos cañeros.
MODIFIED DUAL ROW PLANTING SYSTEM FOR GREEN CANE MANAGEMENT IN THE TROPICS

By

J.S. TORRES, F. VILLEGAS and A. DURÁN

Colombian Sugarcane Research Center, Cenicaña

jtortes@cenicana.org

KEYWORDS: Row Spacing, Sugar and Cane Yields, Control Traffic.

Abstract

AFTER GREEN cane harvesting in high yielding fields, a large amount of residues are left on the soil surface which interfere with the standard cropping practices, normally in burnt fields. A new planting system arrangement has been tested to reduce cane stool damage, soil compaction, cost of residue handling, allelopathic effects, herbicide use, and to improve irrigation efficiency. The so-called modified dual row planting (MDRP) allows for controlled traffic paths of 3.9 m wide followed by a set of three dual rows of cane at 0.8 m between rows and 2.1 m in between two adjacent pairs of dual rows. Total furrow length per hectare is equivalent to a single-row planting at 1.75 m spacing (5714 m of cane row/ha). The 3.9 m strip opens enough space to place the residues during manual cutting and leave the cane rows free of residues. The traffic of wagons loaded with cane is conducted on top of the green trash which later decomposes to enrich these areas with organic matter. During development of the plant cane, other crops can be planted to benefit from these open spaces. The MDRP, tested under different soil and climatic conditions, was found to produce a lower cane yield (10 to 20 t/ha) in plant cane as compared to the single-row planting spacing at 1.75 m spacing. After the harvest of the plant and several ratoons, the benefits of the MDRP, due to controlled traffic and less compaction, resulted in a more stable cane production; the cumulative cane production after four cropping cycles showed a higher cane production than the single-row planting. The MDRP also allows for a good separation of the cane windrows from the trash swaths which results in at least 1% higher sugar recovery.

Introduction

The use of large farm machinery for sugarcane cultivation and harvesting has resulted in higher efficiencies at the expense of sound agronomic practices and crop sustainability (Torres and Rodríguez, 1996; Bull et al., 2001). Direct cane stool damage by cane loader and infield transport equipment was more important than compaction itself in determining cane yield of the following ratoon crop (Torres and Villegas, 1993). Later on, Torres and Pantoja (2005) reported that, under wet conditions, controlled traffic of the mechanical harvesting system resulted in similar cane yields as the plots without infield traffic. Therefore, they advised that traffic of infield machinery should be controlled to sustain production in any harvesting system under the conditions of the Cauca Valley in Colombia.

In Australia, Bull and Bull (1996 and 2000) presented a new planting system with dual, triple and quad rows. Row spacing was reduced from 1.5 m to 0.5 m resulting in a linear increase in cane yield of up to 60 t/ha. This system has management limitations due to lack of machinery to fit the narrow spacing. All three farming systems have in common the adoption of strip traffic lanes between the set of cane rows where the soil remains compacted, and no ripping is executed within this area to accommodate machinery traffic. The area between the set of cane rows corresponds to
minimum tillage zones where the soil remains uncompacted promoting soil health. Therefore, new planting systems with dual, triple and quad rows were proposed to improve soil structure. The three high density farming systems outlined by Bull et al. (2001) involved the use of controlled traffic zones, minimum tillage and precision planting.

Harvesting of sugarcane during rainy periods is a common practice that creates problems in the succeeding crop. The use of large capacity wagons with high flotation tyres has not been sufficient to reduce the field problems of compaction and direct crop damage. Matching infield machinery tracks to fit inter-row spacing is required to reduce direct cane stool damage and to limit compaction to the inter-row.

The Colombian sugar industry has been shifting from 1.5 m row spacing to new plantings at 1.65 m and 1.75 m. These spacings open more room to accommodate the large amount of green cane residues in the inter-row after trash lining and, at the same time, look for a better fit to the track widths of the existing infield machinery.

Torres and Rodriguez (1996) presented a review paper describing the forces acting on the soil during the compaction process and compiled a list of the most desirable management practices to minimise, offset or eliminate soil compaction. In general, infield machinery should be lighter, be mounted on high flotation tyres, track widths should match row spacing, and controlled traffic paths should be implemented to reduce stool damage.

In order to adopt most of the well known recommendations to reduce soil degradation, eliminate stool damage, improve fertiliser use efficiency, decrease the need for herbicides, increase irrigation efficiency and minimise the extra cost for green cane residue handling, a new farming system, so-called modified dual row planting system (MDRP) is under experimentation in the Cauca Valley of Colombia.

**Materials and methods**

Within the Colombian sugar industry, infield machinery varies in size, weight and track widths, so it is almost impossible to select a single-row spacing that can eliminate compaction or cane stool damage while opening enough inter-row space to accommodate cane residues to reduce allelopathic effects on ratoon regrowth. The new planting system corresponds to a modification of the conventional dual-row planting where a set of two rows of cane is planted at a distance that varies between 0.3 m to 1.0 m apart and a fixed distance (1.3 to 1.8 m) is kept to separate the centres of dual rows.

Using computer graphic aids, different row-spacing arrangements and infield machinery track widths were plotted to select the best row spacing that could help to achieve the objectives of the system. No single-row spacing was identified to suit the traffic of infield equipment.

Therefore, it was necessary to favour the establishment of a dedicated traffic strip where any infield machinery track width could be accommodated without running over the nearest cane row (Figure 1). The so-called Modified Dual Row Planting has a traffic strip width of 3.9 m and three dual rows of cane at 0.8 m apart and 2.1 m in between two adjacent pairs of dual rows.

Planting of the cane using the new configuration required modification of the furrow opener and the use of surveying equipment to mark the row direction and the spacing between dual rows. The new system was initially planted in a small area at Cenicaña’s experiment station and later on was presented at a cane grower meeting.

The new idea seemed so interesting that a few months later (in 2003), the planted area amounted to 424 ha. Growers at Cenicaña were worried that a new idea that had not been fully proven experimentally was at a high risk.

Fertilisation of the cane row was executed at 50 days after planting as it was necessary to adjust the position of the chisels and hose outlets of the fertiliser box to apply half of the fertiliser dosage on each side of the cane rows.
In order to avoid the convergence of the dual rows into a single row of cane due to intensive cane tillering at such a close spacing (0.8 m), a small duck foot cultivator blade was run over the centre of the dual rows during a hilling up operation. At the same time, the inter row between the dual rows was ready for furrow irrigation. The surface area that comes in contact with the irrigation water is reduced to 25% of the planted area, leaving room for more storage of rainfall water. When a newly planted field under conventional single row spacing is surface-irrigated, the applied volume of water normally amounts to 2500 m$^3$/ha while the irrigation of the MDRP consumed only 500 m$^3$/ha of water increasing the water use efficiency.

The new MDRP planting system has been evaluated and compared to planting at either 1.65 m or 1.75 m spacing at commercial scale under different soil types and climatic conditions using cane varieties CC 85-92, CC 84-75, CC 93-744, CC 92-2198, CC 93-7510 and MZC 84-04.

**Results and discussions**

**Furrow irrigation**

The inter-row between the pair of cane rows was shaped to obtain a parabolic furrow able to carry up to 8 litres per second (L/s) of water. The furrow irrigation system was evaluated at the Mayaguez sugar mill using furrow discharge rates of 4, 5 and 6 L/s applied to the single-row planting at 1.75 m and to the MDRP. As the discharge rate increased, the amount of water applied to MDRP decreased from 1160 m$^3$/ha with 4 L/s to 600 m$^3$/ha with a flow rate of 6 L/s due to a shorter advance time of the water while the volume of water applied to the 1.75 m spacing varied between 1540 m$^3$/ha (4 L/s) and 1250 m$^3$/ha (6 L/s). In terms of depth of water applied to the soil, using a discharge rate of 6 L/s in MDRP resulted in 90 mm of water while, at 1.75 m spacing using the same discharge rate, the applied water depth was equivalent to 125 mm. It is necessary to consider that rainfall events in the tropics can occur at any time; therefore, it would be advantageous to leave some storage capacity in the soil for those rainfalls.

**Cane and sugar yields**

The cane yield and sugar recovery of the plant cane crops were used to calculate the sugar yields which are presented in Figure 2 as isoproduction curves. At a first glance, three cane
productivity groups could be identified as a function of the row spacing. The highest cane yield group consisted of plantings made at 1.65 m spacing with cane yields above 170 t/ha and sucrose content (IRSC) of 11.5%. A second group consisted of plantings at 1.75 m with cane yields between 140 and 170 t/ha and sucrose content below 11.5%.

A third productivity group included the MDRP which showed a great dispersion in cane yields varying from 80 to 150 t/ha due to the lack of sufficient plant population per unit area and because of the effects of soil, climate and cane varieties planted.

In general, a cane yield difference of 20 to 25 t/ha in favour of the single-row plantings at either 1.65 m or 1.75 m was registered. At the same time, the MDRP showed a tendency to form a cluster with high sucrose content above 11.5% as a result of the cleaner cane sent to the factory.

The big differences in cane yield between the plant cane of the new planting system and the single-row plantings caused dissatisfaction and aversion of the cane growers to continue evaluating the new system. A remedial action was taken by Cenicaña and new plantings were conducted at CIAT’s experiment station and the Pichichi sugar estate to test new options to improve the cane yield of the MDRP.

The wide open strips of 3.90 m by 120 m long, intended to accommodate the residues and be a dedicated area for the traffic of the cane wagons, occupy an area of 0.37 ha (37%) which is quite large and has a definite impact on cane yield. A hypothesis emerged to upgrade the cane yield of the new system (Figure 3).

If the reduced population density was the cause of the lower cane yield of this system, it would be necessary to increase the density by planting one or two extra rows of cane in the centre of the 3.9 m strip that may result in a cane yield of the MDRP as high as the ones from the single-row spacing.

After the harvest of the plant cane, the extra rows of cane could be discarded to merge into the MDRP system. It is expected that after harvesting the plant cane all the benefits of the system, such as controlled traffic zones, reduced compaction and stool damage would accrue to sustain a higher cane yield during the following ratoon crops with the possibility that the crop would last longer.
The proposed hypothesis was tested at CIAT’s experiment station by planting one extra row in the MDRP (Figure 4). After three consecutive crops, the cumulative cane production of the MDRP system amounted to 468 t/ha while the cane production at 1.75 m was 459 t/ha, which agrees quite well with the hypothesis. It was clear that, after harvest of the plant cane, the benefits of the system allow for a more stable cane yield, and the crop is expected to last for more ratoons. In addition to the benefits of a more sustainable cane production, an economic analysis including the cost of water, labour savings, reduced use of herbicides and soil improvement due to build-up of organic matter in the wide strips would be necessary.
wagons loaded with cane. The grab loader runs in the 2.1 m space that separates two pairs of adjacent dual rows, without causing serious compaction or stool damage.

The continual addition of residues after three crops of cane to the traffic strips on a clay soil (Vertisol) that was previously used as grazing land has resulted in a build up of soil organic matter. The organic matter content on the 2.1 m spacing that separates the dual row was 3.9% from 0 to 20 cm and 3.35% from 20 to 40 cm depth in the soil profile while, in the traffic strip where there is accumulation of residues, the organic matter content increased to 5.4% from 0 to 20 cm and to 3.4% from 20 to 40 cm depth.

Conclusions

We strongly believe that the MDRP system is a good option to manage cane in a sustainable way, to reduce compaction and stool damage problems, reduce the use of water for irrigation and opens the possibility to intercrop leguminous and other crops such as potatoes, beans or tomatoes. Once the benefits of the system are properly quantified and the temporal differences in cane yield in relation to the single-row planting spacing are accepted or compensated with the planting of one or two extra rows of cane, the adoption of this system may become a reality.

REFERENCES

plantation en double-rang modifiée (MDRP) tient compte des chemins de roulement de 3.9m de large comprenant entre eux 3 lignes jumelées de 0.8m entre rangs et 2.1m entre paires de rangs. La longueur totale de sillons par hectare est équivalente à une plantation en rang simple de 1.75 m d’écartement (5714 m/ha). Les allées de 3.9 m de large laissent assez d’espace pour les résidus provenant de la coupe manuelle et laisse les lignes de cannes sans résidus. Le passage des remorques chargées de canne s’effectue sur les résidus verts qui se décomposent ensuite pour enrichir le sol en matière organique. Durant le développement de la canne plantée, d’autres cultures peuvent être plantées sur ces allées ouvertes. Le MDRP, testé sous différentes conditions de sol et de climat, a produit un rendement plus faible (10 à 20 t/ha) en canne plantée que le système en rang simple avec un écartent de 1.75 m. Après la récolte de la canne plantée et de plusieurs repousses, le système MDRP, dû à des passages contrôlés et moins de compaction, entraîne une production plus stable; et après 5 cycles, une production cumulée supérieure à celle du système en rangs simples. Le système MDRP a permis aussi une bonne séparation des andains de résidus de canne et a produit ainsi une qualité de sucre extractible supérieure de plus de 1%.

SISTEMA DE PLANTACIÓN EN DOBLE SURCO MODIFICADO PARA MANEJO DE CAÑA VERDE EN LOS TROPICOS

PALABRA CLAVE: Distanciamiento Entre Surcos, Producción de Azúcar y Caña, Tráfico Controlado.

Resumen

Después de la cosecha en verde en cañaverales de alta producción, queda sobre la superficie del suelo una gran cantidad de residuos que interfieren con las prácticas normales de cultivo en campos quemados. Se evaluó un nuevo sistema de diseño de plantación para reducir el daño a la cepa, la compactación del suelo, el costo del manejo de los residuos, los efectos alelopáticos, el uso de herbicidas y mejorar la eficiencia del riego. El llamado surco doble modificado (MDRP) permite un tránsito controlado por la trocha de 3,9 m de ancho seguida por un conjunto de tres surcos dobles de caña a 0,8 m entre surcos y 2,1 m entre dos pares de surcos dobles adyacentes. La longitud total de surcos de caña que se dispone en una superficie de una hectárea en el nuevo diseño, es equivalente a lo plantado en un diseño de surco simple distanciado a 1,75 m (5714 m de surco/ha). Los 3,9 m de trocha abierta dan suficiente espacio para colocar los residuos que se producen durante la cosecha manual y deja a los surcos de caña libres de residuos. El tránsito de carros cargados con caña se realiza sobre los residuos verdes cuya posterior descomposición enriquece esas áreas con materia orgánica. Durante el desarrollo de la caña planta se pueden plantar otros cultivos, para obtener beneficios en ese espacio. El MDRP, evaluado bajo diferentes suelos y condiciones climáticas, produjo en caña planta una disminución en la producción de caña (10 a 20 t/ha), comparado con la plantación en surco simple espaciados a 1,75 m. Después de la cosecha de la planta y varias socas, los beneficios del MDRP, debidos al tránsito controlado y a la menor compactación, resultaron en una producción de caña más estable y la producción acumulada después de cuatro ciclos mostró mayor producción de caña que en la plantación en surco simple. El MDRP también permite una buena operación de limpieza de la caña que deriva en menores niveles de trash en la materia prima, lo cual resulta en por lo menos 1% más de recuperación de azúcar.
CROTALARIA JUNCEA, CANAVALIA ENSIFORMIS AND MUCUNA SP AS POSSIBLE NITROGEN SOURCES FOR FERTILISATION IN SUGARCANE COMMERCIAL NURSERIES

KEYWORDS: Nitrogen Mineralisation, Green Manuring, Crop Rotation.

Abstract

The objectives of this study were to: a) Evaluate the rotation of “Crotalaria juncea, Canavalia ensiformis and Mucuna sp” and their effect on the production of sugarcane during three sowing times. b) To determine the decomposition of the legume plants, and quantify the contribution of nitrogen of each one to the system. An experiment was carried out in a Mollisol soil of the Finca El Naranjo, located in the low area of the sugar region of Guatemala, evaluating the three species of legumes, on three dates of sowing in the winter, starting with the planting of the legumes on June 6th 2006 and repeating it every 15 days for subsequent dates. In all cases the sugarcane planting was made two months after the planting of the legumes. Two further treatments were included, being the commercial practice without legumes and a control without legumes and without N. Plots of cane with legumes were not fertilised with nitrogen. The experimental design used was randomised complete blocks with three replications. Sowing times were the main plot and the sub-plots were the three species of legumes. In order to quantify the decomposition of the legumes, the methodology used was the same as that used by Resende et al (1999) by the use of degradation bags buried under the plots being evaluated at the 7th, 14th, 21st, 35th, 60th, 75th and 120th day after the incorporation of the legumes. To estimate the decomposition rate, we used the Thomas and Asakawa Model, cited by Resende (2000). The results indicated that all the treatments where the legumes were incorporated exceeded the commercial control in terms of sugarcane seed with Canavalia ensiformis which produced 7.4 TCH more than those which were fertilised. The accumulation of nitrogen from the legumes was between 144 and 349 kg of N/ha during the evaluation period with Crotalaria juncea being the best contributor. The average half time of decomposition for the legumes was similar and varied from 17 to 20 days, while the half time of the nitrogen to be mineralised was 5 to 7 days, with Mucuna sp presenting the lowest average half time of decomposition of residues, and the lowest half time of the nitrogen to be mineralised was the Crotalaria juncea.

Introduction

The Guatemalan sugarcane industry replants annually around 20% of the cultivated area (46 000 ha of 230 000 ha), which means that it should establish 4600 ha of seedbeds for plant supply. These seedbeds are planned over a year in advance and fallowed for 6 to 8 months before
being used, which means that the fields used for such activity are not cropped for about 2 to 4 months, and are covered with weeds and sugarcane volunteers from the previous harvest.

Looking for an agro ecological practice that avoids fallowing, there is an opportunity to rotate three species of legumes aiming to find the best season to rotate them in the fields designated for the commercial propagation of the sugarcane. *Crotalaria juncea*, *Canavalia ensiformis* and the *Mucuna* sp are legumes of fast growth and could contribute up to 275 kg of N/ha (Flores, 2005). In addition, they are species that would improve the soil structure, contribute organic matter, and their cover protects the soil from water and wind erosion.

These species were evaluated to determine their suitability under the conditions of the Finca Naranjo San Diego, and also to measure their contribution in terms of nitrogen to the soil, the mineralisation of the residues, and the increase in the amount of the sugarcane seed compared to traditional methods.

In other sugar agro industries, rotation with legumes has provided benefits in tonnage of cane and seed, and they contribute nitrogen and organic matter to the soil. Resende (2000), in Brazil, evaluated *Crotolaria juncea*, *Canavalia ensiformis* and *Mucuna deeringiana* and determined that these species may fix up to 50% of the total N from the atmosphere for use by the crop.

**Methodology**

Two factors were studied: a) three dates of sowing (of legumes and sugarcane) and three species of legumes. A randomised blocks design with three replications was used. Sowing times were the main plots starting with the first one on June 6th of 2006 and the other two starting 15 and 30 days after. The cane planting was established two months after the legume sowing. Legumes were the sub-plots and they have two controls: one absolute and another fertilised without legumes.

The fertilisation of the sugarcane varied in the treatments depending on presence or absence of a legume crop. In the plots where legumes were planted, the cane did not receive nitrogen. Every plot was fertilised with 60 kg of phosphorus per ha, excepting the absolute control, which did not receive fertilisation. Sixty days after the legume sowing, the experimental units were planted with sugarcane variety CP 72-2086.

To ensure the presence of N₂-fixing micro organism in the legume species to be evaluated, the seeds were inoculated with soil from the seedbeds of *Canavalia ensiformis*. The harvest of legumes was done 60 days after the sowing, where all the materials were cut leaving only the residues scattered on the soil. The residues were incorporated mechanically with skid equipment the day after harvest.

The decomposition of the studied legumes, was determined with the aid of degradation bags like the ones used by Resende *et al.* (1999), burying the samples in the soil. A sample was taken on the 7th, 14th, 21st, 35th, 60th, 75th, 120th day after the burial day. The total amount of nitrogen contained in the samples was determined by the digestion method of Kjeldahl.

To estimate the constant decomposition of the residues, we used the Thomas and Asakawa method cited by Resende (2000): \( Lr/Li = e^{-kt} \), where \( Lr \) = dried biomass of the residues incorporated in the soil \( n \) days after the sowing; \( Li \) = dried biomass of the residues before incorporation (0 days); \( e \) = base of natural logarithms; \( t \) = sample time interval expressed in days, and \( k \) = the rate of the constant of decomposition per day. The value of \( k \), was calculated as the time necessary for the residues to disappear after their incorporation in the soil (\( t/2 \)).

The planting of the sugarcane was made with seed from a semi-commercial seed bed with hydrothermal treatment (Buenaventura, 1990) of the variety CP 72-2086. The planting was made five days after the incorporation of the legume residues. The harvest of the seed of the treatments was made manually with machetes making packages of 30 canes. The harvest was made 7 months after the planting.
The parameters evaluated were the following:

a) for the legumes: weight of green mass, dry weight (kg/ha), nitrogen accumulated in the biomass and also the time of degradation of the residues in the soil;

b) for the cane seed: population of stems (number of stems/ha), diameter of the cane stems in cm and production of cane seeds (TCH).

Data were analysed by the analysis of variance and means were compared by Tukey’s Test.

Results

Weight of seed cane and components of the production

The variance analysis indicated statistically significant effects for the times of sowing and the legumes on weight of seed sugarcane. However, there was no interaction between the two variables.

The averages of the effects of the times of sowing and the legumes for the weight of seed cane, population and diameter of stems appear respectively in Tables 1 and 2.

In relation to species of legumes in rotation (Table 1) the seed weights were between 66.8 and 73.1 tonnes of cane/ha.

Two of the legumes, on average, exceeded the commercial controls. Increases of 7.3 and 4.6 tonnes of cane / ha were obtained with the rotation of Canavalia ensiformis and Mucuna sp respectively, compared to the commercial control without commercial fertiliser.

In relation to the sowing time (Table 2), it is observed that the weight of sugarcane seed varied from 66.8 to 73.1 tonnes of cane/ha, depending on the sowing time. The increased production was achieved when legumes were sown in Time 3, being significantly higher than for the other two times.
**Weight of biomass and nitrogen contribution of legumes**

Tables 3 and 4 show the averages of fresh biomass, total N and N accumulation in biomass, respectively, for the sowing and the species of legumes in rotation.

In relation to species of legumes (Table 3), it is observed that the species with the highest average yield of biomass and the highest N accumulation was *Crotalaria juncea*. This species reaches a yield of fresh biomass of 50.8 t/ha with 81.2% moisture and accumulates 349 kg N/ha in 60 days, contrasting with the yields obtained with the other two species.

Muchovej (1995) quotes that in Florida, United States, the peanut is capable of providing up to 235 kg of N/ha. In Brazil, it is known that *Crotalaria juncea* incorporates around 180 to 200 kg N/ha. On the other hand, Garside *et al.* (1998) reported on the time of harvest of the sugarcane in 1994–1995 with 4 species of legumes: beans cowpea, mucuna, peanuts and soybeans planted at 3 different times. The results showed that, with soybean, around 310 kg N/ha is incorporated; it was the species with the largest amount of nitrogen incorporated into the soil, while the other 3 species incorporated up to 170 kg of N/ha.

Table 4 shows that the highest concentration of total N and increased N accumulation in biomass of the legumes were obtained when sowing was during the first week in July (06–07–06) and decreased as sowing was advanced to the first week of June. During the two later times, the highest amount of N was accumulated in the aerial biomass although, in terms of fresh biomass and more water content, the yield was higher in Time 1 caused mainly by the greater weight of *Crotalaria juncea* at this time.

**Degradation time of legumes residues**

The analysis of variance showed statistically significant effects between sowing time and the legume species in rotation, but not for the interactions between time and legumes. The average of
the constant decomposition per day and average time of degradation of the legume residues per time of planting and legume using the Thomas and Asakawa methodology cited by Resende (2000) are presented in Tables 5 and 6.

Table 5—Time and rate of decomposition of the three legumes evaluated in the study.

Table 5 shows that the decomposition rates of the legume species varied a little from 0.036 to 0.046, and there were minor variations also in the average time of decomposition from 17 to 20 days (Figure 1). These comparisons are supported by the variance analysis and Tukey test.

In practical terms, the rates of decomposition and the average time of decomposition of the three legume species evaluated were very similar and very fast due to the good conditions of temperature and humidity prevailing in the sugarcane region of Guatemala.

Resende (2000) in Brazil evaluated the decomposition rate and the average time of decomposition of four species of legume, *Crotalaria juncea*, *Crotalaria spectabilis*, *Canavalia ensiformis* and *Mucuna deeringianum*. He found that *Crotalaria juncea* was the legume that presented the slowest degradation with a half time of 46 days for decomposition. The *Crotalaria spectabilis*, *Canavalia ensiformis* and *Mucuna deeringiana* had an average of 22, 42 and 45 days respectively.

Resende (2000) reported that the rate and half time difference between *Crotalaria juncea* and the *Canavalia ensiformis* was 0.001 and 3 days respectively, which were similar to results obtained in this study, 0.001 and 1 day respectively.
In terms of sowing time, it was observed that the daily rate of decomposition varied from 0.028 to 0.053. The highest rate was in Time 1 (first week of June sowing), where residues were degraded in a lower average time (15 days) as shown in Table 2.

The highest rate of decomposition of legumes in Time 1 would be associated with a higher humidity on the soil at this time, due to increased rainfall during the initial test compared with the rainfall of Time 3.

The daily decomposition rate of daily nitrogen contributed by the three legume species evaluated (Table 7) varied from 0.114 and 0.135, with variations of one day (5 to 6 days) in the average time of decomposition.

The nitrogen contributed by the legume species that were evaluated had a faster decomposition rate than the decomposition of residues; this agrees with the study conducted by Resende (2000), where residues of legumes evaluated deteriorated in a period of time of 45 days and the mineralisation of nitrogen varied from 14 to 35 days; unlike this study, the residues were left on the floor.

This apparently is because most of the nitrogen is found in the tissues and decompose more rapidly, fixing a small part of the nitrogen compared to more recalcitrant compounds such as lignin and polyphenols, which have slower decomposition (Resende, 2000).

The daily decomposition of nitrogen at various times varied from 0.107 to 0.131, and similar mineralisation was observed between Time 1 and Time 3. The rate of mineralisation was also similar. The highest rate was during Time 3 (first week of July sowing) where nitrogen is mineralised in a period of 5 days.

\[T_{1/2} = \text{Time in which 50% of residues are away from the bag}\]

Conclusions

The rotation of the three species of legumes produced on average more sugarcane seed cane compared to the commercial control without rotation and properly fertilised. Increases were observed of 7.3 and 4.6 t/ha, respectively, with the rotation of *Canavalia Ensiformis* and *Mucuna* sp.

It was determined that *Crotalaria juncea* accumulated an average of 349 kg N/ha to 50 t/ha of biomass in 60 days while *Mucuna* sp and *Canavalia ensiformis* accumulated on average 216 and 144 kg N/ha in the same period.

Half time degradation of the aerial biomass of the legume species took 17 to 20 days with similar daily rates of decomposition; the average time of nitrogen decomposition was 5 to 6 days with similar rates between sowing times.

The average time for degradation of nitrogen between sowing times varied from 5 to 7 days, in Time 2, which was planted on June 21st 2006, and had a lower daily rate of decomposition (k=0.107) than the other two studied.

Résumé

Les objectifs de cette étude étaient : a) d'évaluer la rotation de \textit{Crotalaria juncea}, \textit{Canavalia ensiformis} et \textit{Mucuna sp} et leur effet sur la production de canne à sucre après trois semis. b) de déterminer la décomposition de ces légumineuses, et de mesurer leur contribution en azote au système. Une expérimentation a été menée sur un Mollisol de la Finca El Naranjo, situé dans les zones basses de la région sucrière du Guatemala. Trois espèces des légumineuses ont été évaluées pour trois dates hivernales de semis, en commençant les semis le 6 juin 2006 et en les répétant tous les 15 jours pour les dates suivantes. Dans tous les traitements, la plantation de canne à sucre a été réalisée deux mois après le semis des légumineuses. Deux traitements supplémentaires ont été inclus, la pratique commerciale sans légumineuses et un témoin sans légumineuses et sans N. Les parcelles de canne avec légumineuses n'ont pas été fertilisées avec de l'azote. Le dispositif expérimental était constitué de blocs complets randomisés avec trois répétitions. Les parcelles principales comportaient les dates de semis et les parcelles secondaires, les trois espèces des légumineuses. La méthodologie utilisée pour mesurer la décomposition des légumineuses fut celle employée par Resende \textit{et al.} (1999). Des sacs contenant des légumineuses furent enterrés dans les parcelles correspondantes puis évalués 7, 14, 21, 35, 60, 75 et 120 jours après la récolte et l'incorporation des légumineuses. Pour estimer le taux de décomposition nous avons utilisé le modèle de Thomas et Asakawa, cité par Resende (2000). Tous les traitements où les légumineuses ont été incorporées ont entraîné une production de canne supérieure à celle de la pratique commerciale. Ainsi \textit{Canavalia ensiformis} produisit 7.4 TCH de plus que le témoin commercial fertilisé. Pendant la période d'évaluation, l'accumulation d'azote provenant des légumineuses fut comprise entre 144 et 349 kg de N/ha, \textit{Crotalaria juncea} étant la légumineuse ayant la production d'azote la plus élevée. La demi période de décomposition des légumineuses fut comprise entre 17 à 20 jours, alors que la demi période de minéralisation de l'azote variait de 5 à 7 jours. La demi période de décomposition la plus basse fut observée chez \textit{Mucuna sp}, et la demi période de minéralisation de l'azote fut observée chez \textit{Crotalaria juncea}. 
CROTALARIA JUNCEA, CANAVALIA ENSIFORMIS Y MUCUNA SP COMO POSIBLES FUENTES DE NITRÓGENO EN LA FERTILIZACIÓN DE LA CAÑA DE AZÚCAR DE SEMILLEROS COMERCIALES

Resumen

Los objetivos de este estudio fueron: a) Evaluar la rotación con Crotalaria juncea, Canavalia ensiformis y Mucuna sp y su efecto en la producción de caña de azúcar durante tres fechas de siembra. b) Determinar la descomposición de las plantas leguminosas, y cuantificar la contribución de nitrógeno de cada una al sistema. Se realizó un experimento en un suelo Mollisol de la Finca El Naranjo, ubicado en la zona baja de la región azucarera de Guatemala, evaluándose las tres especies de leguminosas, en tres fechas de siembra invernales, comenzando con el cultivo de las leguminosas el 6 de junio de 2006, y repitiéndose cada 15 días para fechas posteriores. En todos los casos, la plantación de caña de azúcar se hizo dos meses después de la siembra de las leguminosas. Se incluyeron dos tratamientos más: la práctica comercial sin leguminosas y un testigo sin leguminosas y sin N. Las parcelas de caña con leguminosas no fueron fertilizados con nitrógeno. El diseño experimental utilizado fue de bloques completos al azar con tres repeticiones. La época de siembra constituyó las parcelas principales y las sub-parccllas fueron las tres especies de leguminosas. Con el fin de cuantificar la descomposición de las leguminosas, la metodología utilizada fue la misma que la propuesta por Resende et al. (1999) en la cual se utilizan bolsas de la degradación enterradas bajo las parcelas que se evaluaron a los 7, 14, 21, 35, 60, 75 y 120 días posteriores a la incorporación de las leguminosas. Para estimar la tasa de descomposición se utilizó el modelo de Thomas y Asakawa, citado por Resende (2000). Los resultados indicaron que todos los tratamientos donde las leguminosas se incorporaron superaron al control comercial en términos de producción de semillas de la caña de azúcar. Canavalia ensiformis produjo 7,4 TCH más que los que fueron fertilizados. La acumulación de nitrógeno de las leguminosas fue de entre 144 y 349 kg de N/ha durante el periodo de evaluación donde Crotalaria juncea fue la de mayor contribución. El tiempo promedio de la mitad de descomposición de las leguminosas fue similar y varió desde 17 hasta 20 días, mientras que el tiempo medio de mineralización de nitrógeno fue de 5 a 7 días, con Mucuna sp presentando el menor promedio de tiempo de media descomposición de los residuos. El tiempo más bajo de la mitad de mineralización del nitrógeno registrado fue el de la Crotalaria juncea.
PRELIMINARY RESULTS OF A NETWORK OF TRIALS RELATED TO SUGARCANE NUTRITION IN REUNION ISLAND

Abstract

IN REUNION ISLAND, sugarcane is grown under highly contrasting climatic conditions, from the sea level to the highlands (up to 1000 m altitude), with very different soil types. Taking this diversity into account, a network of agronomic trials was implemented in 2005 on grower farms across the island. Four main fertilisation or amelioration techniques were tested: i) reduction of soil acidity using mill ash compared to liming materials, Mag lime and Physiolith; ii) sustainable nutrient management based on soil analysis, iii) effect of a slow release fertiliser-polymer-coated granular urea and iv) effect of splitting nitrogen application. In each trial, the traditional grower practices were used as control. Outcomes of the trials included: correction of soil acidity using mill ash with a sugar yield 10 to 23% higher than the control; a better sugar yield per ha using sustainable nutrient management (in one of two trials); a sugar yield loss using a reduced rate (–30%) of polymer-coated granular urea; a positive impact on ratoon yield when nitrogen application was split into two events. Such a network of trials should facilitate a faster adoption of research recommendations by the growers as it allows a direct exchange of information between sugarcane farmers and agronomists and addresses growers’ issues.

Introduction

Reunion Island is a volcanic island in the Indian Ocean, located at 55°30’ longitude east, and 21°05’ latitude south, with an area of 2510 km² and the highest summit of 3069 m whose soil types are results of:

- The age of lava flows issued from the two volcanos that created the island.
- Varying climatic conditions characterised by a huge rainfall gradient from 600 to more than 4000 mm in sugarcane areas.

The soils are silty clay textured; well-drained and varied in fertility. Heavy applications of phosphorus may be necessary in andic cambisol soil types, whereas their potassium level is naturally very high (Fillols et al., 2007).

In nitisol and andic cambisol soil types, a moderate nitrogen application is generally required. Considering all soil types within the sugarcane area, 36% have pH<5 and 26% have pH between 5 and 5.5, so liming is often advised.
Sugarcane is grown on about 26,000 ha from sea level up to 1000 m altitude and there are slightly fewer than 4000 sugarcane growers. Their farm management practices often differ from the recommendations given by research and development institutes, especially in terms of nutrient management.

A network of trials has been implemented since 2005 on growers’ farms across the island in order to facilitate the adoption of technical advice by farmers. These trials also take into account the island diversity and help researchers to refine their recommendations.

Materials and methods

In total, nine trials have been implemented: eight on grower’s farms across the island and one (T4) in an experimental station (Table 1)

(I): Irrigated

Four topics studied are:
- Liming products: mill ash, Mag lime, Physiolith® (calcified seaweed) (Tables 2 and 3).
- Split nitrogen applications: one application of nitrogen full rate in the furrow at planting (Table 4, T4-M1 and T5-M1), 1/2 rate N at planting then 1/2 rate 2 months later (Table 4, T4-M2 and T5-M2), 1/3 rate N at planting, 1/3 rate 2 months later and 1/3 rate at 4 months (Table 4, T5-M3). In ratoons, the first application of nitrogen was done at 2 months after harvesting and the following applications were done at 2 months apart.
- Physical forms of urea fertiliser: prill urea, coated urea.
- Sustainable nutrient management using soil analysis compared to traditional growers’ practice (Table 5).

(1): dry weight

Soils in all trial sites were sampled and analysed before planting. Liming products and nutrients were applied according to the recommendations of the soil laboratory, unless specified otherwise in the trial procedures (Pouzet et al., 1997).

Liming products were buried prior to planting. If not specified otherwise in the procedures, fertilisers were localised in the furrow at planting and between one and two months after harvest in ratoons. Soil testing was done at least once a year after harvest.

The same trial design was used in all trials, with three replicates and plot size of 20 m * 9 rows, comprising four guard rows, two rows for measurements of stalk number, growth foliar analysis and CCS, and three central rows for yield assessment.

An economic study consisted here of comparing the gross margin in €/ha/y obtained in a tested treatment to the one that resulted from the grower’s usual practice (control).

The expenses taken into account were the cost of products per hectare (liming products, fertilisers), transportation, mechanical application and incorporation (liming products), and application by hand (fertilisers).

All other farming practices were considered similar between treatments and not taken into account in the calculation. Costs of cane hauling and transport after harvest were not included.

The income calculation was based on the payment of cane for a CCS of 13.8%. It was calculated for a 10 ha average farm and the different governmental subsidies were added.

SNM: Sustainable nutrient management. GNM: Grower’s nutrient management.

Results and discussion

Trials on liming products

These trials were implemented on farms where the soil was very acidic and the soil analysis recommended 3.5 to 4 t/ha of CaO + 1.8 to 2 t/ha MgO. However, liming products in Reunion are expensive and growers cannot afford to apply these high rates. This is the reason why Mag lime and Physiolith®, 2 commercial liming products, have been applied at reduced rate in the trials, whereas the full advised rate of mill ash has been used.

In all trials, the application of mill ash, Mag lime and Physiolith® significantly increased cane yield by 19.0%, 15.2% and 14.0% respectively, and sugar yield by 24.0%, 18.1% and 15.5% respectively, compared to the control (Table 6). However, there was no statistical difference in yield response between the three products.

The values of foliar and soil analysis should reflect the nutritional status of the plant and the fertility status of the soil according to the treatments applied, but are not always significantly correlated with cane and sugar yield. Mill ash treatment tended to improve soil parameters (Barry et al., 2001), especially calcium, magnesium, pH and CEC. In trial T3, the mill ash treatment significantly improved soil pH, Ca (Figure 1) and Mg values, but did not affect levels of nutrients in the leaves. In trial T1, foliar values of Ca and Mg were significantly higher in the mill ash treatment than in the Physiolith® and in the control treatments (data not included in this report).

Means in columns followed by the same letter are not significantly different (P = 0.05)

Physiolith® at 1.2 t/ha significantly improved cane and sugar yield compared with the control but did not significantly affect the soil parameters (pH, nutrients). This input represents a small amount of calcium (5.7 to 8.6 times less than mill ash and 2.4 times less than Mag lime) which is insufficient to influence soil cations and pH.

Trials on split nitrogen application and different physical forms of urea fertiliser

For split nitrogen application, there was no significant difference in cane yield, sugar yield or gross margin between a single, two and three applications, which was consistent with the results obtained by K.F. Ng Kee Kong and Deville (1992). However, splitting nitrogen in two applications...
trials T4 and T5, M2) tended to increase cane yield compared to a single application: +5.8% in T4 and +5.1% in T5. Gross margin was increased by 290 €/ha/y in the irrigated trial T4 and by 180 €/ha/y in the non-irrigated trial T5 compared to a single application.

Application of a common granulated NPK fertiliser 16-10-26 just after harvest (T4 – M5) was economically cheaper (+227 €/ha/y) than applying single nutrients: urea + TSP + KCl. Splitting urea in three applications resulted in a cane loss of –7.4 t/ha/y and reduced the benefit by –360 €/ha/y (not significant).

In trials T6 and T7 (Table 7), coated urea (NR) improved cane yield by 7.5% and 4.4% respectively and gross margin by +465 and +180 €/ha/y respectively when compared to prill urea (result was not significant).

</table>
In trial T4, the quality of the coated urea used in M3 plant cane was dubious and may lead to poor results obtained in M3 plant cane. The faulty cane establishment also seemed to affect development of the ratoons resulting in mediocre cane yield for 3 years.

In the coated urea product, urea was protected by a resin coat which slows down urea solubility. This slow release nitrogen fertiliser should improve plant uptake and reduce losses to the environment compared with normal prill urea. A reduced application rate was tested in order to compensate for the high cost of the product (60% more expensive than prill urea in Reunion Island in 2008). However, reducing the rate of coated urea by 30% (T4 – M4) induced cane yield loss of –3.8 t/ha/y and decreased the benefit by 349 €/ha/y compared to applying the full rate of prill urea.

**Trials on sustainable nutrient management**

The two trials on the use of a sustainable nutrient management program led to opposite outcomes.

In trial T8 (Table 8), cane yield increased by 13% where the sustainable nutrient management treatment (FC) was applied compared to the traditional grower’s nutrient management practice (FT) and the gross margin was 646 €/ha/y higher (not significantly different). Mag lime incorporated in the soil prior to planting in treatment FC progressively modified soil pH and composition in exchangeable Ca and Mg (Figure 2).

| Table 8—Trials on sustainable nutrient management. Average of cane yield (tc/ha/y) and sugar yield (ts/ha/y) and difference of gross margin compared to the control in €/ha/y. |
|---|---|---|---|---|
| **Trial** | **Treatments** | **tc /ha/y** | **ts/ha/y** | **Gross margin €/ha/y** |
| **T8** | Sustainable nutrient management | 99.7 | 13.1 | + 646 |
| Average of 3 years | Grower’s nutrient management (control) | 87.6 | 11.6 | – |
| Mean | 93.6 | 12.4 | – |
| CV% | 19.1 | 19.0 | – |
| P | 0.18 | 0.21 | – |
| **T9** | Sustainable nutrient management | 122.8 | 15.4 | – 1461 |
| Average of 2 years | Grower’s nutrient management (control) | 146.4 | 18.1 | – |
| Mean | 134.6 | 16.7 | – |
| CV% | 17.0 | 15.3 | – |
| P | 0.111 | 0.113 | – |

In trial T9, there was no significant difference between the two treatments. However, cane yield obtained by the grower nutrient management practice (FT) was 16% higher than in the sustainable nutrient management treatment (Table 8).

**Fig. 2—Trial T8:** – Impact of Mag lime on soil pH (A) and on soil exchangeable Ca and Mg (B). a, b: significant difference if different letters.
This may result from an abnormally high yield in one FT subplot (+35% higher than the yield average for the trial). In the past, pig manure was frequently spread but unevenly across the field. The soil was very rich in nutrients when the trial started and the fertilisation recommendations were advised accordingly.

A significant difference between the two treatments appeared in the second ratoon for soil pH ($P=0.035$), exchangeable Ca ($P=0.015$) and Mg ($P=0.005$). These significant differences vanished in the third ratoon, possibly meaning that the rate of liming products applied was not sufficient for a lasting efficacy.

The recommendations were also calculated on the basis of a high yield potential for the region. The yield obtained on this field in the grower treatment (FT) exceeded the maximum yield potential originally assessed. This may imply that the recommendations for the sustainable nutrient management treatment were under-estimated. This result highlighted the need to refine the calculation system for fertiliser recommendations based on soil analysis and potential yield.

**Conclusion**

Implementation and follow-up of this network of trials across Reunion Island was challenging but the data obtained will help to adjust or confirm technical advice on nutrient management currently given to sugarcane growers.

Eight trials out of nine were carried out on growers’ farms. The same trends are observed in similar trials, but statistically significant differences between treatments occurred in only four trials. It is likely that the small number of replicates and the few treatments tested explain this lack of precision.

In order to obtain results with significant differences, additional treatments and/or replicates could be considered for future trials. Plot size could be reduced to five rows * 15 m instead of nine rows * 20 m to keep the total size of each trial manageable.

One main outcome of the work is the positive impact of the liming products tested (mill ash, Mag lime and Physiolith®) compared to the un-limed control, with an increase in gross margin of 1575 €/ha/y, 678 €/ha/y and 591 €/ha/y respectively if cane hauling and transport are not taken into account. Mill ash application systematically increases soil pH (significant difference in one trial).

Compared to one single application, splitting nitrogen in two applications resulted in an increase of gross margin by 290 and 180 €/ha/y in the two test trials. Splitting nitrogen into three applications penalised cane production. When compared to a single application of a granulated NPK fertiliser, splitting nitrogen in two did not improve cane yield.

In two trials out of three, using coated urea instead of prill urea increased the gross margin by 180 €/ha and 465 €/ha. In the third trial, quality of the product delivered was dubious and no conclusion could be drawn.

Cane yield was not maintained when the coated formulation, designed for a slow nitrogen release, was applied at reduced rates (~30%).

In one trial, using the sustainable nutrient management strategy resulted in a benefit of 646 €/ha/y compared to the traditional grower fertilisation plan. In another trial, the grower’s practice performed better because the cane positively responded to the additional nutrients applied.

The sustainable nutrient management treatment, based on soil analysis and potential yield, underestimated the real yield potential and therefore advised an inadequately low amount of fertilisers. This last result highlights the need to refine the calculation system for fertiliser recommendations based on soil analysis and potential yield.

MOTS CLES: Saccharum spp., Canne à Sucre, Essais Agronomiques, Fertilisation.

Résumé

A LA REUNION, la canne à sucre est cultivée dans des conditions climatiques très contrastées, du niveau de la mer jusqu’à 1000 m d’altitude, sur des types de sol très variables. En prenant en compte cette diversité, un réseau d’essais agronomiques a été implanté en 2005 chez des planteurs de canne à sucre de l’île. Quatre pratiques de fertilisation ont été testées: i) la réduction de l’acidité du sol en comparant l’utilisation de cendres de bagasse à des amendements chaulant – chaux magnésienne et Physiolith; ii) fertilisation raisonnée basée sur les données d’analyse de sol; iii) effet d’un engrais azoté retard comparé à de l’urée perlée et iv) l’effet d’un apport fractionné d’azote. Pour chaque essai, la pratique du planteur a servi de témoin. Les résultats de ces essais mettent en évidence: une correction de l’acidité du sol par les cendres de bagasse qui augmentent la production de sucre de 10 à 23% par rapport au témoin; un meilleur rendement sucre hectare quand la fertilisation est raisonnée (un essai sur deux); une perte de rendement sucre si la dose d’urée enrobée est réduite de 30%; un impact positif sur le rendement des repousses d’un fractionnement en 2 apports de l’urée. Un tel réseau d’essais devrait faciliter l’adoption des recommandations de la recherche par les planteurs car il permet un échange direct des informations entre ces derniers et les chercheurs.

PALABRAS CLAVE: Saccharum spp., Caña de Azúcar, Ensayos Agronómicos, Fertilización.

Resumen

EN LA ISLA REUNIÓN, la caña de azúcar se cultiva bajo condiciones climáticas altamente contrastantes, desde el nivel del mar hasta el altiplano (hasta 1000 m de altitud), en tipos de suelo muy diferentes. Tomando en cuenta esta diversidad, en 2005 se implementó una serie de ensayos agronómicos en fincas de productores, a lo largo de toda la isla. Se evaluaron cuatro técnicas principales de fertilización o enmienda: i) reducción de la acidez del suelo utilizando cenizas del ingenio, comparadas con cal – cal magnesiana y Physiolit; ii) manejo sostenible de nutrientes, basado en análisis de suelo; iii) efecto de urea granulada con una cubierta de un polímero de liberación lenta y iv) efecto de aplicaciones fraccionadas de nitrógeno. En cada experimento, se usó como testigo la práctica tradicional de los productores. Los resultados obtenidos incluyen: corrección de la acidez del suelo por el uso de cenizas del ingenio, con un rendimiento de 10 a 23% más que el testigo; un mejor rendimiento de azúcar por hectárea con el manejo sostenible de nutrientes (en uno de los dos ensayos); una pérdida en el rendimiento de azúcar por la reducción en la dosis de urea granular con una cubierta de un polímero de liberación lenta (~30%); un impacto positivo en el rendimiento en soca cuando el nitrógeno se suministró en dos aplicaciones. Esta serie de experimentos debería facilitar la adopción por parte de los productores, de las recomendaciones que surgen de las investigaciones, pues permite un intercambio directo de información entre agrónomos y productores, y están enfocados en las necesidades de estos últimos.
THE ROLE OF BIOCHAR IN MANAGEMENT OF SUGARCANE

Abstract

THE SUGARCANE industry in many parts of the world produces food and energy (stationary and fuel). The industry is well positioned to offer greenhouse gas abatement and climate change mitigation. The thermal conversion, via a slow pyrolysis process, of cane residues such as green harvest trash and bagasse can produce additional thermal or electrical energy as well as biochar. Studies have shown that a commercial slow pyrolysis unit could generate over 2MWh of electricity from every four tonnes of dry trash, as well as 1.3 tonnes of biochar per hour. Biochar has characteristics similar to black carbon, and it has recently been suggested as a sequestration pathway to remove CO2 from the atmosphere, long term, due to its very stable chemical structure. One tonne of bagasse derived biochar would sequester in the order of 2.3 tonnes of CO2 equivalents. In addition to C sequestration, biochar has other significant benefits such as offering improved soil quality, CEC, moisture retention etc. It also has the potential to reduce emissions of greenhouse gases from cane soils, including nitrous oxide and methane. Biochars derived from cane trash and bagasse were applied in incubation studies to soils from the Burdekin region in Australia to test for reductions in emissions of greenhouse gases. We found significant declines in emissions of the greenhouse gas, nitrous oxide (N2O), from urea-fertilised soil when bagasse biochar was applied at a rate of 10 t/ha. The agronomic performance of biochar is being assessed in a 15 plot trial conducted on a sugarcane property in the Tweed Valley, NSW. Biochars from waste were tested and included paper mill biochar and council green waste biochar. Controls included lime treatments. Each plot used 3 rows of cane and was 30 m in length to enable commercial-scale harvesting. Although no significant effects in yield were recorded for year 1, this trial is expected to continue for two more seasons allowing additional data on yield effects to be demonstrated. Our work is demonstrating that implementation of slow pyrolysis and biochar utilisation in the sugarcane industry has potential to provide 1) renewable energy 2) income from waste 3) climate mitigation through stabilisation of carbon 4) climate mitigation through reduced emission of N2O from soil, and 5) improved soil fertility and agronomic performance.

Introduction

Anthropogenic enhancement of soil by the application of charcoal has been implemented for several thousand years. The Terra Preta, dark earth, soils of the Amazon (Glaser et al., 2001)
highlight the possibilities of biochar amendment, as these soils maintain very high fertility long after application, while surrounding soils remain poor.

Black carbon manufactured through pyrolysis of biomass has become known as ‘biochar’ (Lehmann et al., 2006). A wide range of biomass sources have been used to make biochar, including: woody materials, agricultural and food wastes (Demirbas, 2004; Ioannidou and Zabaniotou, 2007), greenwaste (Chan et al., 2007) animal manures (Chan et al., 2008) and wastes from the papermill industry (Van Zwieten et al., 2009a).

The application of biochar to soil can improve soil quality and plant growth (Chan et al., 2007; Chan et al., 2008) and reduce emissions of greenhouse gases (GHGs), in particular nitrous oxide (Yanai et al., 2007; Van Zwieten et al., 2009b). Furthermore, biochar is protected from rapid microbial degradation, enabling the carbon stored in biochar to remain for hundreds of years (Lehmann et al., 2006; Krull et al., 2009).

There are many technologies that are capable of making biochar products. These include slow and fast pyrolysis, carbonisation, charcoal retorts and gasification. Slow pyrolysis typically utilises a kiln that is heated externally to achieve temperatures of around 500°C with a residence time of the biomass at this temperature around 30 min (Brown, 2009).

Slow pyrolysis yields two key products, biochar and syngas, although some systems may also yield pyrolysis oil. The syngas is a combustible mixture of methane, hydrogen and carbon monoxide which can be used to generate the heat required to dry and pyrolyse the biomass, with surplus gas being available to generate renewable energy, such as electricity (Downie et al., 2007).

Recent work by Gaunt and Lehmann (2008) used a life cycle assessment approach to assess systems designed solely for energy production and compared these to pyrolysis which produced both energy and biochar. Their findings show that the avoided emissions of GHGs are between 2 and 5 times greater when biochar is applied to agricultural land (2–19 t CO₂/ha/yr) than when used solely for fossil energy offsets.

Between 41–64% of these emission reductions were credited to the retention of C in biochar, the rest to offsetting fossil fuel use for energy, fertiliser savings, and avoided soil emissions other than CO₂. Despite a reduction in energy output of approximately 30% where the slow pyrolysis technology was optimised to produce biochar for land application, the energy produced per unit energy input at between 2 and 7 MJ/MJ is greater than that of comparable technologies such as ethanol from corn.

Additionally, this study by Gaunt and Lehmann (2008) showed that C emissions per MWh of electricity produced range from 91–360 kg CO₂/MWh. Even before accounting for C offset due to the use of biochar, this figure is considerably lower than the lifecycle emissions associated with fossil fuel use for electricity generation (600–900 kg CO₂/MWh).

**Slow-pyrolysis and the sugar industry**

Globally, the requirements for food and energy are increasing. The sugarcane industry is well positioned, in that it can offer both food and energy production, in the form of fuels (first and second generation), and stationary energy from crop residues such as lignin wastes, bagasse and trash.

It provides these products without increasing the quantity of greenhouse gases in the atmosphere. Climate mitigation can be achieved through both displacing fossil fuels, as well as the conversion of labile organic carbon into very stable organic carbon (biochar) that is used as a soil amendment.

Recent work has demonstrated sugarcane residues can generate energy in the form of electricity through combustion of the syngas (methane, hydrogen and carbon monoxide) in a gas engine. Table 1 summarises results:
Table 1—Conversion of sugarcane waste into biochar and energy.

Notes: Pyrolysed at a highest heating temperature of 550°C with mean residence time at this temperature of 40 minutes and a heating rate of 5°C/min. The electricity output is based on the use of a gas engine at 37% conversion efficiency. It should be noted that larger scale applications may use gas or steam cycle turbines with differing conversion efficiencies.

The ultimate analysis (Australian Standards 1038.6.3.3 method) revealed that the molar H/C ratio of feedstock was 1.50 and 1.45 for the trash and bagasse respectively, and this reduced to 0.45 for trash biochar and 0.43 for bagasse biochar. This indicates the disproportional loss of hydrogen as the carbon forms more stable, conjugated aromatic structures. In a review by Krull et al. (2009), it is suggested temperatures above 400°C form chars with H/C ratios below 0.5, and that these ratios demonstrate aromaticity and maturation. In recent work by Kuzyakov et al. (2009), biochars made at temperatures of 400°C were shown to have a turnover rate of around 2000 years. The sugarcane waste biochars in this study were produced at higher temperature (although lower residence time). Therefore, it can be expected that when applied in soil, they will remain there for many hundreds of years, highlighting their climate mitigation potential.

Trash biochar had high levels of total K, while levels of this mineral were lower in the bagasse biochar. In combustion systems like traditional co-generation facilities, alkali compounds such as potassium foul heat transfer surfaces, participate in slag formation in grate-fired units and contribute to the formation of fluidised bed agglomerates (Turn et al., 1997).
The concentrations of potassium in bagasse feedstock are not significant; however, concentrations in the cane trash would certainly contribute to fouling. These fouling problems are overcome through the use of slow pyrolysis. In addition, potassium, an important sugarcane nutrient, is recycled with an almost 100% efficiency back into the biochar for soil application.

Both biochars have small amounts of plant available P (Bray P), but negligible plant available N. The trash biochar has a CEC of 40 cmol(+)/kg, much higher than the bagasse biochar from these analyses or other CECs reported in the literature (Van Zwieten et al., 2009; Chan et al., 2007, 2008). This highlights their potential to be applied in conjunction with fertilisers to enhance fertiliser use efficiency.

The trash biochar had an acid neutralising capacity of 4.6% compared to agricultural lime. Previous research on biochar from papermill residues has demonstrated that much of this acid neutralising capacity from biochar comes from Ca complexes on the surface, such as hydroxides, oxides and carbonates (Van Zwieten et al., 2009).

Many of the biochar trials undertaken have used values of 10 t/ha application rate. This equates roughly to 1% w/w assuming incorporation into the 0–10 cm soil profile. Applications of this rate would be equivalent to increasing soil carbon from a hypothetical value of 2.0% to close to 2.5% carbon, assuming a bulk density of 1.5 g/cm³.

The application would be equivalent to a 200 kg application of K, which would satisfy the K requirement of the crop, as well as a minor addition of P. The pH of soil would be expected to increase, equivalent to an addition of 460 kg agricultural lime. The effects on soil fertility including CEC, however, can not be fully predicted and field assessments are necessary.

It has been estimated that over 2.5 Mt of unutilised biomass exists in the Australian sugarcane industry every year (Bernard Milford, pers. comm.). This waste biomass could generate around 156 MW/h of electricity if processed via slow pyrolysis, and close to 855 000 t biochar production annually.

Putting numbers into perspective, this would equate to ca. 350 000 t avoided CO₂ emissions through offsetting fossil fuels, and around 2 Mt CO₂ equivalents locked up in soil. An average motor vehicle travelling about 20 000 km per year emits an equivalent of 5.2 t CO₂ (US EPA, 2000). This would equate to offsetting emissions from around 500 000 motor vehicles.

**Reduction of non-CO₂ GHG emissions from soil**

Climate change caused by increase in atmospheric concentrations of greenhouse gases (GHGs) is predicted to cause catastrophic impacts (IPCC, 2006). Human-influenced sources of nitrous oxide (N₂O) contributed 3 GT CO₂e (carbon dioxide equivalents), around 8% of global emissions, in 2004.

It was estimated that agriculture was responsible for 42% of this total (Denman et al., 2007). Sources for N₂O emissions from soils include application of N fertilisers, biological N fixation and excreta of grazing animals. A range of factors influence the emission of N₂O including N application rate, crop type, fertiliser type, soil organic C content, soil pH and texture (Dalal et al., 2003).

Soil is both a significant source and sink for the greenhouse gases nitrous oxide (N₂O) and methane (CH₄). Emissions from sugarcane soils in Australia have shown very significant production of nitrous oxide (21% of applied N converted to N₂O) (Denmead et al., 2008). A total of 45.9 kg N/ha was emitted from a northern NSW sugarcane farm in the season following application of 160 kg N fertiliser.

As the global warming potential of N₂O is 298 times greater than the equivalent mass of CO₂ in the atmosphere (Forster et al., 2007), this equated to emissions of 43 t CO₂e/ha. Hence, small reductions in emissions could potentially provide significant benefits for climate mitigation.
Recent work by Van Zwieten et al. (2009b) has demonstrated the potential for biochar to reduce emissions of N$_2$O from soil. Current work using soils from the Burdekin region in Queensland, Australia, and bagasse and trash biochars are demonstrating very significant potential for reducing emissions of this potent GHG from soil.

Experimental microcosms containing soils from the Burdekin cane region in Queensland, Australia were used to demonstrate the GHG reduction potential of biochar. Soils were amended with biochars derived from trash and bagasse, to a rate of 10 t/ha equivalent, and compared to control (unamended) soil. Nitrogen was applied at either 0 or 165 kg/ha to all treatments. The atmosphere in the microcosms was analysed at days 1, 2, 4, 7 and 14. The microcosms were flooded at day 21, and the atmosphere was sampled again at days 21, 22, 23, 24, 28, 35, 42 and 49. Results for nitrous oxide emissions from the bagasse and trash biochars are depicted in Figures 1 and 2 respectively.

![Figure 1](image1.png)

**Fig. 1**—The production of nitrous oxide from control and bagasse biochar amended soils incubated with and without nitrogen amendment.

![Figure 2](image2.png)

**Fig. 2**—The production of nitrous oxide from control and trash biochar amended soils incubated with and without nitrogen amendment.

The control soil with 165 kg N/ha lost 0.7% of total nitrogen as N$_2$O in the 28 days following flooding. All of the N loss as N$_2$O was following flooding. Bagasse biochar significantly reduced N$_2$O emissions (0.55% of total N). A 21% reduction in N$_2$O emission compared to both fertilised control and 38% compared to the trash biochar (0.88% N loss) amended soils. The
bagasse biochar amended, fertilised soil had higher nitrate: ammonium N ratio than either the fertilised control or trash biochar amended soils. This indicates an improvement in N mineralisation through nitrification. Further losses could have been reduced by suppression of denitrification enzymes (Van Zwieten et al., 2009).

**Field assessment of biochar in sugarcane**

A field trial testing biochar was set up on the Tweed Valley, northern NSW. Plots were 30 m long and contained three rows of cane. The outside rows of the cane were used as buffers, and the inside row was used for soil analyses, GHG emissions testing and yield data. At the ends of each row, an additional 2 m buffer was used between plots. Treatments were allocated to experimental units in a randomised complete block design using the three rows of five plots as the blocking factor. Treatments included; control (standard farming practice), papermill biochar at 5 t/ha, council greenwaste biochar at 5 t/ha, council greenwaste biochar at 10 t/ha and lime (1.5 t/ha). Note the chemical properties of these biochars are different to the properties of the sugarcane derived biochars shown in the previous section.

Yield from the first season (2008) following planting is shown in Table 3. Yield measurements were assessed using standard commercial harvesting equipment, and weights of bins were recorded at the completion of each 30 m harvest length. Although no significant differences were seen with yield or leaf nutrient analysis in the first harvest, these trials are expected to continue until 2011, with annual harvesting. It is well recognised that the benefits of biochar application on crop yield may not be expected immediately, but develop over time as soil CEC increases upon biochar oxidation (Chan and Xu, 2009).

**Conclusions**

- The research trials to-date have shown that the slow pyrolysis of sugarcane bagasse and cane trash can provide the energy to generate 1 MWh for each two tonnes of dry material. Cane trash, a material potentially problematic during co-generation was shown to be an ideal feed-stock for slow pyrolysis.
- The research shows that the majority of the nutrients in the cane feedstocks are retained in the biochar; thus can be returned to the field along with the carbon.
- Biochar from trash and bagasse had low molar H/C ratios indicating their aromaticity and hence long-term stability in soils.
- A significant reduction in the emissions of nitrous oxide from soil was shown following the application of varying biochar products.
- This manuscript has demonstrated numerous benefits for the Australian and international sugarcane industry. Field scale assessment of this technology is warranted as significant economic, environmental and climate outcomes may be achieved.

Résumé

Dans de nombreuses parties du monde, l’industrie sucrière à base de canne à sucre produit à la fois des denrées et de l’énergie. Cette industrie procure une diminution des gaz à effet de serre et une atténuation du changement climatique. Par un procédé de pyrolyse lente, la conversion thermique des résidus de canne tels que le paillis de récolte en vert et la bagasse peut produire à la fois une énergie supplémentaire thermique ou électrique et du biocharbon. Des études ont montré qu’une unité de pyrolyse lente pouvait générer plus de 3MWh d’électricité à partir de 4 tonnes de résidus secs ou 1.3 tonnes de biocharbon par heure. Le biocharbon a des caractéristiques similaires au carbone noir, et a été récemment proposé comme voie de séquestration pour éliminer à long terme le CO2 de l’atmosphère, à cause de sa structure chimique stable. Le biocharbon provenant d’une tonne de bagasse pourrait séquestrer environ 2.3 tonnes d’équivalents CO2. En plus de la séquestration de C, le biocharbon a d’autres avantages incontestables tels que l’amélioration de la qualité du sol, de la CEC, de la rétention en eau etc. Il a aussi la capacité de réduire les émissions de gaz à effet de serre provenant du sol, tels que l’oxyde nitreux et le méthane. Des biocharbons provenant des résidus de canne et de bagasse ont été incubés dans des sols du Burdekin en Australie afin de tester les réductions de gaz à effet de serre. Des applications de 10 t/ha de biocharbon de bagasse ont diminué significativement les émissions de gaz à effet de serre comme l’oxyde nitreux (N\(_2\)O) provenant de sols fertilisés avec de l’urée. La performance agronomique du biocharbon a été évaluée dans un essai de 15 parcelles conduit dans une exploitation de la Tweed Valley, NSW. Des biocharbons de détritus, de papeterie et de déchets verts ont été testés. Les témoins incluaient des traitements chaulés. Chaque parcelle était constituée de 3 rangs de canne de 30 m pour permettre la récolte à l’échelle commerciale. Bien qu’aucun effet significatif sur le rendement ne fût observé l’année 1, cet essai doit continuer sur deux cycles supplémentaires pour estimer les effets sur le rendement. Le biocharbon a été inclus dans l’agenda de la conférence de 2012 sur le climat à Copenhague, comme un moyen de séquestrer à long terme le carbone et comme remède sur les terres dégradées pour la production alimentaire et la reforestation. Notre travail est de démontrer que l’utilisation de biocharbon dans l’industrie sucrière peut potentiellement fournir 1) de l’énergie renouvelable, 2) un revenu à partir des déchets, 3) une atténuation du changement climatique au travers de la stabilisation du carbone, 4) une atténuation du changement climatique au travers de la réduction des émissions de CO\(_2\) du sol et 5) une amélioration de la fertilité du sol et des performances agronomiques.

PALABRAS CLAVE: Biocarbón, Pirólisis, Energía,
Fertilidad del Suelo, Gas de Efecto Invernadero (GEI).

Resumen

En muchas partes del mundo la industria de la caña de azúcar produce alimentos y energía (estacionaria y combustible). La industria está bien posicionada para ofrecer reducción de los gases de efecto invernadero y mitigación del cambio climático. La conversión térmica de residuos de caña tales como residuos del corte en verde y bagazo, a través de un proceso de pirólisis lenta, puede producir energía térmica o eléctrica adicional, así como biocarbón. Los estudios han demostrado que una unidad comercial de pirólisis lenta podría generar más de 2MWh de electricidad de cada cuatro toneladas de basura seca, así como 1.3 toneladas de biocarbón por hora. El biochar tiene características similares a las del carbón vegetal, y recientemente ha sido sugerido como una forma viable para fijar CO₂ de la atmósfera a largo plazo - debido a su estructura química muy estable. Una tonelada de biocarbón derivado de bagazo fijaría carbono en el orden de 2.3 toneladas equivalentes de CO₂. Además de la fijación de carbono, el biocarbón ofrece otros beneficios importantes tales como mejoras de la calidad del suelo, de la CIC, retención de la humedad etc. También tiene el potencial para reducir las emisiones de gases de efecto invernadero, incluidos el óxido nitroso y el metano, desde los suelos de caña. Se realizaron estudios de incubación de suelos de la región de Burkedin en Australia a los cuales se les aplicó biocarbón derivado de residuos de caña y bagazo para demostrar la reducción en la emisión de gases de efecto invernadero. Encontramos reducción significativa de la emisión del gas de efecto invernadero, óxido nitroso (N₂O), desde un suelo fertilizado con urea al cual se le aplicó biocarbón de bagazo a una dosis de 10 t/ha. El comportamiento agronómico del biocarbón está siendo evaluado en un ensayo de 15 parcelas realizado en una propiedad con caña de azúcar en Tweed Valley, NSW. Se incluyeron biocarboines de fábrica de papel y de residuos verdes de caña. Los controles incluyeron tratamiento de encalado. Cada parcela fue compuesta por 3 surcos de caña de 30 m de longitud para permitir la cosecha a escala comercial. Aunque no se registraron efectos significativos en el rendimiento durante el año 1, se espera que este ensayo continúe durante dos temporadas más permitiendo obtener datos adicionales que permitan demostrar los efectos sobre el rendimiento. El biocarbón se ha incluido en la agenda del protocolo de Copenhague 2012 como una forma de fijación de carbono a largo plazo, y para rehabilitación de tierras degradadas que se destinarían a la producción de alimentos y la reforestación. Nuestro trabajo está demostrando que la implementación de la pirólisis lenta y la utilización del biocarbón en la industria de la caña de azúcar tiene potencial para proveer 1) energía renovable 2) ganancia a partir de residuos 3) mitigación del cambio climático a través de la estabilización del carbono 4) mitigación del cambio climático a través de la reducción de emisiones de N₂O desde el suelo, y 5) mejoramiento de la fertilidad del suelo y del rendimiento agronómico.
SUGARCANE ROOT SYSTEM DEPTH
IN THREE DIFFERENT COUNTRIES

By

KEYWORDS: Brazil, Côte d'Ivoire, Réunion, Root System, Sugarcane Root Front.

Abstract

THE SUGARCANE root system depth is crucial as it determines the potential depth of soil available for water and nutrient uptake by the crop. It was reported in an early publication that these roots could grow quite deep (6 m), but otherwise very little data are available on the root system depth. The present study was carried out in three countries: Côte d'Ivoire (var. NCo376), Brazil (var. RB72454) and Réunion, France (var. R570) at various sugarcane growth stages. There were no shoot or root growth constraints (deep soil with enough water). For plant cane, the root front growth (RF in cm) was linear. In Côte d'Ivoire, from 45 to 160 days after planting (DAP), RF = 0.81 DAP; R² = 0.91. On the island of Réunion, from 100 to 280 DAP, sugarcane root front growth was: RF = 0.56 DAP; R² = 0.70. When DAP was replaced by thermal time (TT: sum of degree-days), the root front growth patterns were quite similar in Réunion and Côte d'Ivoire (RF = 0.045 and 0.049 TT, respectively). In ratoon conditions, RF was stable when roots from the previous cycle were still in the soil at the onset of the cropping season. Thus, the observed root depth was approximately 4 m in Brazil and Réunion, even though the environment and cultivars were different. These findings showed that, when there is no marked crop growth constraint, roots of modern commercial sugarcane varieties can grow to depths of about 4 m in ratoon crops. While these values were lower than those reported in previous studies, they were higher than those generally accepted at present.

Introduction

The depth of the sugarcane root system determines the volume of soil available for water and mineral uptake. A review of recent results indicates that this depth is still not clearly established (Smith et al., 2005). Evans (1936) found that roots of old sugarcane varieties could grow to a depth of 6 m under very favourable conditions. These estimates have been partially challenged for modern varieties (Blackburn, 1984). Since the 1930s, no publication has reported sugarcane roots growing below a depth of 2 m. However, the rooting depth is a particularly useful factor for crop modelling and for fertilisation and irrigation decision-making. For example, modelling studies carried out by scientists in Réunion were based on a root system depth of about 1.5 m, as roughly estimated in some unpublished studies. The root system depth in live sugarcane plants is particularly hard to assess. Sugarcane plants grow again after the first plant sugarcane cropping season and the first shoot harvest, and the extent of time that the previous root system remains alive is not well-known. Moreover, to our knowledge, very few studies have been published on relationships between the environment (especially deep soil characteristics) and the root front depth.
The authors have pooled root depth findings from three different environments in Brazil, Côte d’Ivoire and Réunion. The aim of this study was to combine these results in order to estimate the root system depth in these three ecosystems so as to come up with more precise root front depth values to be used in decision support tools and crop models. Sugarcane root front data are also essential for determining nutrient and water balances and subsequently identifying the soil limit zone where nutrients switch from being fertilisers to becoming potential groundwater pollutants.

Material and methods

Experimental design, environments and treatments

Studies were carried out at three sites located very far apart: Côte d’Ivoire (Africa), Brazil and Réunion (Indian Ocean), within the framework of agronomic research programs under way to investigate several parameters including the sugarcane root front. There were thus some methodological variations between experiments. The experimental site in Côte d’Ivoire was located at Bouaké (7°40N, 5°5W, 350 m elevation) in a deep (> 2 m) sandy clay oxisol with a high gravel content ranging from 25% in the surface horizon to 50% at depths below 1 m. The soil bulk densities differed very little at the Réunion and Brazil sites, at least in unaltered soils (Table 1). The markedly higher bulk densities in Côte d’Ivoire were due to the presence of coarse elements with bulk density of about 2.7 Mg/m$^3$, but the fine soil structure was favourable for root growth. In Brazil, the experiments were conducted at Londrina University (23°2S, 51°1W, 560 m elevation) in a very deep clayey red eutroferric latosol without gravel. In Réunion, the experimental site was located at Saint Pierre in the southern part of the island (21°S, 55°E, 250 m elevation) in a deep (over 5 m) clayey cambisol, free of coarse elements as in Brazil, but with a lower soil structure quality. The Côte d’Ivoire study was carried out in 1994, but the findings were never published. The Brazilian study was conducted in 2005 and 2006, while in Réunion it was carried out in 2007, 2008 and 2009.

Table 1—Bulk density at the three sites. At the Réunion site: unaltered soil (control) and soil removed from the surface to 2 m depth and put back 4 years earlier.

The three sites have a tropical (Côte d’Ivoire, Réunion) or subtropical (Brazil) climate. Rainfall (with supplementary irrigation in Réunion and Côte d’Ivoire) was sufficient for normal crop growth, particularly for the development of deep roots. During the study periods, mean air temperatures were: 28.4°C, 21.9°C and 23.2°C in Côte d’Ivoire, Brazil and Réunion, respectively, with mean temperatures always above 16°C/d. The sugarcane varieties (NCo376 in Côte d’Ivoire, RB72454 in Brazil and R570 in Réunion) were representative of varieties grown by farmers. The cropping systems were conventional and tailored to local conditions. Spacing between rows was 1.5 m (Côte d’Ivoire and Réunion) or 1.4 m (Brazil). Plant sugarcane only was studied in Côte d’Ivoire, whereas only a ratoon crop was studied in Brazil. In Réunion, the study concerned both plant sugarcane (in 2006 and 2009) and ratoon crops (2007 and 2008). In 2009, plant sugarcane root systems were studied in an area of the site where the soil had been altered (removed and put back)
up to 2 m in depth for soil studies 4 years earlier. The soil put back in each soil horizon was similar to the surrounding soil, except that it remained looser (Table 1). There were thus three treatments in Réunion: plant sugarcane in unaltered and altered soil and a ratoon crop.

**Root depth study: dates, methods, replications**

In Côte d’Ivoire, the study was carried out at three different dates: 45, 113 and 160 days after planting (DAP) using the monolith method (Lee, 1927). Each monolith had the following dimensions: length 0.25 m, width 0.2 m, thickness 0.2 m, with five replications. In Brazil, the ratoon crop root fronts were estimated with the trench profile technique (Chopart et al., 2008a, 2009) adapted from Böhm (1976). The trench profiles were 2 m wide and as deep as the root front. The maximum root depths were measured directly in the field. The study was carried out at 240 and 300 days after ratoon (DAR) with six replications at each measurement date. In Réunion, the plant sugarcane study was performed with the rhizotron (Van de Gien et al., 1994) and the trench profile techniques. Vertical rhizotrons were 1.5 m wide and 1.4 m deep. Measurements were thus limited to the period when the root depth was less than 1.4 m. For plant and ratoon sugarcane, the trench profiles were 1.5 m wide, with depths varying according to the root front. The intersections between the trench profile and the roots were counted and mapped. This made it possible to assess the root length density (RLD) distributions in the profile (Chopart et al., 2008b, 2009). In addition, about 10 cm of soil was removed in the profile at the root front level to monitor the presence or absence of roots in these samples in the field. The soil profiles were about 4.5 m deep. In plant sugarcane, root fronts were studied in two rhizotrons at nine dates and with the trench profile technique at eight dates with one to three replications. The ratoon sugarcane study was carried out on a single date between 235 and 245 DAR, with six replications. Correlations were determined between the crop age and the root front depth. For a better comparison of the results at the various sites, the time from planting or ratoon date was also expressed as a sum of each day’s mean temperature (sum of degree-days[SDD]) above the sugarcane baseline temperature (estimated to be 12°C).

After planting, roots grow from cuttings (sett roots) buried 10 to 20 cm deep. After a few days, shoot roots grow from the first nodes on the new stalks, close to the surface (van Dillewijn (1952). Analysis of these complex rooting dynamics that take place during the first days of the plant cropping season was beyond the scope of the present study. Measurements were first recorded 45 DAP in Côte d’Ivoire or even later in Réunion (70 DAP), once the root system grown from the year’s shoots predominated over the initial system grown from cuttings. To simplify the analysis and future use of the results, regressions between the crop age (or thermal time) and the root front depth were thus assigned a 0 cm y-coordinate on the planting day (DAP = 0). The established relationships were valid only within the range of the measured results, from around 50 DAP.

**Results**

**Plant sugarcane (Côte d’Ivoire and Réunion)**

In Côte d’Ivoire, the root front depth progressed linearly from 45 DAP to 160 DAP, i.e. a growth rate of about 0.8 cm/day (Figure 1A). In Réunion, with the rhizotron technique, plant sugarcane root front growth was also linear between 70 and 170 DAP (Figure 1B), at a rate of approximately 0.7 cm/day. After 170 DAP, the rhizotron, whose depth was limited to 140 cm, could no longer be used. Outside of the rhizotrons, the root front growth rate measured with the trench profile method was approximately 0.56 cm/day, i.e. slightly lower than that noted in the rhizotron (Figure 1C). The difference seemed to be due to the fact that roots were in a relatively less constrained environment against the rhizotron glass panel and could thus grow at a slightly more vertical angle. The results obtained in the rhizotron and through the trench profile technique were complementary. With the rhizotrons, the measurements were obtained more frequently but in somewhat artificial conditions. Data obtained by the trench profile technique were representative of the root front in natural conditions but, as the measurements were more time consuming and costly, they were less numerous. The rhizotron findings confirmed that the root front growth was linear.
The trench profile technique made it possible to assess the growth rate in unaltered soil which was representative of the local soil, i.e. between 0.55 and 0.6 cm/day.

In Réunion, after 170 DAP, root front growth (measured by the trench profile technique only) continued at a constant rate until the end of the study (265 DAP). In the same year, at the same site, but in a soil that was decompacted 4 years earlier and whose bulk density and mechanical resistance to penetration remained lower, the root front was deeper: 200 cm 220 DAP, i.e. 0.9 cm/day (Figure 1C). In unaltered soil, the root front reached 170 cm in only one profile (at 187 DAP). In Réunion, in natural conditions, the mean root front growth rate was 0.55 to 0.6 cm/day.

The growth rate reached as high as 0.9 cm/day when the soil physical conditions were particularly favourable, or when the soil was tilled very deeply some years before measurement. Root front between 280 DAP and harvest (360 DAP) is still being studied. Decreased growth has been observed at the end of the cycle in other tropical crops such as pearl millet and sorghum (Chopart, 1985).

It is therefore quite probable that sugarcane root front growth will not increase during its final stage. We can tentatively assume that in Réunion the plant sugarcane root front depth would be approximately 2 m at harvest. When thermal time was used instead of DAP, the root front growth rates observed in Côte d’Ivoire and Réunion, where the weather is slightly less hot, were closer than rates expressed in number of DAP (Figure 1).

TT: Thermal time (degree-days above 12°C)

This showed the influence of temperature on root front growth in relation to shoot growth, which was also higher. There was still a slight difference, which could be explained by several factors (varieties, soil characteristics, study methods); however, none of these parameters had a major impact.

Ratoon sugarcane (Réunion and Brazil)

In Brazil, in 3rd year and 4th year ratoon sugarcane, the maximum root system depth levelled off between 240 and 300 DAR (Table 2). The soil tillage method used when the sugarcane crop was planted 4 years earlier (between 0 and 30 cm deep) had no effect on the root front depth (data not shown), which was approximately 4 m, with 6 replications on average. In Réunion, at the same cycle stage the mean depth in the 6 replications was 3.70 m (Table 2).
Table 2—Maximum ratoon sugarcane root depth in Brazil and Réunion (mean, standard deviation, highest and lowest root front of 6 replications at both Brazil and Réunion) observed on measurement dates with some related characteristics.

2-D mapping of the root distribution was carried out with the method used in Réunion (trench profile technique, root intersection mapping and root length density from root intersection; Chopart et al., 2008a, b, 2009). In the deepest profile (Figure 2A), the root distribution was very irregular at deep horizons where roots took advantage of soil areas with lower resistance in order to progress vertically. This was not as clear in the less deep profile (Figure 2B). Roots that grew vertically had large diameters, but they had the same appearance and internal structure as roots of the same diameter that were less vertical, or horizontal.

![Fig. 2—Ratoon sugarcane in Réunion: 2-D root length density (cm/cm³) distribution in a 1.5 m large profile. A: deepest profile among the four studied profiles, and B: least deep profile.](image)

Very similar results were obtained in Réunion and Londrina (Brazil), although they were obtained with two different varieties and at sites that were far apart, despite the slightly lower
temperatures in Brazil. However, the sites shared some similar characteristics, including deep soil with low density and resistance to penetration, and variable soil moisture but which was always sufficient to ensure root growth. The 4-m root depth was inferior to the 6-m depth obtained by Evans (1936), but deeper than is generally accepted for sugarcane root systems.

Discussion and conclusion

No definitive conclusion could be drawn on the basis of the results obtained in three countries concerning plant sugarcane and ratoon sugarcane root system depths. However, they provided greater insight into sugarcane root system depths in the studied environments. In particular, in deep moderately compact soils, the root front growth rate was constant after the shooting and root system development stage, i.e. approximately 0.55 cm/day with a maximum of 0.9 cm/day under very favourable conditions (soil tilled to a depth of 2 m four years earlier). These results obtained in very well structured soil up to 2 m deep could explain the particularly spectacular findings of Evans, i.e. 6 m deep roots in ratoon sugarcane.

The marked variation noted in Réunion between the root system depth in the second part of the plant sugarcane cycle (under 2 m) and that observed roughly at the same cycle stage in a 5th year ratoon sugarcane (4 m) suggests that the root front grows deeper from year to year between plant sugarcane and ratoon crops in Réunion. If this is the case, the roots (at least the deepest ones) could remain alive long after the sugarcane crop has been harvested and deeper parts of the root system could sprout new roots during the following growing season. This still has to be confirmed, in particular by studying the root system depth throughout several sugarcane growing seasons in the field with various soil penetration resistance levels. This would be laborious work but the findings could be highly interesting for modelling sugarcane water uptake and growth under water stress conditions in plant or ratoon sugarcane with various numbers of ratoon cycles.

Résumé

La profondeur du système racinaire de la canne à sucre est un paramètre important car elle détermine la profondeur potentielle du sol utile pour l’alimentation hydrique et minérale de la culture. Il a été reporté, dans une publication ancienne, que le système racinaire de la canne à sucre peut atteindre une profondeur de 6 m, mais peu de données récentes sont disponibles sur la profondeur du système racinaire de cette culture. L’étude a été menée dans trois pays: Côte d’Ivoire (var. NCo376), Brésil (var. RB72454) et Réunion, France (var. R570), à différents stades de végétation de la canne à sucre. Il n’y a pas eu de contraintes majeures à la croissance racinaire (sols profonds, avec une humidité suffisante). Pour une canne vierge, la croissance du front racinaire (RF, en cm) a été linéaire, de 45 à 160 jours après plantation (DAP) : RF = 0.81 DAP; R² = 0.91. A la Réunion, le front racinaire de la canne à sucre a été : RF = 0.56 DAP; R² = 0.70, de 100 à 280 DAP. Si l’on remplace DAP par le temps thermique (TT : somme des degrés-jours), les niveaux de croissances des fronts racinaires deviennent alors proches à la Réunion et en Côte d’Ivoire (RF= 0.045 et 0.049 TT, respectivement). En repousse, RF a été stable, les racines du cycle précédent restant encore dans le sol en début de cycle. La profondeur racinaire observée a été de 4 m au Brésil et à la Réunion, dans des environnements pourtant très différents. Ces résultats montrent que, en absence de contraintes marquées à la croissance racinaire, les racines des variétés modernes peuvent atteindre 4 m en repousse. Bien que ces valeurs soient plus faibles que celles avancées dans des travaux anciens, elles sont supérieures à celles généralement admises actuellement.

PROFUNDIDAD DEL SISTEMA RADICULAR DE LA CAÑA DE AZUCAR EN TRES DIFERENTES PAISES

Por

J.L. CHOPART1, M.C.B. AZEVEDO2, L. LE MÉZO1 y D. MARION1
1Centre de coopération internationale en recherche agronomique pour le développement (CIRAD), France
2Instituto Agronómico do Paraná (IAPAR), Brazil

PALABRAS CLAVE: Brasil, Costa de Marfil, Reunión, Sistema de raíz, Frente de raíz de la Caña de Azucar.

Resumen

La profundidad del sistema radicular de la caña de azúcar es crucial pues determina la profundidad del suelo disponible para la absorción potencial de agua y nutrimentos por parte del cultivo. En una publicación anterior a esta se reportó que las raíces podrían crecer muy profundas (6 m), pero por otra parte, hay disponible muy poca información sobre la profundidad del sistema radicular. El presente estudio fue realizado en tres países: Costa de Marfil (variedad NCo376), Brasil (variedad RB72454) y Réunion, Francia (variedad R570) en diferentes etapas de crecimiento de la caña de azúcar. No hubo impedimentos para el crecimiento de la parte aérea o de la raíz (suelo profundo con suficiente humedad). En la plantilla, el frente de crecimiento de la raíz (RF en cm) fue
lineal. En Costa de Marfil de 45 a 160 días después de la siembra (DAP), RF = 0.81 DAP; R² = 0.91. En la isla de Réunion, de 100 a 280 DAP, el frente de crecimiento las raíces de la caña de azúcar fue: RF = 0.56 DAP; R² = 0.70. Cuando DAP fue substituido por tiempo térmico (TT: suma de grados-día), los patrones del frente de crecimiento del sistema radicular fueron similares en Réunion y Costa de Marfil (RF = 0.045 y 0.049 TT, respectivamente). En condiciones de soca, al inicio del nuevo ciclo del cultivo y cuando las raíces del ciclo anterior todavía estaban en el suelo, el RF fue estable. De esta forma, la profundidad observada de la raíz fue de aproximadamente 4 m en el Brasil y Réunion, aunque el ambiente y los cultivares fueron diferentes. Estos resultados demostraron que, cuando no hay impedimento para el crecimiento del cultivo, las raíces de las variedades comerciales modernas de caña de azúcar pueden alcanzar profundidades de casi 4 m en socas. A pesar de que estos valores fueron menores que los reportados en estudios anteriores, fueron mayores que los actualmente aceptados.
FUNCTIONAL RELATIONSHIP BETWEEN SUGARCANE ROOT BIOMASS AND LENGTH FOR CROPPING SYSTEM APPLICATIONS

KEYWORDS: Specific Root Length, Root Length Density, Root Model, Réunion, Côte d’Ivoire.

Abstract

Sugarcane root length density (RLD, m/m³) and root biomass are key characteristics for respectively determining: (i) the crop nutrient and water uptake capacity, and (ii) carbon partitioning in plants and balance in soil. In previous studies, often only one of these parameters was measured. It is therefore useful to link the RLD and root biomass density (RBD, g/m³) to evaluate one parameter in relation to the other. Relationships between RLD and RBD and specific root length (SRL, m/g) were studied in Côte d’Ivoire and Réunion. Mean SRLs of fine roots were independent of the root location in the soil profile and plant age but higher in Côte d’Ivoire (68 m/g, SD = 19) than in Réunion (35 m/g, SD = 10). The best fit between the RBD and RLD of thick roots was a power function (RLD = 21.3 RBD⁻¹.⁷⁴⁵; R² = 0.⁸⁵). Mean SRL was 7 m/g. When all roots were studied together, the best fit between RBD and RLD was also a power function, with little variation between the two sites or between plant and ratoon sugarcane. The fits calculated with all data except those obtained very close to the plant stem were: RLD = 85.⁵ RBD⁻¹.⁷⁴² (R² = 0.⁸⁸) and mean SRL = 27 m/g (SD =13). Relationships between root length and biomass were neither fixed nor fully random. Due to SRL variability, it was hard to pinpoint any mechanistic links between root length and biomass. Conversely, for simple field evaluations, a rough and ready RLD estimate can be made on the basis of RBD, and vice-versa.

Introduction

Sugarcane root length density (RLD) and root biomass are key characteristics for respectively determining: (i) the crop nutrient and water uptake capacity, and (ii) carbon partitioning in plants and balance in soil. In previous studies, often only one of these parameters was measured, depending on the study objectives and methods used.

Root biomass cannot be evaluated directly with minirhizotron methods (Box, 1996) or different trench profile techniques (Böhm, 1976; Vepraskas, 1988; Chopart, 1999; Chopart et al., 2008) that are focused on RLD evaluation. On the other hand, conventional methods involving soil cores and monoliths (Lee, 1927), in which roots are removed from soil, can be used to measure dry weight easily, whereas RLD measurement is a substantially longer operation that is seldom performed for want of time.

Several sugarcane crop models such as CANEGRO (Inman-Bamber, 1991) or APSIM (McCown et al., 1996) used to model root biomass production require a link between the root biomass density (RBD) and RLD. However, little is currently known about the relationship between root weight and length or evaluation of the specific root length (SRL, in m/g). Initial studies on sugarcane indicated that SRL ranged from 6 to 23 m/g, with a mean of around 18 m/g in Brazil.
(Ball-Coello et al., 1992). Other authors (van Antwerpen et al., 1993) obtained substantially lower values in South Africa: around 3 to 5 m/g for plant sugarcane aged 50–180 days after planting (DAP).

This study was carried out to gain further insight into the relationship between root weight and length in plant and ratoon sugarcane, for both fine and thick roots, while focusing only on identifying simple and functional relationships without any deterministic motives. To our knowledge, this is the first root type-based study that has been carried out on sugarcane crops grown in commercial plantation conditions.

Material and methods
Experimental design, environments and treatments
The studies were carried out at two sites: Côte d’Ivoire (Africa) and Réunion (Indian Ocean). The experimental site in Côte d’Ivoire was located at Bouaké (7°40′N, 5°5′W, 350 m elevation) in a deep (> 2 m) sandy clay oxisol with high coarse element (> 2 mm) contents ranging from 25% in surface horizons to 50% below 1 m. In Réunion, the experimental site was located at Saint-Pierre in the southern part of the island (21°S, 55°E, 250 m elevation) in a deep (over 5 m) clayey cambisol without any coarse elements.

The climate was tropical at both sites. Rainfall (with supplementary irrigation) was sufficient for normal plant growth, especially deep root growth. Varieties under study, namely NCo376 in Côte d’Ivoire and R570 in Réunion, were representative of sugarcane varieties grown by farmers. Conventional cropping systems (tillage, fertilisation, 1.5 m inter-row spacing) were used.

In Côte d’Ivoire, the study was focused on plant sugarcane at two dates (45 and 113 DAP), with measurement depths up to the root front (0.4 m and 1.1 m at 45 and 113 DAP, respectively). In Réunion, the study was undertaken on both plant sugarcane (four replicates, maximum measurement depth 0.8 m) and ratoon crops (eight replicates, maximum measurement depth 1.2 m).

In Réunion, roots were sampled in the soil using the soil core technique with 251 cm³ metal cylinders. In Côte d’Ivoire, the monolith method used was very similar to the soil core method, but with larger sample volumes (0.2 × 0.2 × 0.25 m) and no replication. At both sites, samples were obtained at three horizontal distances along the sugarcane row: 0–0.25 m, 0.25–0.50 m and 0.5–0.75 m and at several depths, in 0.2 m steps in Côte d’Ivoire and 0.1 m steps in Réunion. Roots were separated from the soil by sieving (1 mm mesh).

Non-root organic fragments were carefully removed. Roots were separated into two subsamples: fine and thick. We decided to set the diameter boundary at 1 mm because our non-quantitative observations suggest that shoot-born roots have a diameter > 1 mm and most other lateral roots have a diameter < 1 mm. Separation (handmade and with a blade) between the two types of roots was made by visual evaluation. A few fine roots could not be entirely separated from thick roots, but the effect on the specific root length of thick roots samples remained very low. Roots were dried (60°C; 24 h) and weighed separately. Their respective lengths were evaluated using the intersection method (Newman, 1966) modified by Tennant (1975).

Analysis
Relationships between RBD and RLD were investigated by regression analysis of samples distributed throughout the soil profile at various vertical and horizontal distances. All sample SRLs were analysed (mean and standard deviation). We tried to establish links between root sample SRL variability and parameters that are easy to recognise in the field, especially their location in the profile: depth or distance from the stem base (DP).

DP is the diagonal between the depth and horizontal distance. The initial analysis revealed that roots located immediately under the stem or row had a very high RBD, often—but not always—with a high proportion of thick roots. Roots located immediately under the sugarcane row between 0 and 0.2 m depth and 0.25 m on each side of the row were thus analysed separately. It was
specified when the results concerned roots close to the stem base, otherwise the roots were located elsewhere. Some samples contained no thick or fine roots, which accounts for the differences noted between the number of pooled root samples and samples with thick and fine roots separated.

Results

Fine root sample analyses (< 1 mm diameter)

In Réunion, linear regressions were obtained between the fine root weight and length for plant and ratoon sugarcane at 113 DAP (Figure 1A, Tables 1 and 2). The SRL did not depend on the sample location in the soil. The SRL determined for plant and ratoon sugarcane roots was 35 m/g (Table 2). Between-sample SRL variability seemed random. In Côte d’Ivoire, the fine root SRL was higher than in Réunion (Table 2).

Thick roots

In Réunion, relationships between the thick root weight and length in plant and ratoon sugarcane were a power function (Figure 1B and Eq. 1):

\[
\text{RLD} = 21.3 \text{RBD}^{0.724} \quad R^2 = 0.85 \quad n = 74 \quad (1a)
\]

\[
\text{RBD} = 0.0482 \text{RLD}^{1.2} \quad R^2 = 0.85 \quad n = 74 \quad (1b)
\]

SRL was therefore not fixed. According to the equation (Eq. 1), it ranged from 9.3 to 2.6 m/g when the RBD ranged from 20 to 2 000 g/m³. However, for simple estimates, a linear relationship could be assumed between the root weight and length. The mean SRL obtained from the pooled SRLs was thus 7 m/g, but with a high standard deviation of 3.7 (Table 2).

All roots (thick and fine)

Relationships between root weight and length in plant sugarcane and ratoon crops in Réunion (Figure 2) showed that: (i) the plant sugarcane and ratoon crop results were very close, (ii) in both cases, the best fit was a power function (Eq. 2). This equation was used to evaluate the root length according to weight, and the symmetrical equation was used to determine the RBD on the basis if the RLD:

\[
\text{RLD} = 85.5 \text{RBD}^{0.742} \quad R^2 = 0.88 \quad n = 108 \quad (2a)
\]

\[
\text{RBD} = 0.0097 \text{RLD}^{1.18} \quad R^2 = 0.88 \quad n = 108 \quad (2b)
\]

The nonlinearity of the relationship between RLD and RBD could have been partly due to a slight increase in SRL as the distance to the stem base increased. However, even when data obtained close to the root front were eliminated (very low RLD, under 80 cm for plant sugarcane), the relationship between the SRL (m/g) and the distance to the plant (DP, m) was not very close (SRL = 0.19 DP + 14; R² = 0.11; n = 118), indicating that DP was not the only SRL variation factor in the soil profile. However, this relationship could be used to take this slight influence of distance to the stem base into account when evaluating the SRL of pooled root samples.
Relationships determined between the root weight and volume in Côte d’Ivoire plant sugarcane were very close to those obtained in Réunion (data not shown). Côte d’Ivoire and Réunion SRLs were therefore pooled. SRLs were relatively stable at various root depths (Table 3), with a slight increase between 0.4 and 0.8 m depths, then a slight decrease from 1 m depth. For roots located less than 0.25 m below the stem base, the mean SRL calculated from the pooled SRLs was 16 m/g (SD = 6). It was 27 m/g for all other samples (Table 2).

Table 3—Mean specific root length (g/m³) at various soil depths for both sites (Réunion and Côte d’Ivoire) pooled. (SD = standard deviation).

Discussion

The root system located less than 0.25 m vertically and horizontally under the stem base had a high but variable proportion of thick roots. SRLs in this area were clearly lower than those in other parts of the soil profile (approx. 16 m/g). These roots located under the stem base are not discussed hereafter. In Réunion, as in Côte d’Ivoire, fine root (Ø < 1 mm) SRL variability was not associated with easy-to-characterise explanatory factors such as depth, distance to the plant, crop age, etc., so this parameter seemed random.

A single SRL value was thus selected for this first stage of the analysis. SRL was clearly higher in Côte d’Ivoire than in Réunion. This difference was unexplained. It may have been due to factors related to the varieties or soils, which differed markedly: in Côte d’Ivoire, for instance, there was a substantial proportion of coarse elements of a few millimetres in diameter in the soil.

For thick roots, both in Côte d’Ivoire and in Réunion, the SRL increased with the distance from the plant—at least in the area between the row and 1.2 m away, i.e. increasing from under 3 m/g to approximately 9 m/g at 1 m depth. This was correlated with the larger root diameters near the stem base and with the presence of finer rank 2 roots in deep horizons. The root weight and length were linked by a power function.

For a simple evaluation, it was also possible to select a single value of 7 m/g for SRL of thick roots. A power function was also established between the root weight and length in the pooled root samples (all, thick and fine roots). However, the relationship was not very useful for predictions as the ratio between thick and fine roots could be variable.

To evaluate the root length on the basis of the root sample weight or vice-versa, it would be advisable to separate roots according to diameter. The root classification used in this study only very partially represents the sugarcane root system complexity, and the 1 mm limit between the two classes may seem arbitrary.

However, simplification was necessary to be able to take SRL differences in relation to measured root diameters into account and to be able to use SRL in crop models. The SRL of roots located immediately under the sugarcane stem and less than 25 cm from the stem core should also be assessed separately.

Some authors suggest values of 3–5 m/g (van Antwerpen et al., 1993) based on pot studies, while others report a very broad range of values, i.e. 6 to 26 m/g (Ball-Coello et al., 1992). The SRLs obtained were higher than those suggested by these authors. This difference could be due to environmental and genetic factors. It could also be due to the method used to calculate the mean
SRL based on a dataset containing highly variable RLD or RBD values, with an asymmetrical distribution. In this study, we decided to calculate the mean of SRLs, not the SRL from the mean length and the mean weight.

Conclusion

It seemed that the thick root SRL results obtained in Côte d’Ivoire and Réunion could be applicable in a broad range of conditions. However, the fine root SRLs obtained at both sites seemed to depend on the variety, physical environment or even genotype x environment interactions. It would be interesting to gain greater insight into the factors responsible for this variability. The fine root SRLs depended relatively little on the crop age and root location in the profile, which should facilitate future studies. The results obtained at both sites are not mechanistically representative of SRLs under all conditions, but they should be helpful for making rough and ready RLD estimations on the basis of RBD and vice-versa. They should also be useful for establishing better correlations and for modelling two agronomically and ecophysiologically important root functions: water and mineral uptake, and the carbon sink/source that the root system represents in the soil/crop system.

MOTS CLES: Longueur Massique Racinaire, Longueur Racinaire Volumique, Modèle Racinaire, Réunion, Côte d’Ivoire.

Résumé

La longueur (RLD m/m\textsuperscript{3}) et la biomasse racinaires sont des paramètres clés pour déterminer respectivement : (i) les capacités d’alimentation hydrique et minérale, et (ii) la partition du carbone dans les plantes et le bilan de carbone dans le sol. Dans des études précédentes, très souvent, un seul de ces deux paramètres était mesuré. Il est donc utile de relier la RLD et la densité de biomasse racinaire (RBD) pour évaluer l’un des paramètres à partir du second. Des relations entre RLD et RBD et donc les longueurs massiques des racines (SRL) ont été étudiées en Côte d’Ivoire et à la Réunion. Les SRLs moyennes des racines fines n’étaient pas dépendantes de la localisation dans le profil et de l’âge de la culture, mais plus élevées en Côte d’Ivoire (68 m/g, SD = 19) qu’à la Réunion (35 m/g, SD = 10). Le meilleur ajustement entre la RBD et la RLD des grosses racines a été une fonction puissance (RLD = 21.3 RBD\textsuperscript{0.745}; \( R^2 = 0.85 \)), avec une SRL moyenne de 7 m/g. En étudiant toutes les racines ensemble, le meilleur ajustement est aussi une fonction puissance, avec peu de différence entre les deux sites et entre des cannes à sucre vierge ou en repousse. L’ajustement calculé avec toutes les données, sauf celles situées très près du pied, a été: RLD = 85.5 RBD\textsuperscript{0.742} (\( R^2 = 0.88 \)). En moyenne, la SRL = 27 m/g (SD=13). Les relations entre longueurs et poids racinaires n’ont été ni fixes ni complètement aléatoires. A cause de la variabilité de la SRL, il est difficile d’établir un lien mécaniste entre poids et longueur racinaire. Toutefois, pour des évaluations agronomiques simples, la RLD peut être estimée grossièrement sur la base de la RBD et vice versa.

PALABRAS CLAVE: Longitud específica de raíces, Densidad de longitud de raíces, Modelo de raíces, Réunion, Costa de Marfil.

Resumen

La densidad de longitud de raíces (RLD, m/m\textsuperscript{3}) de la caña de azúcar y la biomasa de la raíz son características claves para determinar respectivamente: (i) la capacidad de la absorción de nutrimentos y agua del cultivo, y (ii) el partecionamiento de carbono en las plantas y su balance en el suelo. En estudios anteriores, a menudo solamente uno de estos parámetros fue medido. Por lo tanto es muy útil ligar la RLD y la densidad de biomasa de raíces (RBD, g/m\textsuperscript{3}) para evaluar cada
parámetro y su relación con el otro. Las relaciones entre RLD y RBD y longitud específica de raíz (SRL, m/g) fueron estudiadas en Costa de Marfil y Réunion. Las SRL’s de raíces finas fueron independientes de la localización de las raíces en el perfil de suelo y de la edad de planta pero mayores en Costa de Marfil (68 m/g, SD = 19) que en Réunion (35 m/g, SD = 10). El mejor ajuste entre RBD y RLD de raíces gruesas se logró con una función de potencia (RLD = 21.3 RBD$^*0.745$; $R^2 = 0.85$). La SRL promedio fue de 7 m/g. Cuando todas las raíces fueron estudiadas juntas, el mejor ajuste entre RBD y RLD fue también una función de potencia, con poca variación entre los dos sitios o entre plantilla y soja. Los ajustes calculados con todos los datos excepto aquellos obtenidos cerca de los tallos de las plantas fueron: RLD = 85.5 RBD$^*0.742$ (R$^2 = 0.88$) y el promedio de SLR = 27 m/g (SD=13). Las relaciones entre la longitud de la raíz y la biomasa no fueron fijas ni completamente aleatorias. Debido a la variabilidad de la SRL, fue difícil establecer claramente alguna relación entre longitud de raíces y biomasa. Por el contrario, para realizar evaluaciones simples en campo, se puede hacer una estimación aproximada y rápida de la RLD con base en la RBD, y viceversa.
OPPORTUNITIES FOR AND POTENTIAL CONSEQUENCES OF REDUCING NITROUS OXIDE EMISSIONS FROM SUGARCANE CROPS

Abstract

USE OF nitrogen fertiliser is a major cause for increased atmospheric concentrations of nitrous oxide, a potent greenhouse gas. To reduce greenhouse gas emissions from sugarcane production, and so increase the crop’s attractiveness as a sustainable biofuel, it will be important to have a better understanding of nitrous oxide emissions and how they can be reduced. However, few measurements of nitrous oxide losses have been reported so far. Thus, our knowledge about nitrous oxide emissions from sugarcane production systems, and how they might vary in response to different environmental and management conditions, is limited. We compared measurements of nitrous oxide emissions with predictions from the cropping system model APSIM. We then simulated whole-of-crop nitrous oxide emissions over a range of environments and management practices in Australia. Predictions of nitrous oxide emissions were consistent with the measurements available, and greater than those from other intensive crops. Nitrous oxide emissions were predicted to vary considerably between regions, and were higher on irrigated soils and increased when trash was retained. Also, as expected, emissions were related to N fertiliser applications. Adoption of recent recommendations for reducing N fertiliser use was, in an example, predicted to reduce emissions by 40%. Further reductions in N applications and emissions, which may occur if emission trading schemes are adopted and fertiliser prices increase, were shown to reduce both emissions and profitability of sugarcane production. However, the economic value of reduced emissions is likely to be considerably less than that of the lost production. Experimental confirmation of these conclusions would be valuable.

Introduction

Concentrations of nitrous oxide, which is a potent greenhouse gas, have increased significantly over the past century as a result of anthropogenic alterations to the global nitrogen cycle (Crutzen et al., 2008; Schlesinger, 2009). Significant nitrous oxide emissions result from application of nitrogen (N) fertiliser to crops (Bouwman et al., 2002), and these emissions reduce the greenhouse gas benefits of biofuels (Crutzen et al., 2008). Hence, understanding nitrous oxide emissions from sugarcane production systems is an essential prerequisite for maximising the benefits of biofuels production, as well as minimising overall environmental impacts.

There are few measurements of nitrous oxide emissions from sugarcane and most have been conducted in Australia (Weier et al., 1996, 1998; Weier, 1999; Denmead et al., 2008; Wang et al., 2008; Allen et al., 2008; Macdonald et al., 2009). Emissions have been higher than expected compared with other cropping systems in Australia (Galbally et al., 2005). To reduce greenhouse gas emissions, it will be valuable to gain additional information on nitrous oxide emissions from
sugarcane systems and, if as high as currently indicated, identify management practices to reduce them.

Simulation models are increasingly being employed in addition to experiments to gain information on nitrous oxide emissions from cropping systems (e.g. Del Grosso et al., 2009). APSIM is a farming systems simulator (Keating et al., 2003) with a well developed capacity to simulate N dynamics in sugarcane systems (Thorburn et al., 2005). Recently, the denitrification processes in APSIM have been tested and the capability added for partitioning denitrified N into the different gasses produced by the process, nitrous oxide and dinitrogen (Thorburn et al., 2010a). Thus, APSIM is now a useful tool for exploring potential nitrous oxide emissions from sugarcane production systems in areas and/or for issues where measurements are unavailable.

In this paper, we use APSIM to investigate nitrous oxide emissions from a range of conditions found in sugarcane production in Australia. The simulations support the high nitrous oxide emissions previously measured, and suggest emissions are possibly greater in other sugarcane growing regions in Australia. We also explore some options for reducing nitrous oxide emissions and the impact they may have on sugarcane farming profitability.

**Methodology**

Contrasting sugarcane production systems were analysed using long term (40–60 years) simulations to investigate how nitrous oxide emissions varied (full details are given by Thorburn et al., 2010a). The systems were based on soils, climate and crop management information from previous studies of sugarcane production in four regions. These spanned a wide range of environments, including the super-humid tropics (Tully; ~17.9S, 145.9E), dry tropics (Burdekin River Irrigation Area; ~19.8S, 145.9E), humid tropics (Mackay, two soils; ~21.2S, 149.0E) and dry sub-tropics (Maryborough; ~25.5S, 152.7E).

Nitrous oxide emissions have previously been measured in the Mackay region, at Eton (Weier et al., 1998) and Te Kowai (Denmead et al., 2008; Macdonald et al., 2009). Hence, this study provided the first insights into potential nitrous oxide emissions in the other regions.

A range of management practices and soils were represented in the simulations. In Australia, there is a wide range of potential planting times, both within and between regions and this variation is represented in the systems simulated. The planting time influences the length of fallow before planting, and a range of fallow lengths is represented in the systems simulated. Irrigation management varied, with sugarcane fully irrigated in the Burdekin simulations, grown under supplementary irrigation in Maryborough simulations and not irrigated in the other systems. Simulations for the two soils in Mackay each had two different trash managements (retention and removal).

The amount of N applied in the simulations reflected common practice in the regions, ranging from over 200 kg/ha (averaged across all crops and fallows) in the Burdekin region to less than 130 kg/ha in the Tully and Maryborough regions (Figure 1). Soils ranged from clays in the Burdekin and the Eton site in Mackay, to sandy-clay-loams at the Te Kowai site in Mackay. Average cane yields in the simulations ranged from 74 t/ha (averaged across all crops), at Maryborough, to 80–84 t/ha for the loamy soils at Tully and Mackay (Te Kowai), to 87–91 t/ha in the clay soils of Mackay (Eton) and the Burdekin.

For the Te Kowai site in Mackay, cane yield, nitrous oxide emissions and partial gross margin (PGM) to farmers of sugarcane production were also simulated for a wide range of N application rates (35–200 kg/ha), keeping all other management factors the same as in the previous simulations. The PGM was calculated from the income from sugarcane (assuming a sugar price of AUS400/t and CCS of 13.5) less the cost of N fertiliser. The N application rate corresponding to the highest PGM was identified over a range of fertiliser prices to explore the possible sensitivity of nitrous oxide emissions, which are a function of N rate, to N price.
Results and discussion

Extent of emissions

Simulated long-term nitrous oxide emissions varied from 4–6 kg N/ha at the rainfed sites (Mackay and Tully) to 5–11 kg N/ha for the irrigated sites (Burdekin and Maryborough). The simulated emissions are consistent with previous measurements of emissions from rainfed sugarcane (Denmead et al., 2008; Allen et al., 2008; Wang et al., 2008; Macdonald et al., 2009). In particular, at Te Kowai near Mackay, nitrous oxide emissions of 4.1–4.7 kg N/ha were measured from a crop in 2006–07 (Denmead et al., 2008) and over the first 60 days of a crop in 2007–08 (Macdonald et al., 2009), similar to average long-term simulated values of 3.2–4.2 kg N/ha. Our simulations suggest these results are representative of longer time frames.

Nitrous oxide emissions were equivalent to 2–5% of N fertiliser applied (Figure 1) in the simulations. These relative emissions were consistent with the processes known to drive nitrous oxide emissions. At the Mackay sites, for example, emissions were higher from the clay soil at Eton than the more loamy soil at Te Kowai. Also, retaining trash on these soils increased simulated denitrification and nitrous oxide emissions, as expected from experimental results (Weier et al., 1998). Emissions were simulated to be high at the Burdekin site, reflecting the heavy clay nature of the soil combined with the high number (16) of irrigations in the simulation.

Our results (Figure 1) support the conclusions from several previous experiments (Denmead et al., 2008; Allen et al., 2008; Wang et al., 2008; Macdonald et al., 2009) that nitrous oxide emissions from Australian sugarcane crops are substantially greater than expected for the level of N fertiliser use and experience in other crops (Galbally et al., 2005), and suggest the cause is the relatively warm and moist climate and the availability of carbon in the soils.

Additionally, we provide the first estimates of emissions for fully irrigated production in Australia’s dry tropics (Burdekin), partly irrigated production in the sub-tropics (Maryborough) and rainfed production in the wet tropics (Tully). It will be valuable to experimentally confirm our predictions for these regions. However, we suggest that nitrous oxide total emissions in Australian sugarcane production may generally be equivalent to 3 to 5% of N fertiliser. While very high
emissions (~20% N fertiliser) have been measured from sugarcane growing on organic soils with shallow water tables (Denmead et al., 2008; Wang et al., 2008), these areas are relatively small in Australia and are unlikely to represent the general situation.

Global warming potential of nitrous oxide emissions from Australian sugarcane production has been estimated at 1.3 Mt CO$_2$-e/year (Weier, 1998), compared to total nitrous oxide emissions from agricultural soils in Australia of 15 Mt CO$_2$-e/y (NGGI, 2007). Our predicted nitrous oxide emissions are equivalent to 2.2–3.8 Mt CO$_2$–e/year for the amount of N traditionally applied to sugarcane in Australia (~80 Mt/year; Fertiliser Industry Federation of Australia, pers. comm.). Thus, we suggest that global warming potential of sugarcane in Australia is substantially greater than the previous estimate.

Applying our results to global sugarcane production for the area occupied by the crop (FAO, 2007) and average N application rates (Roy et al., 2006) suggests the global warming potential of nitrous oxide emitted from all sugarcane production may be equivalent to 60–100 Mt CO$_2$–e/year. This is 2–3% of the global warming potential previously attributed to nitrous oxide emissions from all fertilised croplands (Stehfest and Bouwman, 2006). This result, together with the fact that nitrous oxide emissions account for more than half the greenhouse gasses emitted during sugarcane production (Thorburn et al., 2009), suggests that reducing nitrous oxide from sugarcane is likely to be a higher priority than may have been previously thought for increasing the sustainability of sugarcane production both in Australia and globally.

Reducing emissions

As expected (Bouwman et al., 2002), nitrous oxide emissions increase with increasing N fertiliser application (Figure 2a). Thus, emissions can be reduced by reducing N applications. This may come about in two ways:

Firstly, improved N recommendations have shown there is considerable scope for reducing N rates in Australian sugarcane production without significantly reducing productivity (Schroeder et al., 2006; Thorburn et al., 2010b). Thus, at Te Kowai for example (Figure 2a), reducing N application from 170 kg/ha (the recent average in that region) to 120 kg/ha would reduce nitrous oxide-N emissions by ~40%. This reduction in emissions would not be associated with a loss of income as yields are likely to be maintained at these N application rates (Thorburn et al., 2010b).

Secondly, nitrogen applications may also be reduced if the price of N fertiliser increases. Price increases are likely if emissions trading schemes are introduced, because the cost of energy used in the manufacture and distribution of fertiliser will rise, and the possibility of an emissions levy on fertiliser.

As N fertiliser prices increase, maximum profitability occurs at lower N application rates (Figure 2b). So farmers may respond to price increases by reducing N applications, which would result in lower nitrous oxide emissions. However, with increased N price, not only is the N rate at which maximum profitability reduced, the maximum profit itself also decreases.

Thus, higher N prices could result in both lower nitrous oxide emissions and lower farm profitability if farmers respond by reducing N applications. In the simulations for Te Kowai, the trade off between nitrous oxide emissions and farm profitability can be illustrated for varying N prices by taking the N rate at which maximum PGM occurs (i.e. the dots on the curves in Figure 2b) and calculating the corresponding nitrous oxide emissions and PGM values over a range of N prices (Figure 3).

In this example, nitrous oxide emissions decrease by ~0.46 kg N$_2$O-N/ha for each unit (i.e. AU$1) increase in N price. If the price of carbon is AU$20/t CO$_2$-e the value of the reduced nitrous oxide emissions is ~AU$4.25. The corresponding decrease in PGM is ~AU$98 per unit increase in N price, or more than 20 times the value of nitrous oxide emissions.
The economic impact of increased N prices will be even greater if price increases are such that they drive N applications low enough so that cane yields and sucrose concentrations are reduced. In this situation, the reduced cane and sugar supply would potentially reduce mill profitability. This analysis illustrates the point that decreases in N fertiliser rate below recommended rates as a response to higher N prices could have substantial negative net economic effects.

The nitrous oxide emissions are enhanced by high concentrations of nitrate and carbon in the soils and anaerobic soil conditions. Thus, as well as reducing N fertiliser applications, other management practices affect nitrous oxide emissions. In our simulations, as expected, the highest relative emissions occurred in the two irrigated production systems, Burdekin and Maryborough (Figure 1). In irrigated production systems, minimising water logging following irrigation will help reduce nitrous oxide emissions. Also, as expected, retaining crop trash also increased emissions (Figure 1).

Given the advantages of this widely-adopted practice in Australian sugarcane production (Weier et al. 1998; Robertson and Thorburn, 2007), other methods to reduce emissions will need to be employed. Practices such as splitting N fertiliser applications may help (Weier 1999; Allen et al., 2008), as might slow release fertilisers or nitrification inhibitors (Wang et al., 2008), although the benefits of these practices have not been consistent.
Conclusions

Our study supports the proposition that nitrous oxide emissions from Australian sugarcane production are considerably greater than expected compared with measurements in other intensive crops, and so reducing emissions will be important for increasing sustainability of the industry. Adoption of contemporary recommendations for reducing N fertiliser use is a likely pathway to significantly reducing emissions.

Further reductions in N applications, which may occur if emission trading schemes are adopted and fertiliser prices increase, may not only reduce emissions, but profitability of sugarcane production. The economic value of lost production is likely to be much greater than the value of reduced greenhouse gas emissions. Experimental confirmation of these conclusions would be valuable. Simulating the relative efficacy of these different management practices may guide experimentation in that area. APSIM’s ability to represent such management options in detail (Keating et al., 2003; Thorburn et al., 2005) will make it a useful tool for these investigations.

MOTS-CLÉS: APSIM, Biocarburants, Émissions de Gaz à Effet de Serre, Émissions de Protoxyde D'azote, Engrais d'Azote, Canne à Sucre.

Résumé

L'UTILISATION de l'engrais azoté est une cause majeure de l'accroissement des concentrations atmosphériques en protoxyde d'azote, un gaz à effet de serre potentiel. Pour réduire les émissions de gaz à effet de serre provenant de la production de canne à sucre, et augmenter ainsi l’intérêt de cette plante comme biocarburant durable, il serait important d'avoir une meilleure connaissance des émissions de protoxyde d'azote et des façons de les réduire. Cependant, peu de mesures de pertes en protoxyde d'azote ont été relatées jusqu'ici. Ainsi, notre connaissance sur les émissions de protoxyde d'azote des systèmes de production de canne à sucre, et leur variabilité selon les conditions environnementales et les pratiques culturales, est limitée. Nous avons comparé des mesures d’émissons de protoxyde d'azote aux prévisions du modèle de croissance APSIM. Nous avons ainsi simulé des émissions de protoxyde d'azote de parcelles sur une gamme d’environnements et de pratiques culturales en Australie. Les prévisions des émissions de protoxyde d'azote furent conformes aux mesures disponibles, et supérieures à celles d'autres cultures. Les émissions de protoxyde d'azote ont été simulées pour des régions très variées, et furent plus élevées sur sols irrigués et accrues quand les résidus de récolte étaient restitués. En outre, comme prévu, les émissions furent liées aux applications d'engrais azoté. L'adoption des recommandations récentes pour réduire l'utilisation d'engrais azoté, dans un exemple, réduisit les émissions de 40%. D'autres réductions des applications d'azote et des émissions, qui peuvent se produire si les plans de taxation des émissions sont adoptés et si les prix d'engrais augmentent, ont montré une réduction à la fois des émissions et de la rentabilité de la production de canne à sucre. Cependant, la valeur économique des émissions réduites est vraisemblablement plus faible que celle due à la réduction de production. Une confirmation expérimentale de ces conclusions serait très utile.
OPORTUNIDADES Y CONSECUENCIAS POTENCIALES DE LA REDUCCIÓN DE LAS EMISIONES DE OXIDO NITROSO EN CULTIVO DE CAÑA DE AZÚCAR

PALABRAS CLAVES: APSIM, Los Biocarburantes, Gases de Efecto Invernadero, Emisiones de Óxido Nitroso, Fertilizantes de Nitrógeno, Caña de Azúcar.

Resumen
El uso de los fertilizantes nitrogenados es la principal causa de incremento de las concentraciones atmosféricas de óxido nitroso, un potente gas de efecto invernadero. Para reducir las emisiones de gas de efecto invernadero en la producción de caña de azúcar, y para incrementar la atractividad del cultivo como un biocombustible sostenible, será importante tener un mejor entendimiento de las emisiones de óxido nitroso y de cómo pueden reducirse. Sin embargo, pocas mediciones de pérdidas de óxido nitroso han sido reportadas hasta el momento. Por lo tanto, nuestro conocimiento es limitado sobre las emisiones de óxido nitroso desde los sistemas de producción de caña de azúcar, y de cómo podrían variar en respuesta a las diferentes condiciones ambientales y de manejo. Hemos comparado mediciones de emisiones de óxido nitroso con predicciones hechas a partir del modelo de sistemas de cultivo APSIM. Luego, hemos simulado las emisiones de óxido nitroso del cultivo completo sobre un rango de ambientes y prácticas de manejo en Australia. Las predicciones de las emisiones de óxido nitroso fueron consistentes con las mediciones disponibles, y mayores que aquellas provenientes de otros cultivos. Se predijo que las emisiones de óxido nitroso variarían considerablemente entre regiones, y fueron más altas en los suelos irrigados e incrementadas cuando se mantuvo el residuo de la cosecha. También, como se esperaba, las emisiones estuvieron relacionadas a las aplicaciones de fertilizantes nitrogenados. En un ejemplo, la adopción de las recomendaciones recientes para la reducción del uso de fertilizantes nitrogenados, predijo la reducción de las emisiones en un 40%. Además, las reducciones en las aplicaciones de nitrógeno y en las emisiones, que pueden ocurrir si se adoptan los planes propuestos en los protocolos, y el precio de los fertilizantes aumenta, demostramos que se reducen tanto las emisiones como la rentabilidad de la producción de caña de azúcar. Sin embargo, el valor económico de las emisiones reducidas es probablemente considerablemente menor que el de las pérdidas de producción. La confirmación experimental de esas conclusiones debería ser evaluada.
EVALUATING AN ECOLOGICALLY-BASED SYSTEM FOR SUSTAINABLE MANAGEMENT OF NITROGEN FERTILISER

KEYWORDS: Nitrogen Surplus, Sugarcane Nitrogen Concentration, Farm Profitability, Best Management Practice, Environmental Impact.

Abstract
SUSTAINABLY managing N fertiliser is an increasing challenge for sugarcane production, as losses of N impact the health of ecosystems and contribute to climate change (through emissions of the greenhouse gas nitrous oxide). The N Replacement (NR) system is a new, ecologically-based concept for N management in sugarcane designed to meet this challenge. The NR system aligns N applications with actual cane production, rather than potential production, by relying on soil N reserves to buffer differences in crop N needs and N fertiliser supply in individual crops. We evaluated the NR system in 11 on-farm experiments in Australia, conducted over a wide range of environments for up to five years. Average yields in the NR treatment were similar to those achieved with the farmers’ conventional N management that had average N applications 66 kg/ha greater than in the NR treatments. Yields increased relative to the farmers’ conventional N management through time, from ~5 t/ha lower in the first crops of the experiments to 2.6 (standard error = 1.2) t/ha higher in the fourth, suggesting a physiological response in the crops to the variable N applications in the NR system. The crop N surplus, an estimate of N potentially lost to the environment, was 55% lower in the NR treatment compared with conventional N management. This reduction in N surplus was not as great as had been anticipated, as N concentrations and N uptake in cane for most crops in all treatments were lower than those previously reported. The results show that the ecologically-based N Replacement system may deliver superior environmental outcomes without significantly reducing production. The results also show that predicting yield of the coming crop, a common basis for N management, is not necessary in sugarcane N management, provided N applications and production are matched in the longer term.

Introduction
Controlling N losses from cropping systems is important because of the impacts of N on human health and ecosystems (predominantly as NO₃) and its role in contributing to climate change (through N₂O emissions). These are challenging issues for sugarcane production, which has generally high use of N fertiliser (Roy et al., 2006) and is increasingly used for biofuel production (Macedo et al., 2008). It is unlikely that traditional N fertiliser recommendations for sugarcane will meet these challenges. Potential crop yields are a feature of many recommendation systems (e.g. Legendre, 2001; Schroeder et al., 2006) and so result in over-application of N in the common situation where actual production is less than potential (Meyer et al., 2007).

Sugarcane is a deep rooting semi-perennial crop (i.e. it is allowed to ratoon after harvesting) grown in subtropical and tropical areas where soil N cycling is often rapid. This rapid N cycling allows large amounts of N to be immobilised and subsequently mineralised over the long term (Ng Kee Kwong et al., 1986; Meier et al., 2006) where it can be efficiently retrieved by the deep root system (Smith et al., 2005). Therefore sugarcane may be well suited to a more ecologically-based
approach to N management (Drinkwater and Snapp, 2007), where N fertiliser applications are geared to maintaining soil N stores so they can provide the crop’s N needs, rather than more directly ‘feeding’ the crop.

Such an ecologically based N management system, known as N Replacement (NR), was proposed for sugarcane by Thorburn et al. (2004). They linked N applications to crop N off-take in the previous crop. The assumption was that, if the yield of the coming crop was larger than that of the previous crop, additional N requirements would be supplied from soil N stores. Conversely, these N stores would be ‘topped up’ when a small crop followed a large one. They suggested a potential saving in N fertiliser up to 40% compared with common N fertiliser applications in Australia, and consequently the N surplus (an estimate of the N potentially lost to the environment) may be reduced by 90%.

In this paper we report on 11 field experiments established to test this concept in the diverse soils and climates of the Australian sugarcane industry. As well as evaluating whether the NR system can maintain sugarcane productivity with lower N fertiliser inputs and environmental impacts, we also discuss the implications of the results for general sugarcane N management strategies.

**Methods**

Experiments were established on commercial farms in 2003 or 2004 located from the wet tropics around Cairns (~16°S – Mossman, Mulgrave and Innisfail, Table 1), to the dry tropics near Townsville (~19°S – Burdekin), and the sub-tropics (~25°S to 28°S – Bundaberg, Maryborough and Condong). Crops at sites BK-1, BK-2, BU-1 and MB-1 were irrigated and the others rainfed. The irrigated crops, except at BU-1, were burnt at harvest. Others were harvested unburnt with all trash retained on the soil surface. The NR system was compared with the farmers’ conventional N fertiliser management (NF).

The amount of N fertiliser (kg/ha) applied in the NR approach was targeted to be 1 kg N/t cane harvested in the previous crop where trash was retained and 1.3 kg N/t cane where the crop was burnt (Thorburn et al., 2004). This is less than general application rates to sugarcane (Roy et al., 2006) and, particularly where trash is retained, less than current recommendations in Australia (Schroeder et al., 2006). In five of the experiments, a lower N rate treatment (NL) was also included to examine the time taken for productivity to decline as a consequence of low N applications. The lower rate was approximately equivalent to that which would occur with the NR scheme following a very poor crop.

**Table 1**—Details of the experimental sites and the average annual N applied in different treatments (NL-N Low; NR-N Replacement; NF-N Farm).

<sup>a</sup> Soil C concentration determined by combustion with a LECO CNS analyser.

<sup>b</sup> The NL treatment was not established at every site.
Generally the sites had been managed using the farmers’ normal practice prior to the experiments. The exception was BU-1, where the experiment was established in the first ratoon crop of a pre-existing N rate experiment (Thorburn et al., 2003).

In this experiment, the NR treatment was applied to plots that had received no N fertiliser in the preceding plant crop (yielding 83 t/ha). Also, unlike the other sites, the NL treatment had received a lower-than-recommended rate of fertiliser since 1996.

A participatory approach was taken to the experimental designs at each farm, so these were decided jointly with collaborating farmer groups. Seven experiments were established as randomised designs with treatments replicated, while four were non-replicated demonstration experiments (Table 1).

All cultural practices and the timing of these operations were determined by the collaborating farmers. This approach was taken to ensure crop production reflected that achieved on commercial farms, and not higher yields often achieved in more carefully managed experiments.

Plots were generally large enough to allow harvested cane yield and sugar content to be determined from commercial harvesting and milling operations.

Crop biomass and N concentrations were determined prior to harvest to allow calculation of crop N dynamics. Where treatments were replicated and run over multiple harvests, the results were subject to analysis of variance using a strip-plot design.

The surplus of N was calculated for each treatment as the difference between N applied and that lost through crop harvest and, where applicable, trash burning.

The amount of N in the crop and trash was determined from mass and N concentration in the harvested cane and trash. N surpluses are calculated from the sum of all the harvest years and reported as an annual average.

**Results**

Yields were generally similar in the NR and NF treatments (Figure 1). However, there was a trend for yields in the NR treatments to be less than those in the NF treatment in the first year of the experiment, but increase relatively in each successive year.

In the five experiments in which at least four crops were grown, the yields in the NR treatment were 2.0 (standard error = 0.6) and 2.6 (1.2) t/ha greater than those in the NF treatment in the 3rd and 4th crops, respectively.

The relative increase in yield in the NR treatment was most marked at the BU-1 site. At this site, the NR treatment was established on a plot in which soil N reserves had been run-down.

So the relationship between yield-response to increasing N applications in the first two crops was not surprising.

More surprising was the higher average yields in the NR treatment for the third and fourth crops at this site.

There were no significant yield differences in the replicated experiments, despite the fact that N applications were on average 66 kg/ha lower using the NR treatment than the NF.

Yields in the NL treatment averaged 11 t/ha lower than those in the NF treatment receiving higher N (Figure 1).

The biggest difference was at the BU-1 site where the NL treatment had been imposed for 8 years prior to this experiment, and so soil N is likely to have run down.

Excluding this site, the average yield reduction was 6.2 t/ha, trending from 5 t/ha in the first crop after the treatments were imposed, to 8 t/ha in the third.
Cane N concentrations, a major component of crop off-take of N, were variable between sites (Figure 2), e.g. ranging from ~0.3% in some crops at sites BK-1 and BK-2 to <0.1% at MB-2. Cane N concentrations also varied between years, e.g. 0.2% in 2005 and 0.1% in 2006 at site IN-3. They also tended to be lower in the NL treatment, presumably responding to the markedly lower N applications in this treatment (Table 1). There was little difference in N concentrations in cane from the NR and NF treatments in most experiments, exceptions being sites BK-1 and ML-1 where there was a trend in three of the four years for cane N concentrations to be lower in the NR treatment.

The amount of surplus N generally increased with increasing N applications, averaging 5 kg/ha in the NL treatment, 63 kg/ha in the NR treatment and 141 kg/ha in the NF treatment, although the values were highly variable across sites (Figure 3).

Despite the variability, N surplus in the NR treatment was less than those in the NF treatments at all sites, except CD-1 where there was little difference between the N fertiliser applied in these two treatments. The average reduction in N surplus (55%) was less than that predicted by Thorburn et al. (2004), the reason being that the N concentrations measured in most crops (Figure 2) were lower than the 0.3% assumed by Thorburn et al. (2004) based on previous measurements (Wood et al., 1996).
Fig. 2—Concentrations of N in cane of sugarcane crops in the experiments. Treatment designations are the same as in Figure 1. Note: Samples at sites IN-1 and MS-4 were not obtained in all crops.

Fig. 3—The N surplus (i.e. the difference between N applied and that lost in harvested cane and, at some sites, burnt trash) averaged over all sugarcane crops harvested from the experiments. Treatment designations are the same as in Figure 1. Note: There are no results for site IN-1 in 2006 due to cyclone damage.

Discussion
These results suggest the NR system has promise for meeting the productivity needs of N fertiliser management in sugarcane while reducing potential environmental losses of N for the range of conditions represented in the 11 experiments of this study. Yields were similar to those with
higher and more conventional (Schroeder et al., 2006; Roy et al., 2006) applications of N (Figure 1), especially in the second and subsequent crops after the treatments were imposed. N surpluses (Figure 3), and so potential environmental impacts, were also reduced by ~55% compared with conventional N management.

The improved outcome of the NR system over the farmers’ conventional management was potentially due to a number of factors.

Firstly, yields in all treatments were generally lower than potential yield benchmarks in the regions which drive current thinking on farmers’ N management. For example, potential yields in the regions in which the experiments were located were generally 120 t/ha, and 180 t/ha in the Burdekin region (Schroeder et al., 2006). These yields were only reached or exceeded in 7 of the 37 crops grown in the experiments. And in those crops, e.g., CD-1 in 2005 or MB-2 in 2007 (Figure 1), there was no evidence that the lower N applied in the NR treatment was limiting yields.

Secondly, cane N concentrations (Figure 2) were generally lower than expected from previous studies (Wood et al., 1996) across all treatments and sites, meaning that the crops’ N needs were lower than anticipated.

Thirdly, this improved outcome suggests that the philosophy of drawing on dynamic N cycling in sugarcane soils (Ng Kee Kwong et al., 1986; Meier et al., 2006) to buffer some of the short term differences between crop N needs and N supply from fertiliser is applicable in sugarcane production. This final point suggests that the concept of applying N to ‘feed’ potential yields may not be necessary for sustainable sugarcane production, particularly when actual yields do not realise their potential. A more ecologically-based approach to N management, where fertiliser applications are geared towards maintaining soil N stores, as advocated by Drinkwater and Snapp (2007), may be applicable to sugarcane.

The results from these experiments allow us to explore the degree to which N fertiliser applications need to match ‘expected yields’, and hence the degree of buffering soil N reserves provided to these sugarcane crops. Since, in the NR system, N applied is based on yield of the previous crop, N applications will only be equal to the ‘needs’ of the coming crop if yields are constant over a number of crops. Where yields increase through time, N applications will be lower than those needs, and so crops must draw on soil supplies, as would be the case when yields are higher than expected.

This situation happened in the NR treatment at site MB-2. Yields of the 2006 and 2007 crops were 25 and 30% higher than the previous crop (Figure 1), resulting in actual N applications of ~0.8 kg N/t cane relative to the achieved yield. Yet, applying extra N fertiliser (average of 47 kg/ha) in the NF treatment in these years did not significantly increase yield, particularly in the 2007 crop. Additionally, the NR treatment at the BU-1 site was established following a crop that received no N, yet after two crops yields had recovered to averages greater than those of the NF treatment that had received 45 kg/ha extra N fertiliser. These results show that, from crop to crop, actual yields can be considerably higher than expected yields without N supply being limiting.

As hypothesised by Thorburn et al. (2004) in conceiving the NR concept, the soil N cycling processes provided sufficient N for crop N needs in the N replacement system in the short term, and it is more important to match N applications to longer-term actual production.

There were some unexpected physiological responses in the crops of the experiment. Firstly, as discussed above, cane N concentrations (Figure 2) were generally lower than those previously measured in Australian sugarcane crops (Wood et al., 1996). These unexpectedly low cane N concentrations may be possibly due to the physiology of modern Australian varieties which, if so, indicates that there may be potential for further reductions in N fertiliser applications to sugarcane crops. Rather than seeking N rates for optimum yield, a more useful approach for determining the
potential reductions may be to ask the question; what is the minimum long-term N surplus required to maintain crop yields?

The NR treatment had an average N surplus of 63 kg/ha (Figure 3), or ~0.5 kg N/t cane, and this was sufficient to maintain productivity (Figure 1) compared with the higher N applications (Table 1). It was also sufficient to overcome a deliberate rundown of soil N reserves at the BU-1 site within one or two crops. The question now is whether productivity can be maintained at lower N surpluses?

The second physiological response was the trend for yields in the NR treatments to increase relative to those in the NF treatment over successive crops (Figure 1). This result suggests that the crops were ‘compensating’ for the lower, but variable, N application in this treatment. Sugarcane crops can respond to N through deeper root development (Smith et al., 2005), a possible explanation for the results in this experiment.

Such compensation, together with the lower than expected cane N concentrations observed in these crops suggest that there are further gains to be made in lowering N inputs to, and hence environmental impacts of, sugarcane production.

Résumé
LA GESTION durable de la fertilisation azotée est un défi croissant de la production de canne à sucre, car les pertes en N affectent la santé des écosystèmes et contribuent au changement climatique (par des émissions de protoxyde d'azote, un gaz à effet de serre). Le système de remplacement de N (NR) est un concept nouveau, à base écologique, de gestion de N en canne à sucre, conçu pour relever ce défi. Le système de NR préconise des applications d'azote en accord avec la production réelle de canne, plutôt que la production potentielle, et tenant compte des réserves du sol en N pour tamponner les différences entre les besoins en N par la plante et les fournitures en azote par le sol. Nous avons évalué le système NR sur 11 essais menés sur exploitation en Australie, conduits sur un large éventail d'environnements pendant cinq années. Les rendements moyens dans le traitement NR furent similaires à ceux produits par la gestion conventionnelle de N des exploitants qui a nécessité des applications d'azote moyennes 66 kg/ha, bien plus grandes que celles des traitements NR. Comparés à la gestion conventionnelle, les rendements produits par le système NR a augmenté dans le temps, passant de ~5 t/ha dans les premières récoltes à + 2.6 t/ha dans le quatrième récolte, suggérant une réponse physiologique variable des plantes aux applications d'azote dans le système NR. L'excédent d'azote, potentiellement perdu vers l'environnement, était 55% plus faible dans le traitement NR qu'avec la gestion conventionnelle de N. Cette réduction d'excédent de N ne fut pas aussi grande que prévue, car les concentrations en N de la canne et la mobilisation de N par la plante dans la plupart des traitements furent inférieures à celles précédemment rapportées. Les résultats montrent que le système écologique de remplacement de N mobilisé peut améliorer l’impact environnemental sans réduire de manière significative la production. Les résultats montrent également que le rendement prévu, un critère commun du calcul de l’azote à fournir, n’est pas nécessaire dans la gestion de N chez la canne à sucre, si les applications de N et la production sont raisonnées à plus long terme.

Resumen

El manejo sustentable de los fertilizantes nitrogenados es un desafío creciente para la producción de caña de azúcar, porque las pérdidas de N impactan la salud de los ecosistemas y contribuyen al cambio climático (a través de las emisiones de óxido nitroso como gas de efecto invernadero). El sistema de Reemplazo de N (NR) es un concepto nuevo, ecológicamente basado en el manejo del N en caña de azúcar diseñado para responder a este desafío. El sistema NR relaciona las aplicaciones de N con la producción actual de caña, más que con la producción potencial, teniendo en cuenta las reservas de N del suelo para atenuar las diferencias entre las necesidades de N del cultivo y la adición de fertilizante nitrogenado en cada cultivo. Evaluamos el sistema NR en 11 sitios experimentales en Australia, sobre un amplio rango de ambientes por un período de hasta cinco años. Los rendimientos promedios en los tratamientos NR fueron similares a aquellos registros de los agricultores con manejo convencional de N, que hicieron aplicaciones promedio de 66 kg/ha de N, más altas que en los tratamientos NR. Hubo incrementos de rendimientos relativos de los agricultores de manejo convencional de N a través del tiempo, desde menos de 5 t/ha en el primer cultivo (año) de los experimentos, hasta 2.6 t/ha en el cuarto, sugiriendo una respuesta fisiológica en los cultivos a la variable aplicación de N en el sistema NR. El N excedente en el cultivo, un estimado de N potencialmente perdido hacia el ambiente, fue 55% más bajo en el tratamiento NR comparado con el manejo convencional de N. Esta reducción en el excedente de N no fue tan grande como había sido anticipada, porque las concentraciones de N y la asimilación de N en la caña para la mayoría de los cultivos en todos los tratamientos fueron menores que aquellas previamente reportadas. Los resultados mostraron que sistema de reemplazo de N basado ecológicamente puede extraer (aprovechar) más la entrega ambiental sin reducción significativa de la producción. Los resultados mostraron también que la predicción de rendimiento del cultivo siguiente, una base común para el manejo del N, no es necesaria en caña de azúcar, siempre que las aplicaciones de N y la producción estén igualadas en el largo plazo.
CHANGES IN SOIL ORGANIC CARBON STOCKS RESULTING FROM SUGARCANE CROPPING IN THE HUMID TROPICAL CLIMATE OF MAURITIUS: RESULTS FROM $^{13}$C NATURAL ABUNDANCE

KEY WORDS: Soil Organic Carbon, Delta $^{13}$C, Sustainable Sugarcane Production.

Abstract

A DECLINE in productive capacity of soils as a consequence of long-term sugarcane monoculture, combined with an intensification of the production system, has become a major issue in several sugarcane producing countries. Maintenance of adequate levels of soil organic carbon (SOC) is crucial for the biological, chemical and physical functioning of soils. This study was conducted to determine the impact of long-term sugarcane monoculture on SOC stocks and to quantify the loss of native SOC and accretion of sugarcane-derived C following the adoption of new management practices namely derocking/landgrading and mechanised harvesting. Five study sites representing the five major soil groups under sugarcane in Mauritius were studied and a classical ‘paired-plot’ design was adopted where two sites with similar starting conditions were developed in different ways over time, with one representing the reference soil (virgin land with predominantly C$_3$ type vegetation) and the other representing the following cropping treatments: (i) fields continuously cultivated with sugarcane for more than 25 or 50 years without derocking or land grading, (ii) fields under long-term sugarcane but having undergone derocking and land grading for mechanised harvesting in the last 3 years. Soil samples were taken to a depth of 50 cm and analysed for total organic C, $^{13}$C abundance, bulk density and stone content. Long-term sugarcane cultivation reduced SOC stocks in the surface 0–15 cm layer compared to uncultivated virgin soil but increased subsoil organic C indicating a redistribution of SOC in the deeper layers of the soil profile. Changes in total C stock in the 0–50 cm profile, following 50 years of cane cropping were not significant ($P< 0.05$) compared to virgin land at any site. Data from $^{13}$C abundance measurements revealed that long-term sugarcane cultivation in fact resulted in a depletion of original SOC by 34 to 70%. However, this loss was fully compensated by C input from sugarcane residues at all sites studied, resulting in no net change in SOC stock. Moreover, adoption of mechanised cropping, which entails intensive derocking and land grading, did not have any detrimental effect on SOC stocks due to C inputs from crop residues.

Introduction

In recent years, there has been increasing evidence of a decline in productive capacity of soils as a consequence of long-term sugarcane (Saccharum officinarum L.) monoculture combined with intensification of the production system (Garside et al., 1997a; Meyer and van Antwerpen, 2001). Excessive tillage at time of planting, severe compaction resulting from mechanised cultural operations as well as practices that deplete organic matter have also been identified as major factors
contributing to the yield decline (Pankhurst et al., 2003). Collectively, these management practices result in degradation of the soil in chemical, physical and biological properties as evidenced by reduced levels of SOC, lower CEC and pH, high bulk density, less microbial biomass and a build-up of detrimental soil organisms (Garside et al., 1997b).

In Mauritius, analysis of the trend in productivity expressed as the average annual yield of sugar per hectare also showed a decline during the last 30 years in spite of the introduction of higher yielding cane varieties and the adoption of improved management practices.

While research examining the link between the observed declining productivity trend and soil degradation is lacking for the sugarcane industry in Mauritius, the management practices adopted are in many ways similar to those that are known to have contributed to yield decline elsewhere.

In this context sugarcane cropping in Mauritius is strongly monoculture-based and in order to facilitate mechanisation of cultural operations, land preparation involves deep tillage and derocking of the topsoil and subsoil followed by levelling of the soil surface through cut and fill method. As a result of this monoculture and soil disturbance, it is feared that the SOC levels may have declined.

Indeed as reviewed by Haynes and Hamilton (1999), most studies on the long-term effects of sugarcane production have reported a decline in SOC, the magnitude of this loss varying widely depending on soil type, period of cropping and management practices.

The determination of losses of original SOC from native vegetation and its replacement by C derived from sugarcane origin is thus of capital importance to understand the dynamics of organic carbon in soils of Mauritius.

The use of $^{13}$C technique was preferred as it enables the separation of organic C pools into that of old and new vegetation so long as the two types of vegetation have contrasting photosynthetic pathways (C$_3$ versus C$_4$) (Balesdent et al., 1987).

The cultivation of a C$_4$ crop such as sugarcane in a soil developed under C$_3$ natural vegetation can provide information on the turnover of the original organic matter as well as the contribution of the C$_4$–C to the SOM pool.

A study was therefore initiated to evaluate the impact of long-term sugarcane monoculture and of changed management practices on SOC stocks in Mauritius by means of natural $^{13}$C natural abundance measurements.

**Materials and methods**

**Study sites**

The study was carried out at five locations representing the five major soil types of Mauritius. The soils at the study sites fall into two main soil groups: the mature ferralitic soils also known as Ferralsols (FAO-ISRIC-IUSS, 2006) or Oxisols (Soil Survey Staff, 1999) derived from highly weathered basalt and the immature latosolic soils also known as Cambisols (FAO-ISRIC-IUSS, 2006) or Inceptisols (Soil Survey Staff, 1999) derived from moderately weathered basalt rock. The main characteristics of the soils are given in Table 1.

The cropping systems studied at each of the five sites were:

1. natural vegetation (treatment NV)
2. continuous sugarcane for > 50 years under conventional practice (treatment 50Y) and
3. continuous sugarcane for > 50 years under conventional practice followed by recent (three years) derocking and mechanisation (treatment 3M).

In addition, a fourth treatment consisting of 25 years sugarcane under conventional practice (treatment 25Y) was included at two sites (Riche Terre and Médine).

</table>

The natural vegetation plots consisted of native trees and shrubs (C₃ photosynthetic pathway) but could at times have included some exotic C₄ grasses and had never been tilled or cultivated with sugarcane.

The conventional practice for sugarcane consisted of tillage to a depth of 20–30 cm and replanting of sugarcane every seven to 10 years with N, P, K fertilisation at recommended rates, and manual harvesting with trash retention, though at times pre-harvest burning of some fields might have been practised.

Derocking of soils (treatment 3M) involved tillage to more than 50 cm depth, raking of surface and subsurface rocks and boulders which were then removed from the field, followed by the levelling of the soil through cut and fill.

The study plots at any site were located one to two kilometres apart and were thus subjected to the same climatic and drainage conditions.

**Soil sampling and analysis**

For each cropping treatment, there were three field replicates of one hectare each and within each field replicate there were four sampling plots of 50 m². At each sampling plot, two trenches 1.5 m long, 0.3 m wide and 0.5 m deep were dug, extending from the middle of one cane interrow across the row to the middle of the next interrow.

Soil samples were collected from the trenches in four different depth layers namely 0–5, 5–15, 15–30 and 30–50 cm. All samples were air dried and sieved to pass a 2 mm screen.

Total C and δ¹³C were determined on a Europa Model 2020 ANCA-SL continuous flow isotope ratio mass spectrometer with a triple collector (Europa Scientific, Crewe, UK) and expressed as per mil deviation from V-PDB standard (Peterson and Fry, 1987).

**Calculation of C derived from C₃ and C₄ vegetation**

Fraction of total soil organic C derived from sugarcane (f) was calculated using the following isotope mass balance equation (Balesdent and Mariotti, 1996):
where $\delta_{\text{sample}}$ is the average $\delta^{13}C$ value of the sample for a given depth layer from sugarcane soil, $\delta_{\text{reference}}$ is the average $\delta^{13}C$ value of the corresponding sample from natural vegetation (reference) soil and $\delta_{\text{sugarcane}}$ is the average $\delta^{13}C$ value of sugarcane crop residues ($-12.05 \%$). Total SOC stocks (t/ha) were calculated using the following equation:

$$\text{Total SOC stocks (t/ha)} = \%C \times Z \times B \times (100-S) \quad (\text{Equation 2})$$

where $\%C$ is the carbon content of sample (percent), $Z$ is the layer thickness (m), $B$ is the bulk density (t/m$^3$) and $S$ is the stone content of soil (percent). Soil C stocks were corrected to an equivalent mass basis according to Solomon et al. (2002).

**Statistical analysis**

Statistical analysis of the data was carried out using the linear model analysis of variance (ANOVA) procedure of SAS statistical package (Enterprise Guide 4, SAS International 2006). Post hoc comparisons among treatment means were done using the Tukey test at $P=0.05$.

**Results and discussion**

**Effect of long-term cane cultivation on total C stocks**

In the Ferralsols, SOC stocks in the 0–50 cm profile under native vegetation increased from 98.7 t C/ha at Riche Terre (subhumid zone) to 117.6 and 160.2 t C/ha respectively at Mon Desert Alma (superhumid zone) and Beau Champ (humid zone) (Figure 1).

Although the soil at Mon Desert Alma has developed under the superhumid zone, its lower SOC stock compared to Beau Champ could be attributed to its lower silt plus clay content (59% at Mon Desert Alma v/s 83% at Beau Champ).

In the Cambisols, SOC stocks of uncultivated soils were similar, Medine (101.4 t C/ha) and Savannah (103.0 t C/ha), in spite of differences in rainfall regime and could be attributed to the higher silt plus clay content at Medine (81%) compared to Savannah (57%). Although a positive correlation between silt plus clay content and native SOC levels has been widely reported (Feller and Beare, 1997; Barthes et al., 2008), such a relationship was not consistent over all the soil groups of Mauritius.

In order to assess changes in SOC stocks between cropping systems, the SOC data for individual depth layers sampled were summed over two depth ranges (0–15 cm representing the topsoil and 15–50 cm representing the subsoil. In the Ferralsols, long-term sugarcane cropping decreased SOC stocks in the surface 0–15 cm layer by 24 t C/ha compared to the uncultivated virgin soil (representing 31% of the initial C stock) at Beau Champ. Similarly, surface C stock at Mon Desert Alma and Riche Terre declined by 6.3 and 4.9 t C/ha although these losses were not significant at $P<0.05$.

Further, the decline in topsoil organic C was accompanied by an increase in subsoil organic C of 15.3, 20.8 and 10.5 t C/ha respectively at Beau Champ, Mon Desert Alma and Riche Terre. These observations concord with the findings of McGarry et al., (1996) and Skjemstad et al., (1999) who reported a decline in organic carbon content in surface horizons but an increase in subsurface horizons after different periods of sugarcane cultivation in Australia. An accumulation of SOC in deeper soil layers under sugarcane has been attributed to rhizodeposition and continual turnover of root material at lower depth as evidenced by a higher proportion of sugarcane-derived C in the subsoil compared to topsoil organic matter as reported by De Resende et al., (2006).

However, our data on measurements of $\delta^{13}C$ in the present study showed that the topsoil was more depleted in native organic C than the subsoil (Table 2) suggesting that repeated ploughing resulted in a greater loss of original SOC and hence lower SOC stock.
Fig—1. Soil organic carbon stocks (t C/ha) in 0-15 and 15-50 cm depths under different cropping systems at the five study sites. (NV: land under natural vegetation; 50Y: >50 years sugarcane conventional practice; 25Y: 25 years sugarcane conventional practice; 3M: >50 years sugarcane conventional practice with recent mechanisation). For a given site and soil depth, bars with the same lower case letter were not significantly different at P= 0.05; bars with the same upper case letter indicate that SOC for the 50 cm profile were not significantly different at P= 0.05.

It could also be due to a downward redistribution of organic matter-rich topsoil due to tillage and disk harrowing carried out at the time of replanting (Maslica et al., 1986; McGarry et al., 1996) or to a vertical migration of organomineral complexes (Basile-Doelsch et al., 2009). In the Cambisols (Medine and Savannah), changes in SOC stocks in topsoil and subsoil resulting from long-term cane cultivation were not significant (P< 0.05).
Table 2—Proportion of sugarcane-derived C and loss of native C in 0–15, 15–50 and 0–50 cm depth layers after 25 years, > 50 years of sugarcane monoculture and recent mechanisation. Within one site, values along the same column followed by the same lower case letter were not significantly different at P > 0.05. Within one site, values along the same row followed by the same upper case letter were not significantly different at P > 0.05. 50Y: >50 years sugarcane monoculture; 25Y: 25 years sugarcane monoculture; 3M: >50 years sugarcane monoculture with recent mechanisation.

In this study, long-term sugarcane production resulted in a decline in SOC in the top 15 cm layer but not in total SOC stock in the 0–50 cm profile at any of the sites studied. Most previous reports of a decline in SOC under sugarcane cultivation have been based on measurements of SOC changes in the surface 10–20 cm depth layer only (Cerri and Andreux, 1990; Blair, 2000; Dominy et al., 2002) or over a short period of cane cultivation (e.g. Hartemink, 1998). On the other hand, Skjemstad et al., (1999) showed that SOC stock in the 0–80 cm profile did not decline as a result of long-term sugarcane cultivation in Australia.

Loss of original native C and incorporation of sugarcane-derived C

Although total SOC stocks in the 50 cm profile did not decline after long-term sugarcane cultivation, there was a marked depletion of the native SOC at all the study sites (Figure 2). The amount of native C lost ranged from 35 to 70% of the native C stock in the corresponding virgin soils (Table 3) and represented between 26 and 84 t C/ha. The highest loss of 70% was measured at Medine and could only partly be attributed to a decrease in soil clay content from an initial 63% in the virgin soil to 50% after >50 years of cane cropping. Although it is generally reported that clay and silt contents play an important role in the protection of SOC against mineralisation (Bationo and Buerkert, 2001; Bationo et al., 2007), a consistent relationship between the proportion of C lost and the soil clay content was not observed for all sites in the present study. Instead, factors such as climatic variations, mainly temperature, and cultural practices such as the frequency and intensity of tillage operations could have influenced the loss of native SOC.

Most of the loss in native C occurred in the surface 15 cm of soil, indicating that repeated tillage of topsoil at planting resulted in enhanced mineralisation of native C stocks. The measured losses of native carbon in this study were generally similar to values reported earlier. Thus Cerri et
al. (1985) showed that 50% of the original C$_3$–C in a Brazilian Ferralsol was lost during 12 years after conversion of forest to sugarcane production. The loss of native SOC was fully compensated by C inputs from sugarcane at all sites studied (Figure 2). This is in contrast to the generally reported net loss of total SOC due to a slower accretion of crop–derived C than the loss of native C (e.g. Dominy et al., 2002; Solomon et al., 2002).

Fig. 2—Native and sugarcane-derived soil carbon stocks in the surface 50 cm of soil at five sites. (NV: land under natural vegetation; 50Y: >50 years sugarcane conventional practice; 25Y: 25 years sugarcane conventional practice; 3M: >50 years sugarcane conventional practice with recent mechanisation). For a given site, bars with the same lower case letter indicate no significant difference (P> 0.05) in native C; bars with the same upper case letter indicate no significant difference (P> 0.05) in total C.

After >50 years of sugarcane cultivation, sugarcane–derived C constituted between 31 and 68% of the existing C in topsoil (0–15 cm), the remaining 32 to 61% being attributed to native C (Table 2). The proportion of sugarcane–derived C decreased with depth in the humid and superhumid soils, but was more uniformly distributed in the 50 cm profile of the subhumid zone. Roots constitute an important source of C in sugarcane farming systems (Suman et al., 2009) and the size and distribution of the root system is strongly influenced by the distribution and availability of soil water (Baran et al., 1974). The observed differences in distribution of sugarcane-derived C were presumably due to a lower root density in the generally water saturated layer of humid and superhumid soils at lower depths, compared to a more uniform distribution of roots down to the 50 cm depth in the subhumid soils.

Over the 50 cm profile, percent contribution of sugarcane-derived C to the total SOC stock varied from 32% at Riche Terre to 65% at Medine (Table 3). Cerri and Andreux (1990) found that sugarcane-derived C constituted 20% and 45% of the total SOC after 12 and 50 years respectively of sugarcane cultivation in a Brazilian Ferralsol. The data in Figure 2 suggest that accretion of
sugarcane-derived C was dependent on the amounts of original C lost and tended to continue until the initial level of SOC is restored.

The effects of period of sugarcane cultivation on SOC changes were studied at Medine and Riche Terre. At Medine, SOC declined by 33% (33.5 t C/ha) relative to the uncultivated land after 25 years of sugarcane (Table 3). With a longer period of cultivation (>50 years), native SOC declined further to reach about 31% of the initial value. Sugarcane-derived C represented about 33% of the total C stock after 25 years and increased to 65% after >50 years of sugarcane cultivation so that loss of native C was nearly totally compensated.

Table 3—Amounts of native SOC and sugarcane-derived SOC (t C/ha) under soils cropped for different lengths of time at Medine and Riche Terre.

Within one site, values along the same column followed by the same letter were not significantly different at P= 0.05.

Similar results have been reported by Dominy et al. (2002) who found that sugarcane-derived C in a Cambisol in South Africa increased over time until it accounted for 61% of total SOC in the surface soil after 50 years of sugarcane cultivation. However, in their study, the newly added C did not compensate the loss of original C. At Riche Terre, on the other hand, original SOC declined at a much slower rate so that, at 25 years, 82% of the existing SOC still had the original C signature, and this value decreased only slightly to 74% after more than 50 years of cane cultivation.

The difference in loss of original C between the two sites could be attributed to the lower initial clay content at Medine (63% compared to 75% at Riche Terre), which declined further with increasing period of cane cultivation. The importance of clay-organic matter associations as a mechanism for organic matter protection has been reported by a number of authors (e.g. Hassink, 1997; Feller and Beare 1997; Dieckow et al., 2009). Carbon inputs from sugarcane represented 29% of existing SOC after 25 years and adequately replaced the loss of native C at the Medine site.

While these results demonstrate that long-term sugarcane cultivation under the conditions in Mauritius does not have any detrimental effect on overall SOC stock, they also emphasise the importance of sugarcane crop residues in the rehabilitation of SOC under intensive sugarcane cropping. Although several studies have shown the beneficial effects of sugarcane trash retention on SOC (Graham et al., 2002; Robertson and Thorburn, 2007), few studies have quantified the actual contribution of sugarcane-derived C to the total SOC stock.

Effect of mechanised sugarcane cropping on soil carbon stocks

It was expected that the physical impact caused by intensive derocking and aggressive tillage in preparation for mechanisation would lead to a decline in SOC, as this will favour microbial activity through enhanced aeration and the exposure of formerly aggregate-protected SOC fractions (Wright and Hons, 2005; Zotarelli et al., 2007). However, mechanised cropping generally had no significant effect on topsoil or subsoil SOC stocks except at Beau Champ where total SOC declined by 37 t C/ha compared to the conventional practice (Figure 1).
The change from conventional to mechanised practice at this site was also accompanied by a decrease in the clay content from 66 to 42%. The lower SOC stock in the mechanised cropping system was presumably due to the lower clay content rather than mechanisation per se. Moreover, measurements of $\delta^{13}$C natural abundance showed that land preparation activities generally did not influence the loss of native C relative to the conventional practice except at Riche Terre and Beau Champ where land under mechanised cropping lost 24 and 16 t C/ha more C than under conventional practice (Figure 2 and Table 3). Likewise, mechanised cropping generally did not impact negatively on replacement of lost carbon by sugarcane-derived C except at Beau Champ where about 20 t C/ha less sugarcane-C was incorporated relative to the conventional practice.

**Conclusion**

Using the $\delta^{13}$C natural abundance technique, this study has demonstrated that long-term sugarcane cropping under the humid tropical climate of Mauritius resulted in significant decline in native SOC. However, losses of native SOC were adequately compensated by SOC input from sugarcane crop residues and root C turnover so that total SOC stocks in the profile generally remained unchanged.

The results further emphasise the importance of trash retention in restoring SOC under sugarcane farming systems in Mauritius. The adoption of mechanised cropping in recent years did not have any detrimental effect on soil organic carbon.

MOTS CLÉS : Carbone Organique Du Sol, Delta $^{13}$C, Production Durable De Canne à Sucre.

Resume

Le déclin de la capacité productive des sols suite à une monoculture à long terme de canne à sucre, associé à une intensification du système de production, est devenu le problème principal de plusieurs pays producteurs de canne à sucre. Le maintien du carbone organique de sol (SOC) à des niveaux adéquats est crucial pour le fonctionnement biologique, chimique et physique des sols. Cette étude a été entreprise pour déterminer l'impact de la monoculture à long terme de canne à sucre sur les stocks de SOC, pour mesurer la perte de SOC naturel et l'augmentation de C provenant de la canne à sucre suite à l'adoption des nouvelles pratiques culturaux, notamment l'épierrage, le nivellement et la récolte mécanique. Cinq sites représentatifs des cinq principaux groupes de sol cultivés en canne à sucre à l'île Maurice ont été étudiés et un dispositif classique de parcelles appariées a été adopté. Pour chaque site, deux emplacements ayant des conditions initiales semblables ont été traités de différentes manières dans le temps, avec un emplacement représentant le sol de référence (terre vierge avec principalement une végétation de type C3) et l'autre emplacement constitué des traitements suivants (i) champs cultivés sans interruption avec de la canne à sucre pendant plus de 25 ou 50 ans sans épierrage et nivellement, (ii) champs contenant de la canne à sucre cultivée sans interruption mais épierrés et nivelés pour permettre une récolte mécanique les 3 dernières années. Sur des échantillons de sol prélevés jusqu'à une profondeur de 50 centimètres ont été analysés le C organique total, l'abondance en $^{13}$C, la densité apparente et la teneur en pierre ou refus. La culture à long terme de canne à sucre a diminué les stocks de SOC dans la couche 0–15 cm par rapport au sol vierge non cultivé, mais a augmenté C organique du sol sous-jacent, indiquant une redistribution de SOC dans les couches plus profondes du profil de sol. Sur tous les sites, les évolutions des stocks totaux de C dans le profil 0–50 centimètres, après 50 ans de culture de canne n'étaient pas significativement différentes (P<0.05) de celles relatives à la terre vierge. La culture à long terme de canne à sucre a en fait eu comme conséquence un épuisement de SOC original de 34 à 70%. Cependant, cette perte a été entièrement compensée par les entrées de C issues des résidus de canne à sucre sur tous les sites étudiés, avec pour résultat aucun changement net des stocks de SOC. De plus, l'adoption de la culture mécanisée, qui nécessite l’épierrage et le nivellement, n'a eu aucun effet néfaste sur les stocks de SOC à cause des entrées de C provenant des résidus de récolte.
CAMBIOS EN LOS CONTENIDOS DE CARBÓNó ORGÁNICO DEL SUELO RESULTANTE DEL CULTIVO DE LA CAÑA DE AZÚCAR EN EL CLIMA TROPICAL HÚMEDO DE MAURITIUS: RESULTADOS DE ABUNDANCIA NATURAL DE $^{13}$C

PALABRAS CLAVE: Carbono Orgánico del Suelo, Delta $^{13}$C, Producción Cañera Sostenible.

Resumen

LA DISMINUCIÓN en la capacidad productiva de los suelos como consecuencia del monocultivo de la caña de azúcar a largo plazo, combinada con una intensificación del sistema de producción, se ha convertido en un problema grave en varios países productores de caña de azúcar. El mantenimiento de niveles adecuados de carbono orgánico del suelo (COS) es crucial para el funcionamiento biológico, químico y físico de los suelos. Este estudio se realizó para determinar el impacto a largo plazo del monocultivo de caña de azúcar en los niveles COS y cuantificar las pérdidas de COS nativo y la acumulación de C derivado de la caña de azúcar a causa de la adopción de nuevas prácticas de manejo como la eliminación de piedras, la nivelación y la cosecha mecanizada. El estudio se realizó en cinco sitios que representan los cinco principales grupos de suelos cañeros de Mauricio mediante la utilización de un diseño de parcela pareada. En cada una de las experiencias se evaluaron dos sitios con similares características iniciales, que se desarrollaron de forma diferente, uno en representación el suelo de referencia (campo virgen con predominio de vegetación de tipo C3) y el otro que representa los siguientes tratamientos de cultivo: (i) campos continuamente cultivada con caña de azúcar por más de 25 o 50 años sin eliminación de piedras o nivelación de los terrenos, (ii) campos de caña de azúcar a largo plazo, pero que hayan sido sometidos a la eliminación de piedras o nivelación de los terrenos para la cosecha mecanizada en los últimos 3 años. Se tomaron muestras de suelo a una profundidad de 50 cm y se analizó C orgánico total, abundancia de $^{13}$C, densidad aparente y el contenido de piedra. A largo plazo el cultivo de la caña de azúcar redujo las existencias de COS en la capa superficial de 0–15 cm en comparación con el suelo virgen sin cultivar, pero aumentó de C orgánico del subsuelo lo que indica una redistribución de la COS en las capas más profundas del perfil del suelo. Cambios en las existencias de C total en el perfil de 0-50 cm, después de 50 años de cultivo de caña no fueron significativos ($P <0.05$) en comparación con la tierra virgen en todos los sitios. Los datos de mediciones de la abundancia $^{13}$C revelaron que a largo plazo, el cultivo de caña de azúcar dio lugar a un agotamiento de COS original entre el 34 al 70%. Sin embargo, esta pérdida fue totalmente compensada por la entrada C de los residuos de la caña de azúcar en todos los sitios estudiados, sin cambio neto de las cantidades de COS en el suelo. Por otra parte, la adopción de la mecanización de cultivo, lo que implica la eliminación intensiva de piedras y nivelación de los terrenos, no tiene ningún efecto perjudicial sobre las cantidades de COS, debido al ingreso del C proveniente de residuos de la cosecha.
ASSESSMENT OF CHLOROPHYLL AND LEAF RELATIVE WATER CONTENT AS INDICATORS OF DROUGHT TOLERANCE ON SUGARCANE INITIAL GROWTH

KEYWORDS: Saccharum spp., Water Stress, SPAD Index, Photosynthetic Pigments, RWC.

Abstract

WATER deficiency is the major environmental stress that affects sugarcane production worldwide. Physiological traits associated with drought tolerance can be suitable indicators for screening of drought tolerance of sugarcane clones to reduce the negative effects on crop yield. The aim of this study was to evaluate the ability of physiological parameters to identify drought tolerant and susceptible sugarcane clones. These parameters included estimated leaf chlorophyll content via SPAD index, photosynthetic pigments (chlorophyll \(a\), \(b\), \(a + b\) and the ratio of chlorophyll \(a\)/chlorophyll \(b\)) and leaf relative water content (RWC). The experiment was carried out under greenhouse conditions. Eight clones (CP92-675, HoCP85-845, HoCP01-523, L01-283, TCP87-3388, TCP89-3505, TCP02-4620 and TCP02-4624) variable in drought tolerance were used to assess the relation between these parameters and drought tolerance. Drought stress was imposed by withholding irrigation for 21 days and then rewatering for 6 days on plants grown at 90 days after planting. The results showed that during the drought stress the parameters SPAD index, chlorophyll \(a\), \(b\), \(a + b\) and RWC showed a progressive reduction independent of clone, but the decrease was much less in CP92-675, HoCP01-523, TCP87-3388 and TCP89-3505. After rehydration, these clones recovered most rapidly from stress condition, although the initial values were not reached. HOCP85-845, TCP02-4624, TCP02-4620 and L01-283 showed a strong negative and residual effect of drought stress in terms of chlorophyll content and RWC, and L01-283’s photosynthetic apparatus was most damaged because this clone did not show response after rewatering. Among chlorophyll parameters, chlorophyll \(a / b\) ratio was little affected by water deficit in the clones HoCP01-523, TCP89-3505, TCP87-3388 and CP92-675. Results suggest that chlorophyll and RWC could be considered to differentiate between drought tolerant and susceptible clones. We concluded that clones CP92-675, HoCP01-523, TCP89-3505 and TCP87-3388 performed as tolerant, HoCP85-845, TCP02-4620 and TCP02-4624 as intermediate, and L01-283 as drought susceptible during the initial growth.

Introduction

Sugarcane is a crop of global importance and it is cultivated between the 32º North and South parallels. In many areas over the world, rainfall is not sufficient for crop supply and water deficiency can limit crop production. Depending on the deficiency level, specifically for the sugarcane crop, growth and yield can decrease and result in great socioeconomic losses (Munns, 2002).
Drought is a multi-dimensional stress, which causes various morphological, physiological and biochemical effects on plants. The identification of markers linked to drought tolerance could be a useful tool to manage and adapt the sugarcane crop to adverse conditions (Domaisingue, 1996; Blum, 1996; Jamaux et al., 1997).

The degree of limitation of yield by environmental stresses varies even among genotypes within every species (Wolfe et al., 1988; Aguilera et al., 1999). Therefore, the ability to maintain key physiological processes, such as photosynthesis during moderate drought stress, is indicative of the potential to sustain productivity under water shortage.

Some parameters can be used as reliable indicators to evaluate efficiency of the photosynthetic system and yield performance of genotypes under water deficit.

According to Schlemmer et al. (2005), the plant’s photosynthetic potential is directly proportional to the amount of chlorophyll present in the leaf tissue. Leaf relative water content (RWC) also seems to be positively correlated to the level of photosynthesis because the prevention of water stress needs a fine regulation of water loss, in order to maintain adequate CO₂ uptake (Colom and Vazzana, 2003). To our knowledge, little is known about changes in chlorophyll and relative water content under drought stress in sugarcane genotypes.

In this context, we studied the effects of water deficiency on chlorophyll and leaf relative water content of eight sugarcane clones differing in drought tolerance.

Materials and methods

Plant material and treatment

The experiment was carried out in a greenhouse belonging to Texas AgriLife Research/Texas A&M University, in Weslaco–TX–USA. We used isolated buds of eight sugarcane clones with varying drought tolerance—four tolerant varieties (HoCP85-845, HoCP01-523, TCP89-3505 and TCP02-4620) and four susceptible varieties (CP92-675, L01-283, TCP02-87-3388 and TCP02-4624).

Cane was planted in 22 L pots, filled with vermiculite-based substrate and 55 g of the NPK formula 14-14-14. During the experiment, average air temperature was 18.1–22.6°C, relative humidity was 60–70% and photosynthetic photon flux density (PPFD) was 600–800 µmol/m²/s. Plants were grown for 60 days after planting (DAP). After that period, water was not supplied for 21 days and then re-established for 6 days.

Evaluations

Physiological parameters were measured five times during the study: 0, 7, 14, 21 days after drought stress treatment (DAT) and again 7 days after relief of stress at 28 DAT.

Leaf chlorophyll content (SPAD index) was estimated nondestructively, using a SPAD-502 chlorophyll meter (Minolta Corp., Ramsey, New Jersey, USA).

This index was selected preferentially, due to the close relationship between the readings of the portable chlorophyll meter and leaf chlorophyll content (Markwell et al., 1995), and because it has been used as a reliable nondestructive tool for rapid screening for drought tolerance in sugarcane (Silva et al., 2007). The average of four measurements taken on the leaf + 1, i.e. first fully expanded leaf, from different plants in each plot was recorded.

For the evaluation of leaf chlorophyll and water content, four 1.3-diameter discs were taken from the leaf 1 of each plant with a cork borer and then stored in thermal boxes with ice.

Chlorophyll was extracted from two leaf discs submerged for 24 h in dimethyl formamide acid (DFA). The levels of \(a\), \(b\) and \(a + b\) chlorophyll and carotenoids were determined according to Porra et al. (1989), with absorbance optical analysis in spectrophotometer on wave lengths of 480, 647 and 664 nm (Beckman DU-6400). Chlorophyll \(a/b\) ratio was calculated with the values previously determined.
Both remaining discs were used to evaluate leaf relative water content (RWC). Leaf disk fresh weight (Wf) was determined within 2 h of excision. The turgid weight (Wt) was obtained after hydration in deionised water for 24 h at room temperature.

Leaf discs were quickly blotted dry and oven-dried for 48 h at 80ºC before recording the dry weight (Wd). RWC was calculated from the following equation (Matin et al., 1989):

\[
RWC = \left[ \frac{(W_f - W_d) \cdot (W_t - W_d)^{-1}}{W_t - W_d} \right] \times 100
\]

Statistics
The experimental design was a completely randomised design, arranged in 40 combinations, within a two-factor factorial 8 x 5, where the first factor consisted of eight clones and the second consisted of five evaluation dates (0, 7, 14, 21 and 28 DAT), with three replicates. Variance analysis was applied for statistical procedure. Clones and evaluation dates were compared by the Tukey test.

Results and discussion
The ANOVA revealed that estimated chlorophyll content (SPAD), leaf chlorophyll a (Chl a), leaf chlorophyll b (Chl b), total leaf chlorophyll (Chl a + b), ratio chlorophyll a/b (Chl a/b) and leaf relative water content (RWC) were significantly affected by clone (C) and evaluation date (ED). C x ED interactions were also found to be significant for all six parameters. These results are in agreement with the ones reported by Colom and Vazzana (2003) for another C4 grass, Eragrotis curvula.

Drought stressed plants showed a progressive reduction of estimated chlorophyll content (SPAD index), during drought development (Figure 1). Positive effects of clone on drought response were evidenced by different results for three groups of clones after 21 days of stress. Clones HoCP01-523, TCP89-3505, CP92-675 and TCP87-3388 had their SPAD indexes less affected by water deficit (~35.50–41.73 SPAD units), whereas clones HoCP85-845, TCP02-4620 and TCP02-4624 showed intermediate values (~17.27–26.33 SPAD units).

The clone L01-283 was the most affected by drought stress (10.10 SPAD units). During rewatering, SPAD index increased for all clones, except for L01-283, but clones from the intermediate group reached lower SPAD (~28.70–33.27 SPAD units) than clones HoCP01-523, TCP89-3505, CP92-675 and TCP87-3388 (~40.93–46.27 SPAD units).

Chlorophyll degradation is one of the consequences of drought stress and may result from sustained photo-inhibition and photo-bleaching (Long et al., 1994), and even though other plant processes, such as cell division and cell expansion, are the earliest to respond to water deficit stress (Dale, 1988), a decline in SPAD index is a sensitive and readily measurable trait that could be used to screen for stress tolerance (O’Neill et al., 2006).

Silva et al. (2007) reported that the tolerance-susceptibility classification of a clone cannot be related to the average chlorophyll content, but rather, to the extent of the chlorophyll degradation under a stressful condition.

Chlorophyll a, chlorophyll b and chlorophyll a + b showed similar results for the clones studied, either during drought stress or after water re-establishment. During drought, chlorophyll a decreased in all clones (Figure 2). After 21 days under withholding water, a significantly higher value of chlorophyll a was found in TCP 87-3388 (19.57 µg/cm²), and the lowest value in L01-283 (8.29 µg/cm²) and TCP02-4624 (8.54 µg/cm²).

All the other clones showed intermediate performance. Chlorophyll a increased during rewatering in all clones, except L01-283 which did not show any recovery. Among the clones that increased chlorophyll a, only HoCP01-523, TCP89-3505, TCP87-3388 and CP92-675 reached values close to those observed in the beginning of the experiment.
Similarly to the results for chlorophyll $a$, chlorophyll $b$ and chlorophyll $a+b$ decreased after drought for all clones. However, clones varied in degree of stress impact on chlorophyll $a$ and $a+b$ up to 21 days after water interruption and also at 6 days after water re-establishment (Figures 3 and 4). Similar results were observed by Pardo and Delgado (1989), who also reported different contents of chlorophyll $a$ and $b$ of two sugarcane clones under drought. These authors stated that the clone susceptible to drought immediately decreased chlorophyll rates. Therefore, according to the results of this work, the clone TCP87-3388 showed the lowest decrease of chlorophyll $b$ after 21 DAT (6.76 µg/cm$^2$). A lower value of chlorophyll $b$ was observed for the clone TCP89-3505 (3.49 µg/cm$^2$), but this material was not significantly different from HoCP85-845, HoCP01-523, L01-
Nevertheless, after water re-establishment, values of chlorophyll $b$ (Figure 3) and $a + b$ (Figure 4) were almost completely restored for the clone TCP89-3388. Additionally, chlorophyll $b$ and $a + b$ significantly increased for the clones HOCP01-523, CP92-675, TCP87-3505 and TCP02-4620. The clones HOCP85-845 and TCP02-4624 had intermediate restoration of chlorophyll values. Irreversible damage can be caused by drought in the integrity of photosynthetic pigments, and this was evidenced in the clone L01-283 that did not show any recovery after water re-establishment. Colom and Vazzana (2003) reported drought affecting chlorophyll content in leaves of *Eragrotis curvula* and the susceptible clone showed the largest reduction.

![Fig. 3](image1.png)

**Fig. 3**—Mean chlorophyll $b$ ($n = 3$, ±S.E.) measured at 0, 7, 14, 21 and 28 days after onset of the drought experiment in eight sugarcane clones.

![Fig. 4](image2.png)

**Fig. 4**—Mean chlorophyll $a + b$ ($n = 3$, ±S.E.) measured at 0, 7, 14, 21 and 28 days after onset of the drought experiment in eight sugarcane clones.

Chlorophyll $a / b$ ratios responded distinctively depending on the clones under water deficiency (Figure 5). The clones HoCP01-523, TCP89-3505 and CP92-675 showed constant results, around 3.0–3.5 during all the period. For the clones HoCP85-845 and TCP87-3388, this
ratio was constant up to 14 DAT, and slightly decreased, up to 21 DAT, to about 2.8–3.0, increasing after water re-establishment, until reaching the initial values. As for the clones TCP02-4620 and TCP02-4624, the ratio was also constant up to 14 DAT, but decreased to 2.0 between 14 and 21 DAT.

![Graph](image)

**Fig. 5**—Mean ratio chlorophyll \(a\)/chlorophyll \(b\) (\(n = 3, \pm S.E.\)) measured at 0, 7, 14, 21 and 28 days after onset of the drought experiment in eight sugarcane clones.

The clone L01-283 showed chlorophyll values similar to the initial ones up to 7 DAT, decreasing to 2.0 between 7 and 21 DAT, and values increased after water re-establishment up to the initial value. According to the results, it is possible to infer that tolerant clones show a mechanism of defence against drought, keeping chl \(a\)/chl \(b\) ratio about 3.0–3.5. A second group of clones show this ratio up to 14 DAT, and they could be considered intermediately tolerant. The sensitive clones would be the ones that do not show the established values during drought.

Contradictory results can be found in literature, in relation to effects of water deficiency on the chlorophyll \(a\)/\(b\) ratio. Pardo and Delgado (1989) concluded that the chl \(a\)/chl \(b\) ratio decreased for sugarcane clones that were tolerant to drought due to an increase in the chlorophyll \(b\) content, as a possible mechanism of defence. Other authors showed that this ratio was not affected neither for tolerant nor susceptible clones of *Eragrostis curvula* under water deficiency (Colom and Vazzana, 2003).

RWC reduced as drought evolved, but the response differed among clones (Figure 6). After 21 DAT, the clone HoCP01-523 showed lower decrease in RWC values (81.2%), followed by the TCP89-3505 (78.5%) and HoCP85-845 (76.5%).

Lower values were observed for the clones L01-283 (60.3%) and TCP02-4624 (63.5%). During water re-establishment, RWC values increased for all clones. The clones HoCP01-523, HoCP85-845, TCP02-4620, TCP89-3505 and TCP87-3388 reached the values reported before drought. The clones CP92-675 and TCP02-4624 intermittently restored the original values, whereas, L01-283 showed the lowest results (70.6%).

The characteristic of maintaining a higher amount of water in the leaves during drought results in higher tolerance for some clones, because the higher capacity of saving water does not limit the CO\(_2\) absorption so much and, consequently, the efficiency of the photosynthetic process, due to better preservation of the integrity of the PSII system (Maxwell and Johnson, 2000). Then, it can be inferred that the clones with lower decrease in the RWC and higher capacity to restore the
initial conditions after water re-establishment can be considered tolerant. Besides, Silva et al. (2007) reported that drought tolerance was found to be positively correlated to RWC in sugarcane under drought conditions. Therefore, this parameter might be used as a selection criterion to differentiate sugarcane clones under drought stress.

The present study showed that it is possible to distinguish sugarcane clones under water deficiency conditions during initial growth measuring chlorophyll and leaf relative water content. Therefore, these traits could be considered as useful tools during the crop breeding procedure in order to make this process faster and cheaper. Besides, this information should be used in hybridisation programs to find parents with greater ability to transfer drought tolerance genes as expressed in different agronomic traits.

In conclusion, according to the results of this experiment, it was possible to separate the eight clones studied into three groups. The clones CP92-675, HoCP01-523, TCP89-3505 and TCP87-3388 showed lower chlorophyll degradation and higher capacity to preserve water in the leaves during the initial growth; so, they can be considered as tolerant to drought. The clones HoCP85-845, TCP02-4620 and TCP02-4624 were intermediately tolerant, whereas, the L01-283 was susceptible to drought due to irreversible chlorophyll degradation.

Résumé

Le manque d’eau est le stress environnemental principal qui affecte la production de canne à sucre dans le monde entier. Les caractéristiques physiologiques directement liées au stress hydrique sont des indicateurs appropriés pour le criblage de variétés de canne à sucre tolérantes à la sécheresse. Le but de cette étude était d’évaluer la capacité de ces paramètres physiologiques à identifier des variétés de canne tolérantes ou sensibles à la sécheresse. Ces paramètres incluaient la teneur estimée en chlorophylle des feuilles à l’aide de l’indice SPAD, les pigments photosynthétiques (chlorophylles $a$, $b$, $a + b$ et le rapport $a/b$) et la teneur en eau relatives des feuilles (RWC). L’expérience a été effectuée sous serre. Huit variétés (CP92-675, HoCP85-845, HoCP01-523, L01-283, TCP87-3388, TCP89-3505, TCP02-4620 et TCP02-4624) de tolérance variable à la sécheresse ont été employées pour évaluer la relation entre ces paramètres et tolérance de sécheresse. Sur des cannes plantées âgées de 90 jours, un stress hydrique fut appliqué en arrêtant l’irrigation pendant 21 jours, puis en puis en irrigant de nouveau pendant 6 jours. Pendant le stress hydrique, une diminution progressive de l’indice de SPAD, des chlorophylles $a$, $b$, $a + b$ et du RWC a été observée quelque soit la variété. Cependant la diminution fut moindre pour les variétés CP92-675, HoCP01-523, TCP87-3388 et TCP89-3505. Après réhydratation, ces 4 variétés récupérèrent plus rapidement, bien que les valeurs initiales des paramètres ne furent pas atteintes. HoCP85-845, TCP02-4624, TCP02-4620 et L01-283 ont montré un effet négatif et résiduel élevé du stress hydrique en termes de teneur en chlorophylle et RWC. Le système photosynthétique de L01-283 fut le plus endommagé, cette variété n’ayant pas montré de réponse lors de la remise en eau. Parmi des paramètres liés à la chlorophylle, le rapport des chlorophylles $a/b$ a été peu affecté par le stress hydrique chez les variétés HoCP01-523, TCP89-3505, TCP87-3388 et CP92-675. Ainsi la chlorophylle et RWC pourraient être considérés comme des paramètres capables de différencier des variétés sensibles et tolérantes à la sécheresse. Nous en avons conclu que les variétés CP92-675, HoCP01-523, TCP89-3505 et TCP87-3388 étaient tolérantes, HoCP85-845, TCP02-4620 et TCP02-4624 intermédiaires, et L01-283 sensible à la sécheresse pendant la croissance initiale.
EVALUACIONES DE CLOROFILA Y CONTENIDO RELATIVO DE AGUA EN LA HOJA COMO INDICADORES DE TOLERANCIA A LA SEQUÍA DURANTE EL CRECIMIENTO INICIAL DE LA CAÑA

Resúmen

LA DEFICIENCIA de agua es el estrés ambiental más importante que afecta a la producción mundial de caña de azúcar. Las características fisiológicas asociadas con la tolerancia a la sequía pueden ser usadas como indicadores de la tolerancia a la sequía de los clones de caña de azúcar y de esta manera reducir los efectos negativos sobre el rendimiento del cultivo. El objetivo de este estudio fue evaluar la utilidad de usar parámetros fisiológicos para identificar clones de caña de azúcar tolerantes y susceptibles a la sequía. Estos parámetros incluyeron contenido estimado de clorofila en las hojas calculado por índice SPAD, pigmentos fotosintéticos (clorofila A, B, A + B y la relación de la clorofila a / clorofila b) y el contenido relativo de agua en la hoja (RWC). El experimento se llevó a cabo bajo condiciones de invernadero. Ocho clones (CP92-675, HoCP85-845, HoCP01-523, L01-283, TCP87-3388, TCP89-3505, TCP02-4620 y TCP02-4624), variables en cuanto a tolerancia a la sequía fueron utilizados para evaluar la relación entre estos parámetros y tolerancia a la sequía. El estrés hídrico fue impuesto por deprivación de riego por 21 días y posterior irrigación durante 6 días a plantas de 90 días de edad. Los resultados mostraron que durante el periodo de stress por sequía los parámetros índice SPAD, clorofila A, B, A + B y RWC mostraron reducción progresiva independientemente del clon, pero la reducción fue mucho menor en CP92-675, HoCP01-523, TCP87-3388 y TCP89-3505. Después de la rehidratación, estos clones se recuperaron más rápidamente de la condición de estrés, aunque los valores iniciales no fueron alcanzados. HOCP85-845, TCP02-4624, TCP02-4620 y L01-283 mostraron un efecto residual negativo causado por la fuerte sequía en términos de contenido de clorofila y RWC, y el aparato fotosintético de L01-283 fue el más dañado ya que este clon no mostró respuesta después del riego. Entre los parámetros de la clorofila, la relación clorofila a / b fue poco afectada por el déficit de agua en los clones HoCP01-523, TCP89-3505, TCP87-3388 y CP92-675. Los resultados sugieren que la clorofila y la RWC podrían ser considerados para diferenciar entre clones tolerantes y susceptibles a la sequía. Concluimos que los clones CP92-675, HoCP01-523, TCP89-3505 y TCP87-3388 se comportaron como tolerantes, HoCP85-845, TCP02-4620 y TCP02-4624 como intermedios, y L01-283 como susceptible a la sequía durante su crecimiento inicial.
TRASH MANAGEMENT AFTER GREEN CANE HARVESTING AND ITS EFFECT ON PRODUCTIVITY AND SOIL RESPIRATION

KEYWORDS: Crop Residues, Sustainability, Soil Organic Matter, Carbon Dioxide Emission.

Abstract

A LONG-TERM trash management experiment is in progress at Cenicañas´ experiment station to evaluate the effect of continual retention of cane residues on the soil surface after green cane harvesting. The soil is a Mollisol with medium organic matter content (3.6%), high content of P (42 ppm) and K (0.46 cmol/kg) at the beginning of the study. Three trash loads of residues produced by the crop were evaluated: zero, single and double load of fresh residues were retained or removed from the soil surface of each treatment. To evaluate the nutrient supply from each load of residues, six fertiliser doses of N (0–200), P (0–75) and K (0–90) kg/ha were applied. During the plant crop, all treatments yielded close to 150 t/ha. After the eighth crop cycle, the plots without trash retention and without fertiliser application yielded 80 t/ha. The presence of residues or the application of fertilisers increased cane yield by 30 t/ha, while the combination of residues and the application of fertilisers maximised the yield up to 160 t/ha. In general, the cane yield of the trash loaded treatments tended to increase as the dosage of NPK was higher. As an indicator of soil microbial activity and crop metabolism, CO\(_2\) fluxes from the soil surface were measured just before harvest of the seventh ratoon and two more times at 75 and 93 days in the eighth ratoon crop. CO\(_2\) gas emissions from plots with single and double load of residues were three fold (303 mg/m\(^2\)/h) of the plots without trash retention (115 mg/m\(^2\)/h). The following two CO\(_2\) samplings detected lower emission rates but the pattern was similar to the sampling before harvest. From the results obtained up to now, it is concluded that higher fertiliser doses are not enough to compensate for the negative effect of residue removal from cane fields.

Introduction

The long-term maintenance of soil chemical, physical and biological fertility in soils devoted to sugarcane production depends largely on the management of the crop residues. Leaving the sugar cane residues after green cane harvesting on the soil surface, a large proportion of the nutrients removed in the biomass during the crop cycle will return to the soil. Sugarcane is a crop with high soil nutrient extraction. In the aerial biomass (leaves, leaf sheaths and stems) of the cane variety CC 85-92 under typical production conditions prevailing in Valle del Cauca, the total nutrient extraction observed was 136, 31 and 245 kg/ha of N, P and K respectively per 100 tonnes of cane stalks (CENICAÑA, 2009). From the total extraction of major elements in the aerial biomass, 57, 9 and 103 kg/ha of N, P and K stay in the field in crop residues (leaves and leaf sheaths). From a nutritional point of view, it is important to highlight the importance of the nutrient return to the soil. Nutrients in the crop residues represent 42% of N and K and 29% of P present in the total aerial biomass (leaves, leaf sheaths, and stems) to produce 100 tonnes of cane stalks in this area. Among the benefits achieved by a proper waste management are: reduction of erosion by wind
and water, increased soil organic matter (SOM), increased retention of water available to plants and increase in beneficial organisms (Andrews, 2006). Despite the benefits of keeping crop residues in the field, the effects vary between sites so, in some production systems with high incorporation of crop residues in the temperate zone, an increase in diseases and low seed germination has been reported (Linden *et al.*, 2000). A trash blanket is a positive factor in well-drained soils because better soil moisture conservation allows high water use efficiency by the crop. However, the advantage of a trash blanket can turn into a problem in areas with poorly drained soils where the trash cover can increase problems derived from waterlogging (Wood, 1991).

Increased microbial biomass is a good indicator of SOM dynamics because it responds rapidly to changes in C supply and differences can be detected as they can be measured by the total organic matter content (Gregorich *et al.*, 1997). One way to assess the soil microbial activity and root system respiration is to measure CO$_2$ emission from the ground which is a good indicator of the agro-ecosystem metabolism (Ryan and Law, 2005). It is estimated that nearly half of soil respiration is produced by metabolic activity to maintain and develop roots and associated mycorrhizae (Hanson *et al.*, 2000; Hogberg *et al.*, 2001). Most of the remainder is associated with the respiration of heterotrophic microbial communities that use organic matter as an energy substrate (Trumbore, 2000; Giardina *et al.*, 2004). Therefore, CO$_2$ emission is a good index to indirectly measure soil microbial activity and crop physiology.

Faced with the imminent stopping of the sugarcane burning practice before harvesting in Valle del Cauca, the need to know the long-term impact of sugarcane residues from green cane harvesting on the physical, chemical and biological soil fertility is crucial. In 2000, Cenicaña set up an experiment to be continued for an indefinite period, under three different management schemes of crop residues. At present, this experiment is starting its tenth cropping cycle, and this paper provides a summary of cane productivity from the plant to the seventh ratoon crop harvested and a preliminary view of SOM content.

**Material and methods**

The experiment was established in lot 19 of the Experimental Station San Antonio (EESA) of Cenicaña. The soil is classified as Cantarina (Pachic Vertic Haplustoll), fine textural family (IGAC-CENICAÑA, 2006) 6H1 agroecological zone (CENICAÑA, 2006) with pH near neutrality, medium content of SOM (3.63%) and high P content (42 ppm) and exchangeable K (0.46 cmol/kg). The sugarcane variety planted was CC 85-92. The lot was divided into three equal parts and in each of them we established three management schemes of crop residues. At present, this experiment is starting its tenth cropping cycle, and this paper provides a summary of cane productivity from the plant to the seventh ratoon crop harvested and a preliminary view of SOM content.

The experiment was established in lot 19 of the Experimental Station San Antonio (EESA) of Cenicaña. The soil is classified as Cantarina (Pachic Vertic Haplustoll), fine textural family (IGAC-CENICAÑA, 2006) 6H1 agroecological zone (CENICAÑA, 2006) with pH near neutrality, medium content of SOM (3.63%) and high P content (42 ppm) and exchangeable K (0.46 cmol/kg). The sugarcane variety planted was CC 85-92. The lot was divided into three equal parts and in each of them we established three management schemes of crop residues. All the trash was removed (TR) from one of the thirds and placed in another third to accumulate into a double load (DL) of residues arranged following a pattern of two inter-row spaces with residues and two without residues.

The last third was left with the single load (SL) of residues arranged following a pattern of two inter-rows with residues and one inter-row without residues. Each third assigned to a trash management scheme was divided in three equal areas to be used as replications. Each replication was sub-divided into six plots consisting of 10 rows of 12 metres in length, with 1.5 m between rows. In each of the plots, one of six doses of N, P and K as fertilisation treatments was applied. Three treatments consisted of three levels of N-P-K (low, medium, and high), two with the medium level of N and without P or K, and one treatment with no application of fertilisers.

The fertilisation treatments were randomised according to a complete block design within each area of residue management. Soil tillage during ratoon crops was limited to cultivation between rows to control weeds and to incorporate the fertiliser applied. Statistical analysis was done separately for each area representing a scheme of crop residues management. An analysis of variance using the mixed procedure (SAS, 2008) was performed in order to detect differences in productivity parameters under the six fertilisation treatments applied into each one of the three areas with different trash management schemes.
Fertilisation treatments were applied 45 days after planting or harvest with the exception of P and K which were applied to the bottom of the row before plant cane sowing. Population density and stem height were evaluated at 3, 4.5 and 6 months after planting. At the same time, leaf tissue samples were taken to evaluate foliar content of major and minor elements. Crop cycle length was about 13 months. Height of millable stalks was measured prior to harvest and a sample of millable stalks was taken to the laboratory for juice analysis. At the beginning of the experiment and after each harvest, four soil samples 0–20 cm depth were taken and bulked to represent each plot. Soil samples were analysed for pH, SOM, P, Ca, Mg, and Na. At plant cane harvest, soil texture was determined from the soil sampling.

This paper reports on cane yield (TCH), sucrose % cane (SPC) determined by the direct analysis of cane method (DAC) and soil organic matter (SOM) determined by the dichromate methodology (Walkley and Black, 1934), during eight crop cycles. Emission of carbon dioxide (CO2) from samples taken two days before the harvest of the eighth cycle, and two more at 75th and 93rd days of the ninth cycle was also recorded. Gas samples were taken in plots fertilised with 150-50-60 kg/ha of NPK inside of each one of the trash management schemes. In each of the sampled plots, 2 PVC chambers were installed (one between rows and one in-row), and a sequence of four samples of gases at intervals of 0, 10, 20 and 30 minutes were taken. Gas samples were analysed with a CO2 gas analyser with NaOH and silica gel trap.

**Results and discussion**

In areas with single (SL) and double trash (DL) loads, average TCH over the eight crop cycles resulted in lower cane production under no fertilisation treatments (Table 1). Although, in the area with a double trash load, the difference in cane production among treatments with varying fertilisation was not significant, it followed a similar pattern to cane production under single trash load where differences were significant at 6% level (Table 1). The negative effect of crop residues removal (TR) on fertiliser efficiency is evident by the no response of TCH to the increase of NPK dose and the highly significant difference among plots with fertiliser application and plots without fertiliser application (Table 1).

Under the single trash load scheme, there were no differences in TCH between plots applied with the lowest dose of NPK, plots without K application, and plots without fertiliser application suggesting a suboptimal NPK dose as limiting to cane production. Sucrose content was reduced significantly with no application of fertilisers under single and double trash loads, while no difference between fertilised and non-fertilised plots was visible under the trash removal (TR) treatment (Table 1). The trend to higher PSC observed in plots with trash removal could be attributed to crop stress due to lower use efficiency of fertilisers caused by the lack of the synergistic effect of crop residues left on the soil.

Means followed by different letter are statistically different to the indicated level. Mean separation by Least Squares Means procedure.
No difference in soil organic matter (SOM) under different trash management schemes or fertiliser treatments was detected and the expected effect of trash removal on SOM was not evident (Table 1). This could be explained by the soil sampling depth used in this experiment (20 cm) and the relatively short life time (10 years). After 59 years, in the long-term experiment located at Mount Edgecombe, difference in organic carbon (OC) from plots with trash burnt before harvest and plant tops raked off (4.3% OC) and plots with green cane harvest with trash retention (5.1% OC) were evident at a depth as far as 5 cm and almost disappeared at 10 cm (Graham et al., 2002).

Based on the factors tested in this experiment, three scenarios could be defined as follows: plots without addition of crop residues or fertilisers, plots with addition of fertilisers or crop residues, and plots with addition of both fertilisers and crop residues. By plotting the results of the cane yield (TCH) under these three scenarios (Figure 1) it has been possible to describe three different situations through to the eighth ratoon crop. Plots without crop residues and without fertilisers (TR – F) had a descending trend in cane yield from about 140 t/ha at plant cane to 80 t/ha at the seventh ratoon. This clearly descendent pattern could be attributed to deterioration of chemical, physical and biological soil fertility.

Contrasting with this situation, treatments with trash and fertiliser application (SL + F and DL + F) diminished their TCH until the third ratoon crop but, after that, a clear uprising pattern was observed until the eighth ratoon crop when a similar cane yield to the plant cane was reached again. This situation shows how important for the sugarcane system to include crop residues with fertiliser addition in order to achieve a synergetic effect that allows the crop to recover productivity levels as high as those of the plant cane (Figure 1). An intermediate situation in terms of TCH was achieved when crop residues or fertilisers were applied individually (SL – F, DL – F and TR + F), cane yield decreased from 150 – 165 t/ha in plant cane to a relatively steady TCH of approximately 125 t/ha from the third to the eighth ratoon crop (Figure 1). It highlights that it is not possible to compensate the negative effect of trash removal by addition of synthetic fertilisers even when applied at higher rates. Furthermore, it was clearly demonstrated that crop residues have not just an effect on chemical fertility but they can also impact positively on physical and biological soil factors.

![Fig. 1—Cane yield (TCH) under three trash management schemes, single load (SL), double load (DL), and trash removal (TR) combined with application (+F) or not (–F) of fertilisers.](image)
Emission of CO$_2$ from plots with double and single trash load was systematically higher than that from plots with trash removal suggesting increased microbial activity and crop physiology enhanced by the crop residues left on the field during eight consecutive crops (Figure 2).

This fact is coincident with the higher crop productivity observed in plots with combined application of residues and fertilisers (Figure 1).

The downshift in emission of CO$_2$ observed 75 days after harvest as compared with the emission rate observed just before harvest could be mainly due to decreased root respiration caused by the interruption of all physiological crop processes after cane cutting (Figure 2).

After cane harvest, a renewed root system starts growing during the succeeding ratoon and this was reflected by the gradual increase of CO$_2$ emission rate observed between the 1$^{st}$ and 19$^{th}$ of June (Figure 2).

Higher CO$_2$ emission from plots with combined trash and fertiliser application (Figure 2) was expected because their higher biomass production (Figure 1) and increased C input by trash application as compared with plots where trash removal was done.

The beneficial effect of crop residues from sugarcane on soil health and crop productivity is shown by the results of this experiment. Under the environmental conditions of this experimental site, it was observed that productivity and sustainability of the system in terms of TCH, was achieved only with treatments where trash was left on the ground and additional fertiliser was applied.

Until the eighth ratoon crop, individual application of crop residues or fertilisers even at high rates, were not sufficient to match the productivity of plots in which fertilisers and crop residues were applied simultaneously.

In plots with trash removal without fertiliser application, productivity declined significantly. This experimental site will be maintained and monitoring will continue indefinitely in order to quantify the long-term effect of continuous addition of crop residues after green harvesting on sugarcane production and soil health.

MOTS-CLÉS: Résidus de Récolte, Durabilité, Matière Organique du Sol, Émission de Dioxide de Carbone.

Abstract
UNE EXPÉRIENCE à long terme concernant la gestion du paillis a été entreprise sur la station expérimentale de Cenicañas pour évaluer l'effet de la conservation des résidus de récolte sur la surface du sol après la récolte en vert de la canne. Le sol est un Mollisol comportant un taux moyen de matière organique (3.6%), une teneur élevée en P (42 ppm) et en K (0.46 cmol/kg) au début de l'étude. Trois doses de paillis produit à la récolte ont été évaluées : aucun paillis, deux doses simple et double de résidus frais ont été enlevées ou maintenues à la surface du sol sur chaque traitement. Pour évaluer l'apport nutritif de chaque dose des résidus, six doses d'engrais en kg/ha de N (0-200), de P (0-75) et de K (0-90) ont été appliquées. En canne plantée, tous les traitements ont produit à peu près 150 t/ha. Après le huitième cycle de récolte, les parcelles sans paillis et sans application d'engrais ont produit 80 t/ha. La présence des résidus ou l'application des engrais a augmenté le rendement en canne de 30 t/ha. L'association des résidus et des engrais ont produit des rendements maximum atteignant 160 t/ha. Généralement les rendements des traitements avec paillis étaient supérieurs car la dose effective de NPK était plus élevée. Comme indicateur d'activité de sol et du métabolisme microbien, les flux de CO2 provenant de la surface du sol ont été mesurés juste avant la récolte de la septième repousse et 75 et 93 jours après cette récolte. Avant récolte, les émissions de CO2 des parcelles ayant reçu des doses simple et double de paillis furent trois fois supérieures (303 mg/m²/h) à celles des parcelles sans paillis (115 mg/m²/h). Les deux prélèvements suivants ont révélé des taux inférieurs d'émission de CO2 mais avec des rapports identiques à ceux mesurés avant récolte. Des résultats obtenus jusqu'ici, on peut conclure que les doses plus élevées d'engrais ne sont pas suffisantes pour compenser l'effet négatif de l'enlèvement des résidus.

MANEJO DE LOS RESIDUOS DE COSECHA EN VERDE Y SU EFECTO SOBRE PRODUCTIVIDAD Y RESPIRACIÓN DEL SUELO

Resúmen
UN EXPERIMENTO a largo plazo sobre manejo de residuos está en marcha en la estación experimental de Cenicaña para evaluar el efecto de la retención o remoción continua de los residuos de cosecha en verde de la caña. El suelo es un Mollisol con contenido medio de materia orgánica (3.6%), altos contenidos de P (42 ppm) y K (0.46 cmol/kg) medidos al comienzo del estudio. Tres cantidades de residuos producidos por el cultivo fueron evaluadas: remoción total, carga sencilla y carga doble de residuos frescos fueron aplicados al suelo en cada tratamiento. Durante la plantilla,
todos los tratamientos produjeron alrededor de 150 t/ha de caña. Después de la octava soca, las parcelas sin residuos y sin aplicación de fertilizantes produjeron 80 t/ha. La presencia de residuos o la aplicación de fertilizantes incrementó la producción de caña en 30 t/ha, mientras la combinación de residuos y la aplicación de fertilizantes maximizó la producción hasta 160 t/ha. En general, la producción de caña de los tratamientos con retención de residuos tendió a incrementarse cuando la dosis de NPK fue más alta. Los flujos de CO₂ desde la superficie del suelo fueron medidos justo antes de la cosecha de la séptima soca y dos veces más a los 75 y 93 días de la octava soca. La emisión de CO₂ desde las parcelas con carga sencilla y doble de residuos fue casi el triple (303 mg/m²/h) de la de las parcelas sin residuos (115 mg/m²/h). En los siguientes dos muestreos se detectaron tasas de emisión menores pero el patrón fue similar al del muestreo de antes de la cosecha. De los resultados obtenidos hasta ahora, se concluye que altas dosis de fertilización no son suficientes para compensar el efecto negativo de la remoción de residuos de los campos de caña.
EFFECTS OF LOCATION AND TIME OF HARVEST ON YIELDS OF THE THREE MAIN SUGARCANE VARIETIES IN MEXICO

KEYWORDS: Sugarcane, Harvest Scheduling.

Abstract

In México, during the past three years, a mean 650 000 hectares of sugarcane were cultivated, which delivered more than 46.5 Mt of cane with a maximum commercial cane sugar content of 11.43 to 57 sugar mills, distributed throughout the Pacific Ocean Coast, a transversal belt around parallel 19 and the Mexican Gulf Coast. In this diversity of climates and soils, more than 20 varieties are cultivated, but approximately 65% of the area is planted with three varieties: Mex 69-290, CP 72-2086 and Mex 79-431. In order to determine accurately the effects of time of harvest on these three varieties for optimum harvest scheduling, two field trials were planted in October 2003, with the three varieties mentioned above in two highly contrasting localities in climate and soil, within the country's main sugarcane region. The trials were harvested at six times during the December/2004 – May/2005 harvest season. In the dry zone, cane yield was highest early in the harvest season, in December, January and February, while yields declined from March. In contrast, in the moist zone, the harvest season began with a trend of low cane yields in December and January, reached a maximum in February and March, and again declined during April and May. Reducing sugars in the dry zone showed, in CP 72–2086, low values early in the harvest season, which began to increase significantly in March and maintained high values until the end of the harvest season in May; Mex 69–290 recorded high values in December, which decreased in January, February and March, and increased again in April and May; while Mex 79–431 maintained low values from December to March, with a trend to increase from April. The principal components analysis demonstrated the important effects of locations on cane and sugar yields and time of harvest, the influence of the environment on varietal yields, and verified the dependence of cane yield on its components stalk population, length and diameter. Negative correlations between yield component variables and moisture, reducing sugars and fibre were also found.

Introduction

Nationwide sugarcane cultivation in Mexico occupies approximately 650 000 ha, with an average cane yield of 70.43 t/ha. The State of Veracruz is the largest cane and sugar producer, comprising 22 sugar mills, which crushed 17 797 093 tonnes of cane, with a total sugar output of 1 991 991 tonnes in the 2006–2007 harvest season.

El Potrero Sugar Mill stands out for its high factory efficiency, processing 1 477 426 tonnes of cane, in an area of 20 788 ha, with a sugar output of 187 821 tonnes, thus generating significant economic activity in the region (Manual Azucarero Mexicano, 2008). Two main sugarcane agro-ecological regions can be distinguished in El Potrero: the critical (dry) rainfed zone and the moist rainfed zone.
The main varieties cultivated in the ‘El Potrero’ mill supply area, according to maturity period, are as follows: early-season CP 72 2086 (26.54%), CP 44-101 (9.23%), and others (6.26%); and intermediate-season: Mex 69-290 (36.23%), Mex 79-431 (8.25%), Mex 68 P-23 (4.54%), and others (8.95%) Thus the El Potrero acreage consists of 42.03% of early-ripening and 57.97% of intermediate–ripening varieties. The two main varieties in the ‘El Potrero’ mill supply area are: Mex 69-290 and CP72-2086, which represent 62.77% of the sugarcane cultivated land, hence the need to study the influence of age and time of harvest of these varieties on cane and sugar yields, in the two agro-ecological zones that exist in the mill's supply area.

Materials and methods

General aspects of the trials

The experimental work was carried out in two locations of the ‘El Potrero’ sugar mill, a dry zone, with annual rainfall below 1100 mm, and a moist zone, with approximately 1900 mm of rainfall. The three main varieties grown in the mill areas: CP 72-2086, Mex 69-290 and Mex 79-431, were used in the plant cane cycle. The trials were planted in the two locations in October 2003 and were harvested at six different times from December 2004 to May 2005.

Location 1: Dry zone

Trial 1 was planted at Barrabas Farm located at 19º01’6.5’ N 96º33’58.3’ W, at 260 metres above sea level, in the central zone of the State of Veracruz,. The climate type at this location is Aw 1 (w) warm sub-humid, intermediate between Aw0 and Aw2, with a R/T (index which results from dividing annual rainfall, expressed in millimetres, by the annual mean temperature in °C) between 43.2 and 55.3, and a percentage of winter rainfall below 5.

Maximum temperature averages 31.35°C, and minimum temperature 19.6°C with a mean temperature of 25.7°C, and a mean annual rainfall of 1085 mm. (Irrigation Department, 2008). The trial was planted on Vertisol soil.

Location 2: Moist zone

Trial 2 was planted in the municipality of Atoyac, located in the central, mountainous zone of the State of Veracruz, at 18º53’42.1’ N and 96º47’12.4’ W, at an altitude of 511 metres above sea level.

The climate is warm-moist-regular, with a maximum temperature of 29.73°C, a minimum temperature of 18.99°C and a mean temperature of 24.59°C. Mean annual rainfall is 1866 mm. The trial was planted in an Acrisol type soil (Irrigation Department, 2008).

Varieties studied

CP 72-2086 (Parents: CP 62-374 X CP 63-588)

CP 72-2086 has recorded good germination and tillering, fair trashing, and early and heavy flowering. Mean cane yields of CP 72-2083 were 102 and 90.6 t/ha in plant cane and ratoon, respectively (Marin and Velasquez, 1997; Flores, 2001).

Its mean sucrose (pol) percent cane is 14.49% and the fibre content is 13.1%. It is resistant to Smut and Rust, moderately resistant to Mosaic, and susceptible to stem borer attack and to Orange Rust.

Mex 69 290 (parents: Mex 56-476 X Mex 53-142)

Mex 69-290 has recorded fair germination, early tillering and good growth, and fair trashing. Its leaves remain attached to the stalk and are easily removed by hand. It is resistant to lodging, but susceptible to stalk breakage by strong winds.

Mex 69-290 exhibits little or scarce flowering, and is suited for regions with irrigation and rainfed conditions with annual rainfall above 1500 mm and altitude from 0 to 800 metres above sea level. Average cane yields have been 102 t/ha in plant cane, and 92 t/ha in ratoon (Marin and Velasquez, 1997; Flores, 2001). It is resistant to Smut, Rust and Red Streak, susceptible to Pokkah-Boeng and Eye Spot, and tolerant to mealy bug and to stem borer.
Mex 79-431 (parents: Co 421 X Mex 57-473)

Mex 79-431 has recorded good germination and tillering, and good agronomic appearance, even under adverse drought conditions. Ratooning is excellent. It exhibits scarce to fair flowering, with highest percentages occurring in intermediate altitudes and not at higher altitudes or at sea level. It exhibits fair thrashing.

Cane yields in trials in plant cane and ratoon are 193 and 173 t/ha, respectively, under irrigated experimental conditions (Marin and Velasquez, 1997; Flores, 2001).

In locations with high humidity, it is susceptible to Eye Spot disease and occasional symptoms of Mosaic (SCMV) have been observed.

**Trial layout and treatments**

A sub-split plot factorial arrangement ($2 \times 3 \times 6$) was used in a randomised block design with four replicates. The experimental plots consisted of six rows 12 m long, spaced at 1.15 m and with an area of 82.8 m$^2$, with a net plot of four central 12 m long rows, equivalent to 55.2 m$^2$.

Experimental factors under study were the following.

a) Location: dry zone (L1) and moist zone (L2).

b) Variety: CP 72-2086 (V1), Mex 69-290 (V2) and Mex 79-431 (V3).

c) Month of harvest: December (M1), January (M2), February (M3), March (M4), April (M5) and May (M6).

**Measurements**

Temperature and rainfall were measured at intervals throughout the trials. Soil fertility variables (organic matter, total nitrogen, potassium, phosphorus, micronutrients, clay, silt and sand contents, acidity (pH) and Base Exchange Capacity) were measured to a depth of 30 cm at the two locations.

Sugarcane germination percentage, stalk length, diameter and population at six months of age and prior to each harvest date were measured, as well as cane yield, stalk fibre and moisture, juice purity, brix and reducing sugars, sucrose (pol) and theoretical sugar yield per hectare at harvest were determined, according to established methodologies (IMPA, 1983).

The data collected were analysed by ANOVA, regression and main components analyses, using the SAS system for Windows, release 6.12 (SAS Institute Inc. 1989–1996) and the Principal Components Analyses following the methodology described by Pla (1986) and (Bilodeau and Brenner, 1999), without repeated analyses of the data.

**Results**

**Climate**

In the moist zone (Trial 2), rainfall was 1162 mm greater than that of the dry zone (Trial 1), (Table 1), which indicates a better sugarcane growth in the former than the latter and therefore higher potential cane yields and less deterioration from untimely harvesting, which was one of the factors under study in both zones.

Temperatures in the dry zone were higher than those of the moist zone by 1.62°C, 1.11°C and 0.61°C for maximum, mean and minimum, respectively. In the dry zone, not only did it rain less, but also temperatures were much higher.

**Physical-chemical characteristics of the soils of the studied localities**

As shown in Table 2, the physical-chemical characteristics of the soils of locations were adequate for sugarcane cultivation, but in the case of the dry zone, a greater number of growth limiting factors were present (Arcia, 1997), as indicated by low phosphorus and potassium content and intermediate organic matter content, which implies the need for supplementary applications of these nutrients to the soil for sugarcane production.
Table 1—Rainfall and temperature during October, 2003, to May, 2005, at the two trial locations.

Performance of agricultural and quality variables at harvest

Analyses of variance of agricultural variables (cane population, length, diameter and yield) and quality variables (fibre, moisture, reducing sugars, sucrose and tonnes of sugar per hectare) at harvest (Table 3) were carried out, as well as their respective comparisons of means of the most important interactions (Table 4).

Cane yield

There were highly significant differences between locations, varieties, months of harvest and in the interactions location by variety and location by month of harvest (Table 3). By comparing the means of these main effects and their interactions (Table 4) it can be observed that cane yield was significantly higher in the moist zone in all three varieties under study, which demonstrates the effect of the location on the performance of the varieties, and confirms reports by Mariotti (1987) in Argentina, Ghaderi et al. (1980) in India and Bernal (1986) in Cuba.

By reviewing the interaction location by month of harvest, it can be noticed that, in the dry zone, cane yield was highest early in the season in December, January and February, and from March there was a decline in cane yield, which became significantly lower in April and May. In contrast, in the moist zone, the cane yield trend was toward low yields in December and January, which then increased to a maximum in February and March, and later decreased during the months of April and May. This clearly shows the need to take into consideration the characteristics of the locations in order to optimise harvest scheduling (Milanes et al., 2007).

Percentage of reducing sugars

Highly significant differences were determined (Table 3) between locations, varieties, months of harvest and the interactions location by variety, location by month of harvest and location by variety by month of harvest in percent reducing sugars.

By comparing the means of these main effects and their interactions (Table 4) it can be observed that reducing sugars (Table 4 and Figure 1) show a different time curve for each variety. Thus, CP 72–2086 recorded low reducing sugar values at the beginning of the harvest season, which increased significantly in March, and maintained these values until the end of the harvest season in May.

Variety Mex 69–290 began harvest with high values in December, then decreased during January, February and March, and again increased in April and May. Variety Mex 79–431 recorded high values in December and January, which reduced significantly in February and March, and later increased significantly in April and May.

The results recorded suggest that variety CP72-2086 should be harvested at the beginning of the harvest season and finalised before March, variety Mex 69-290 should be harvested preferably during the months of January, February and March, while variety Mex 79-431 has best harvest timing in February and March.

Principal Components Analyses
Components and eigenvectors

As can be noticed in Table 5, the first four components extracted more than 90% of the total variation of the assessed matrix, and the first two reached 72.72%; consequently, it is considered sufficient to work with the information that these two components extracted. In the first component the important variables were: locality, cane yield, stalk population, stalk length, stalk diameter, fibre, reducing sugars, sucrose and tonnes of theoretical sugar per hectare, and in the second component: juice purity and cane moisture were the most important, with opposite signs, this is, with contrary effects, as expected. It is noticeable that the variables associated with yield components had the same sign as did localities, hence the great effect of the former on cane yield. On the other hand, the effect of reducing sugars is contrary to that of sucrose, almost with the same values of components, but with opposite signs; similar results have been reported by Bernal (1986) and Milanes et al. (2007).

Relationships and importance of the variables

In the correlation circle (Figure 2), it can be noticed that the effects of variables which are cane yield components are directly opposite to the effect of fibre and reducing sugars, while sucrose and juice purity are associated and opposite to stalk moisture, which logically happens. Supplementary variables show little importance, except locations, also in this case related to the cane yield components.

Behaviour of individuals

In the case of individuals, in a chart, components 1 and 2 have been displayed, and the grouping of the 108 studied individuals into two large groups (Figure 3) is noticeable. The components are associated with each of the two studied locations, which confirms the importance of this factor in the performance of the sugarcane crop.

Conclusions

By assessing the location by month of harvest interactions, it is noteworthy that in the dry zone, cane yield was highest early in the season in December, January and February, while yields declined from March. In contrast in the moist zone, the harvest season began with a trend of low cane yields in December and January, and reached a maximum in February and March, and again declined during April and May. This clearly demonstrates the need to take into consideration the characteristics of these locations in order to optimise harvest scheduling.

Reducing sugars presented different trends over time in each variety. In the dry zone, CP 72–2086 exhibited low values (0.297%) early in the harvest season which began to increase significantly in the month of March (0.883%), maintaining these high values until the end of the harvest season in May (1.407%).

Mex 69–290 recorded high values in the month of December (0.617%), which decreased in January (0.288%), February (0.240%) and March (0.507%), and increased again in April and May, with values of 0.797% and 0.873%, respectively.

Mex 79–431 maintained low values from December to March (of 0.470% and 0.500%) with a trend to increase from the month of April (1.003%). These results suggest that variety CP72-2086 should be harvested at the beginning of the harvest season and finalised before March, variety Mex 69-290 should be harvested preferably during the months of January, February and March, while variety Mex 79-431 has best harvest timing in February and March.

The principal components analysis showed important effects of locations on cane and sugar yields and time of harvest, the influence of the environment on varietal yields, and verified the dependence of cane yield on its components stalk population, length and diameter. Negative correlations between yield component variables and moisture, reducing sugars and fibre were also found. The main components analyses demonstrate the total dependence of varietal performance on the conditions of locations and on their harvest management.

PALABRAS CLAVES: Caña de Azúcar, Momento de Cosecha.

Resumen

En México se cultivan con caña de azúcar más de 650 000 hectáreas que tributan las 46.5 millones de toneladas producidas, como promedio de los últimos tres años, a 57 ingenios azucareros, distribuidos a lo largo de la costa del océano pacífico, una franja transversal sobre el paralelo 19 y las costas del golfo de México, los cuales presentan un rendimiento de fábrica de 11.43 como máximo en la mejor zafra; en esta diversidad de clima y suelo, se cultivan mas de 20 variedades, pero el 65% aproximadamente de la superficie está plantada con las variedades: Mex 69-290, CP 72-2086 y Mex 79-431. Con el fin de conocer con precisión el efecto de la edad y la época de cosecha de estas variedades para una óptima programación de su cosecha, se plantaron 2 experimentos, con las tres variedades mencionadas, en dos localidades altamente contrastantes en clima y suelo, del principal macizo cañero del país, los cuales se cosecharon en seis momentos del periodo de la zafra Diciembre/2004 a Mayo/2005. En la zona seca el rendimiento de campo fue mayor a inicios de zafra, en diciembre, enero y febrero, y a partir del mes de marzo se inició un descenso, mientras en la zona húmeda se inició la cosecha con una tendencia de rendimiento bajos en diciembre y enero, que alcanzaron su máximo en febrero y marzo, para declinar durante abril y mayo. Los azúcares reductores presentan un comportamiento específico para cada variedad: En la zona seca, la CP 72-2086 inició cosecha con valores bajos, que se incrementaron significativamente en marzo, manteniéndose altos hasta el final de la cosecha en mayo; la Mex 69-290 inició la cosecha con valores altos en diciembre, que disminuyó durante enero, febrero y marzo, para volver a incrementarse en abril y mayo; y la Mex 79-431 de diciembre a marzo mantienen valores bajos, con una tendencia a incrementarse a partir de abril. El análisis de componentes principales demostró el efecto importante de las localidades en la producción de caña y azúcar y el momento de cosecha, y la dependencia del efecto ambiental de las variedades, y reafirmó la dependencia del rendimiento de campo de sus componentes población, altura y diámetro. También se encontraron correlaciones negativas o inversas entre las variables del rendimiento agrícola con la humedad, la fibra y los azúcares reductores.
PLENE, AN INNOVATIVE APPROACH FOR SUGARCANE PLANTING IN BRAZIL

By

KEYWORDS: Cane Stalk, One-Budded Cane Setts, Setts Treatments.

Abstract
PLENE™ concept is an evolutionary way of planting sugarcane to replace the current high cost path requiring heavy equipment and intensive labour. With Plene™, Syngenta developed a methodology for producing sugarcane one-budded setts treated with proprietary crop protection and coatings that allows germination, crop stand and vigour. This protocol, associated with an industrial cutting and stalk treatment technologies and a lighter planting machine, provides a dramatic improvement in planting operations, reducing the amount of seed cane from 18 t of stalks to 1.5 t of Plene™ per hectare. This technology has the potential to simplify the planting process and represents a good strategy for sustainable sugarcane production. This paper summarises five field trials carried out to evaluate the performance of Plene™ sugarcane technology in São Paulo State, Brazil. Results have shown that the ideal number of buds per linear metre is 8 when a 1.5 m space between rows is adopted. Application of Plene slurry just after the cutting process increased the shelf life time from 2 to 7 days using 70% buds germination as a reference. Emergence trial results showed the importance of crop protection for the Plene™ technology and, at 48 days after planting assessment, Plene™ plots reached 72% emergence compared to 20% in untreated plots. As a conclusion, the combination of crop protection technologies and polymers in Plene™ is able to maintain the viability of the buds before planting and assures ideal germination and crop stand after planting, thus showing this to be an excellent technology for modern sugarcane planting.

Introduction
The current agronomic technology and industrialisation of sugarcane, associated with tradition and infrastructure, are factors that limit the production in Brazil and, to reach ambitious targets in the near future, an expansion of planted area is needed. Research and new technologies are important to ensure progress in yield, productivity and cost reduction, and the Plene™ concept is being developed in this context.

This Syngenta technology consists of production of healthy cane setts, with one bud and 4 cm long, treated with proprietary crop protection and planted with a 'light' planter (similar to a grain planter). This innovative technology for planting is appropriate for renovation or expansion of areas due to less impact from mechanical operations, and is feasible even under minimum tillage.

The possible combination of planting operations and crop management such as insect, fungus and nematode control provides a lower cost, higher efficacy and efficient logistics.

In the past, and even nowadays, several research projects have been carried out to modernise the planting process. Clements (1940) evaluated the effect of different sizes of stalks and number of buds (1 to 5 buds) and found that smaller sizes and fewer buds were the best; however, rot disease
development was higher due to the larger exposed area of the cut faces. Ricci Junior et al. (2009), working with shorter sugarcane stalks (30 cm) and two buds without fungicide, reported that sprouting and tillering were significantly damaged due to pineapple disease (*Ceratocystis paradoxa*).

Casagrande and Vasconcelos (2008) reported that there is a sprouting gradient due to age differences between the buds, from the top (younger) to bottom (older). Alvarez (1975) and Pange et al. (1962) reported that old stalks are unsuitable for planting, the ideal is seven to nine months stalk age, and the top third germinates better than the middle and bottom third.

Valdez Manzano (1976), Rincones (1973), Escobar (1968) and Martín (1951) found that for seed cane without fungicide treatment, the interval between cutting and planting should be the lowest possible, no more than 4–7 days.

This work aimed at studying the best small segment density for planting, sprouting of buds originating from different segments (top, middle and base) of the stalks, planting position of these segments in the ground, and shelf life of the buds produced with the Plene™ technology.

**Materials and methods**

All the trials were conducted at Holambra Field Station (22°38′S, 47°05′W) in Holambra, SP, Brazil, between December 2007 and June 2009. Anova and ‘t’ test were applied for statistical analysis of the five trials.

**Planting density (Trial No. 1)**

Small segments (4 cm long) with one bud were taken off from the middle and top of the cane stalks of the cultivar RB 86-7515. They were treated through industrial proprietary Syngenta crop protection (Plene™).

The segments were planted in furrows 30 cm deep, fertilised in accordance with requirement and covered with 5–8 cm of soil. Plot size was 4 rows of 5 m in length and the experimental design adopted was randomised complete blocks (RCB) and factorial scheme (3 × 2); three density treatments, namely four, eight and 12 segments with one bud per linear metre and two chemical treatments: 1) treated one-bud sett and 2) non-treated one-bud sett. Each treatment was replicated four times. Evaluations of germination (% emergence), height (up to dewlap), stalk diameter (4th knot), cane yield and sugar content were made to derive the optimum density of small segments.

**Segment and age of bud (Trial No. 2)**

Small segments originating from top, middle and bottom of mother stalks were removed from nine and 12 month age cane stalks. They were treated with the industrial proprietary treatment of Plene™. Planting was made in furrow 30 cm deep, fertilised according to requirement and covered with 5–8 cm of soil.

The experimental design adopted was a RCB and factorial scheme (3 × 2); three segment treatments, namely bottom, middle and top and two ages, namely 12 and 9 months. Each treatment was replicated four times; plot-size was 4 rows of 5 m long.

Measurements and data recording included evaluations of emergence, stalk height and diameter, cane and sugar yield.

**Segment size (Trial No. 3)**

Small segments of different lengths (4, 6, 8, 10 and 12 cm) were taken from top and middle of mother stalks. They were treated through industrial proprietary treatment before being planted in furrows 30 cm deep, fertilised at recommended rates and covered with 5–8 cm of soil.

The experimental design adopted was a RCB with 4 replications with plot size of 4 rows of 5 m long. Evaluations of emergence, stalk height, stalk diameter, cane yield and kg sugar/ha were the parameters measured.
Bud planting angle (Trial No. 4)

Small segments were produced in a similar way to those in Trial No. 1 (density of planting trial). They were treated through industrial proprietary crop protection (Plene™) and the management to planting was the same except that eight one-bud setts were planted per linear metre for all the plots.

The experimental design adopted was RCB with four repetitions; plot size adopted was 4 rows of 5 m long. To study the best planting bud position of small segments in the furrow, they were planted at different angles with regard to the soil surface as illustrated in Figure 1. The four treatments had segments placed at: 1) 0º, 2) 90º, 3) 180º, 4) 270º.

![Figure 1—Bud positions at different angles to the soil surface.](image)

Shelf life (Trial No. 5)

A pot trial was carried out in the greenhouse where eight small segments, cut and chemically treated immediately after cutting in comparison to those treated only at planting time, were planted in pots of 20 L.

Periods of storage of small segments were 0, 3, 5, 7, 10 and 12 days. The experimental design adopted was a completely randomised design with a factorial scheme of 2 x 6 (two treatment times and 6 periods of storage); all treatments replicated four times. Germination (% emergence) at 45 days after planting was evaluated.

Results and discussion

Planting density (Trial No. 1)

Emergence of one-budded setts, height and diameter of stalks, yield and sugar/ha were evaluated and showed that bud setts treated with Syngenta products were clearly superior to untreated budded setts, and it was significant for one density at least. Height was the parameter that showed superiority of treated bud setts for the three densities evaluated.

In general, eight and 12 buds/linear metre were superior to four, mainly for yield and sugar/ha. Summarising, the results showed that 8 buds per linear metre, after being treated chemically, showed the ideal density for Plene™ technology for the variety RB86 7515 and the necessity to treat the small segments with chemicals to improve the emergence, height and yield.

These data are in agreement with Ricci Jr et al. (2009) and Clements (1940) where they found the importance of crop protection when the stalk length is smaller than that of conventional cane setts (4 cm and one-bud sett versus 40 cm and 3 buds) (Tables 1, 2, 3 and 4).

Segment/age (Trial No. 2)

Segments of nine month age were shown to be significantly superior to 12 months for all different segments (top, middle and bottom) and all parameters evaluated, except for diameter where 12 month age for all different segments were superior to nine months, as expected because of low stand (Tables 5, 6, 7 and 8). Casagrande and Vasconcelos (2008) reported that there is a sprouting gradient due to age differences between the bud age, from the top (younger) to bottom (older) and Alvarez (1975) and Pange et al. (1962) showed that old stalks are unsuitable for planting, the ideal is seven to nine month stalk age, and the top third germinates better than the middle and bottom third.

Segment size (Trial No. 3)

Evaluations of germination (% emergence) at 24 and 35 DAP, height and diameter at 207 DAP showed that there was no difference between the segment sizes (4, 6, 8, 10 and 12 cm) tested. However, the best cane yield was obtained with segments of 12 cm and the best kg sugar/ha was with 10 cm long setts. Clements (1940), in his studies about sprouting, found working with different sizes and number of buds (1 to 5 buds per stalk), the best size was with the smaller length of stalk and fewer buds (Table 9).

1 DAP: days after planting
2 Treated: industrial proprietary treatment

Bud planting angle (Trial No. 4)

Germination (% emergence) at 25 and 36 DAP was slower with the cane setts/segments placed at 180º and 270º. This may be due to these bud positions requiring more energy to emerge from the soil.

These slower developments resulted in lower stalk height at 125 DAP. Angles of 0º and 90º were the best positions; however, they were similar to the randomised position. Stalk height at 125 DAP confirmed that angles of 0º and 90º were the best positions. Diameter at 125 DAP, yield and kg sugar/ha (550 DAP) of all angles of bud planting, including the randomised position, showed no significant difference between the treatments.

These data are interesting because they show that, if the one-budded setts are treated with Plene’s products, it is not necessary to plant the setts in a determined position. Nickell (1977) found similar results when studying depth and angle of planting (Table 10).

1 DAP: days after planting
2 Planting angle means the angle formed in regarding to ground.

Shelf life (Trial No. 5)

Small segments treated immediately after cutting, assuming a threshold of 70% emergence, storage at room temperature, the evaluation of germination (% emergence) at 45 days after planting showed that shelf life for one-budded setts treated with proprietary crop protection is seven to ten days. However, shelf life of small segments cut and left untreated until planting time, showed a drastic decline after two days of storage.

In the latter case, a high infection level of saprophyte fungi and other organisms was observed that probably killed the majority of buds in five days (Table 11 and Figure 2). Other researchers (Valdez Manzano, 1976; Rincones, 1973; Escobar, 1968; and Martin, 1951) found similar results and reported that, for seedlings without fungicide treatment, the interval between cutting and planting should be the lowest possible, no more than 4–7 days.

Table 11—Shelf life of segments chemically treated immediately after cutting in comparison with segments treated only at planting time. Holambra, SP, Brazil, 2008.

The Plene™ concept is being developed by Syngenta Crop Protection with contribution from Brazilian mills to make a major breakthrough in cane planting. Several aspects covered in this paper show the viability of this technology to revolutionise sugarcane planting, with a simplified process, efficient logistics and sustainable cane production.

MOTS CLEFS: Tige de Cane, Bouture, Traitement de Boutures.

Résumé

LE CONCEPT Plene™ est novateur, il a remplacé la méthode onéreuse habituelle de plantation qui nécessita un degré élevé de mécanisation et une main d’œuvre abondante. Grâce à Plene™, Syngenta a développé une méthode évolutée pour produire des boutures traitées d’un œil possédant des caractéristiques de résistance et de vigueur favorisant une bonne germination et levée. Cette méthode associe la préparation et le traitement industriel des boutures à une plantation espacée, elle améliore l’efficience des opérations de plantation en réduisant la quantité de boutures utilisées de 18 t à 1.5 t par hectare. La technologie Plene™ a la capacité de simplifier la plantation et contribue à une production de canne à sucre durable. Cet article résume cinq essais conduits pour évaluer les performances de la technique Plene™ et réalisés dans l’état de São Paulo au Brésil. Les résultats démontrent qu’avec un espacement de 1.5 m d’espacement entre deux lignes, la densité de 8 boutures est optimum. L’application de la pâte Plene au moment de la coupe des boutures allonge leur durée de vie de 2 à 7 jours dans 70% des cas. Les essais sur la levée montrent l’efficacité de la protection par la technique PleneTM, avec un taux de germination de 72% avec traitement contre 20% sans. En conclusion, la combinaison de la protection offerte par la technique et l’utilisation de polymères PleneTM permet de conserver les boutures en vie avant plantation et d’assurer la germination et la survie des plants, tout ceci pouvant représenter une excellente technique de plantation moderne de canne à sucre.
PLENE, UN ENFOQUE INNOVADOR PARA SIEMBRA DE CAÑA DE AZÚCAR EN BRASIL

PALABRAS CLAVE: Tallo de Caña, Semilla con una Yema, Tratamiento de Semilla.

Resumen

El concepto Plene™ es una forma evolutiva en la siembra de caña de azúcar para sustituir la práctica actual que requiere maquinaria pesada y mano de obra intensiva. Con Plene™, Syngenta desarrolló una metodología para trozos de caña con una yema tratados con recubrimientos protectores de su propiedad que permiten buenas germinación, densidad y vigor. Este protocolo, asociado con tecnologías industriales de corte y tratamiento de las estacas y una máquina sembradora liviana, ofrece una notable mejora en las operaciones de siembra, reduciendo la cantidad de semilla de caña de 18 t a 1.5 t por hectárea con Plene™. Esta tecnología tiene el potencial de simplificar el proceso de siembra y representa una buena estrategia para una producción sostenible de caña de azúcar. Este documento resume cinco estudios de campo llevados a cabo en el estado São Paulo, Brasil para evaluar el desempeño de la tecnología de Plene™. Los resultados han demostrado que el número ideal de yemas por metro lineal es de 8 cuando se adopta un espaciamiento de 1.5 m entre surcos. La aplicación de Plene justo después del proceso de corte aumenta el tiempo de vida útil de 2 a 7 días tomando el 70% de germinación de las yemas como referencia. La emergencia de las yemas en los ensayos puso de manifiesto la importancia de la protección fitosanitaria de la tecnología Plene™ y, a los 48 días al realizar la evaluación de la siembra, las parcelas con Plene™ alcanzaron el 72% de emergencia, frente al 20% en las parcelas no tratadas. Como conclusión, la combinación en Plene™ de las tecnologías de protección de cultivos y polímeros es capaz de mantener la viabilidad de las yemas antes de la siembra y asegura una germinación y densidad de tallos ideales después de la siembra, lo que demuestra que se trata de una excelente tecnología para la siembra moderna de la caña de azúcar.
NITROGEN IN SUGARCANE DERIVED FROM FERTILISER

By

Centro de Energia Nuclear na Agricultura CENA/USP

hjfranco@cena.usp.br

KEYWORDS: Green-cane, $^{15}$N Labelled Urea, Sugarcane Trash, Saccharum spp.

Abstract

NITROGEN fertilisation in the sugarcane crop is a universal practice used to reach sustainable levels of productivity, both in the plant cane and especially in ratoon cycle. However, when evaluating N in the plant derived from fertiliser ($^{15}$N) at crop harvest, one sees that this contribution is in the order of 20% of the total N, which gives rise to questions regarding the efficiency of this fertilisation. Therefore, field experiments were undertaken at two locations with sugarcane mechanically harvested and without burning of the sugarcane in the State of São Paulo, Brazil. Nitrogen fertilisation of both the plant cane (rates of 40, 80 and 120 kg/ha of N as urea) and the first ratoon (rates of 50 and 100 kg/ha of N as ammonium sulfate) was labelled on the stable isotope of $^{15}$N. It was observed that the N from nitrogen fertilisation represented up to 40% of the total N of the plant cane in the initial stages of its growth, decreasing in the stages of pre-maturity and at maturity to levels in the order of 10% at harvest. In the ratoon crop, participation of N fertiliser on crop nutrition was more effective, constituting up to 70% of total N in the initial stages of development, especially at greater rates of N, decreasing through the cycle of the first ratoon. Nevertheless, it stands out that, throughout the growth of the ratoon, the contribution of N fertiliser was greater than that for the plant cane, to the order of 30% of the total N of the plant. This confirms that N fertilisation in the ratoon crop, with little or no soil tillage, together with the maintenance of crop residues on the soil surface, is one of the most important sources of N for the crop.

Introduction

In studies with sugarcane, one of the most controversial and polemical matters is in respect to nitrogen fertilisation at planting (plant cane), considering that many studies have shown sugarcane has little response to this practice (Trivelin, 2000; Franco, 2008). One sees in the literature a lack of response in most experiments with the plant crop when the sugarcane is burnt prior to harvest (Trivelin, 2000). For the regrowth, with burnt cane, most of the experiments showed a response (Trivelin, 2000). Many explanations have been given, such as biological fixation of atmospheric N, losses through leaching of N fertiliser, the vigour of the root system of the plant cane compared to that of the ratoons, the climatic conditions, the improvement in soil fertility associated with liming, mechanical soil preparation and the incorporation of residues from the previous crop (Orlando Filho et al., 1999; Urquiaga et al., 1992). According to the review of Salcedo and Sampaio (1984), in ratoon cane, response is more frequent due to a smaller quantity of mineral N accumulated in the soil profile at the beginning of the ratoon growth cycle compared to that of the plant cane, less mineralisation of N from the soil due to reduced soil tillage, and less efficiency of the ratoon root system in uptake of fertiliser-N.
In this context, for the purpose of understanding in a more detailed way the N cycle in the soil-plant system and its effect on the development and productivity of sugarcane in Brazil, studies with the use of the isotope tracer method for nitrogen ($^{15}$N) were begun in 1983 at the Center for Nuclear Energy in Agriculture, at the University of São Paulo. One of the evaluations that may be undertaken with the use of the isotope tracer technique is an estimate of the percentage of nitrogen in the plant derived from fertiliser (%NDFF) and the efficiency in the use of N fertiliser by the crops. In the sugarcane crop, this technique may be used during its growth cycle. The hypothesis in these experiments with sugarcane is that the F+3 of the plant represents the abundance of $^{15}$N in the above ground part of the crop (shoot of the crop) and in view of this, the isotopic abundance is used to estimate the NDFF of the above ground part (Takahashi, 1967; Sampaio et al., 1984; Trivelin, 2000).

Recently, due to the small contribution, around 20% or less, of the N fertiliser in the total N accumulated in the above ground part of the plants, at the harvest of the sugarcane fields (Sampaio et al., 1984; Trivelin et al., 1995; Trivelin, 2000; Gava et al., 2001; Franco, 2008), the experts of sugarcane management began to question the efficacy of nitrogen fertilisation in the sugarcane producing regions of the Central-South of Brazil. In this context, with the objective of better understanding of the participation of N fertiliser throughout the growth cycles of the plant cane and the first crop regrowth, two field experiments were developed with the objective of evaluating the contribution of $^{15}$N-fertiliser (urea in the plant cane and ammonium sulfate in the first ratoon) in the total nitrogen accumulated in the above ground part of the sugarcane during both growth cycles.

**Material and methods**

**Location, trial design and $^{15}$N labelled fertiliser**

The experiments were developed in two sugarcane producing areas located in the State of São Paulo, Brazil. The first belongs to the São Luiz Sugar Mill (USL), in the Pirassununga county (Latitude 21º55’54’’S, Longitude 47º10’54’’W). This area had been cultivated with sugarcane since 1977. The altitude is 650 m and the climate is Aw (Tropical Savanna, in the Köppen classification). The area presents a slightly rolling slope (< 5%) and the soil is Typic Eutrustox. Planting of the sugarcane occurred from February 21 to 24, 2005. The second area, belonging to the Santa Adélia Sugar Mill (USA) is in the Jaboticabal county (Latitude 21º19.98’S, Longitude 48º19.03’’W), with predominant altitude in the region of 600 m and climate Aw (Tropical Savanna, in the Köppen classification). This area had been cultivated with sugarcane since 1951. The area presents a slightly rolling slope (<5%) and the soil is an Arenic Kandiustults. The experiment was planted from April 4 to 8, 2005. The variety used was SP81-3250, and 17 to 20 buds were planted per metre of row and were covered with soil. In all the plots, at the bottom of the furrow, 120 kg/ha of K$_2$O and 120 kg/ha of P$_2$O$_5$ were applied.

Treatments for the plant cane were three rates of N (40, 80 and 120 kg/ha as urea) applied at the bottom of the planting furrow, plus one control without nitrogen fertiliser. Treatments were distributed in a randomised block design with four replications. The experimental plots consisted of 48 rows of 15 metres in length with a space between rows of 1.5 m. In the inside of each plot (20th row), a microplot was installed, with the dimensions of 2 m in length and 1.5 m width, totalling 3 m$^2$, which received the urea labelled with $^{15}$N (5.04 atoms % of $^{15}$N).

**Harvesting, sampling and statistical analysis**

During the growth cycle of the plant cane, samples were taken to evaluate the accumulation of N in the aboveground biomass of sugarcane. At USL, these evaluations were undertaken on July 7, 2005 (134 days after planting–DAP), October 25, 2005 (244 DAP), December 13, 2005 (293 DAP), February 20, 2006 (358 DAP), April 12, 2006 (413 DAP) and June 6, 2006 (468 DAP), for a total of 6 samplings. In the experiment at USA, sampling occurred on October 11, 2005 (186 DAP), December 9, 2005 (246 DAP), February 8, 2006 (307 DAP), April 5, 2006 (363 DAP) and July 10,
2006 (459 DAP), for a total of 5 samplings. In sampling, collection of the entire above ground part of the plant in 2 metres of the row was made at locations previously drawn by lot. The mass of all the plant material (dry leaves, top and stems) from each plot was obtained directly in the field, by means of weighing on an electronic scale. After weighing, each plant sample was chopped in a forage chopper. The sub-samples were packed in plastic bags and were weighed on an analytic scale, before and after drying in a ventilated laboratory dryer at 65°C (72 hours) for determination of the moisture of the material. The dried sub-samples were ground for the chemical determination of total-N content (g/kg) according to Malavolta et al. (1997).

At the same sampling times of the above ground part of the sugarcane, samples of leaves +3 (F+3) were collected in the microplots that received urea-15N. The F+3 were collected according to the methodology described by Trivelin et al. (1994). In these evaluations, samples of leaves +3 using the Dillewijn system are collected in microplots that received the fertiliser labelled with 15N, for determination of the abundance in atoms % of the isotope, thus allowing the determination of estimates of NDFF (kg/ha); also making use of measurements of N accumulated by the crop, obtained in plants collected in other rows of sugarcane in the same plot (treatment). These samples were dried in forced air circulation laboratory ovens at 65°C and the abundance of 15N (atom % of 15N) in them was determined in a mass spectrometer. With the values of the abundance in atoms % of 15N in the samples of leaf +3 and the accumulated N in the above ground part of sugarcane, it was possible to calculate the NDFF (nitrogen in the above ground part of the plant derived from fertiliser) according to the methodology described by Trivelin et al. (1994).

After the harvest of the plant cane (June 6, 2006 at USL and July 10, 2006 at USA), the plots of the two experiments were split into four subplots that received the treatments: 50, 100 and 150 kg/ha of ammonium sulfate, plus a control without application of nitrogen fertiliser. The application of nitrogen fertiliser was made over the cultural residue (trash) coming from the mechanical harvesting without straw burning, at approximately 20 cm from the row, applying together with this 150 kg/ha of K2O.

Inside the plots of the ratoons that received the rates of 50 and 100 kg/ha of N, microplots were demarcated with dimensions of 2 m length and 1.5 m width (3 m²) which received the ammonium sulfate labelled with 15N (2.31% and 2.97 atoms % of 15N, respectively, in the rates of 100 and 50 kg/ha of N), the application of which followed the same procedure as described for the rest of the plots. The fertilisers were applied on October 8 and on November 1st, 2006, respectively, at USL and USA.

In the cycle of the first ratoon, samples of plant material were undertaken in the two locations. This sampling followed the same procedure adopted for the plant cane, determining the plant dry matter and the accumulated N in the above ground part of the sugarcane in each period.

At the same times of collection of plant material, leaves +3 of plants from the microplots that received the ammonium sulfate labelled with 15N were collected, and the same protocol of collection of the leaves as used in the plant cane was carried out (Trivelin et al., 1994), as well as in determination of the 15N abundances.

The results of total N (kg/ha ) and NDFF (% and kg/ha ) were submitted to ANOVA as plots subdivided in time (rates as main treatment and periods as secondary) and the Tukey test for comparison of the averages within each treatment.

Results and discussion

Plant cane crop cycle

In the two experiments, approximately 180 days after the nitrogen fertilisation at planting (October 2005), the sugarcane had already absorbed practically all the N fertiliser, especially for the doses of 40 and 80 kg/ha of N (Table 1), differently from the total N in the plants, which continued being accumulated with the growth of the crop (Table 2). The accumulation of nitrogen (kg/ha )
increased in a linear way with nitrogen fertilisation in the USL experiment; however, there was no effect at USA. The stalk yield was increased with 40 kg N/ha in the USL site (134 t/ha without N and 142 t/ha with 40 kg N/ha), but in USA there was no response in cane yield to N rates (Franco, 2008). At USL, the increases began to be significant as of October, coinciding with the beginning of the maximum growth stage of the crop (Franco, 2008) when the climatic conditions (temperature, solar luminosity and rainfall) began to be raised.

The quantities of N accumulated by the above ground part of the plant cane (190 kg/ha on average) are much more than the rates of N applied (Table 2).

Consequently, it may be inferred that the majority of N absorbed by the plants originated from other sources; the net mineralisation through soil organic carbon rundown, the mineralisation of crop residues (Ng Kee Kwong *et al.*, 1987), and the biological nitrogen fixation by microorganisms associated with the crop or not (Urquiaga *et al.*, 1992) may be highlighted.

In relation to the results of NDFF (%) and use of the $^{15}$N-urea (kg/ha) by the plant cane, it may be highlighted that in the two experiments, the greatest values of NDFF (%) were obtained in
the first samplings, showing that, in the initial stages of development of the crop, a substantial part of the total N of the plants was derived from the fertiliser, especially in the 120 kg/ha rate of N (Figure 1). This can be related to the soil organic carbon immobilising fertiliser N, creating a direct competition with the crop. In addition, at the end of the plant cane cycle, the N fertiliser represented a small fraction of the total N of the above ground part of the plant, indicating that the sugarcane obtains a significant quantity of N from other sources, as previously cited.

Fig. 1—Nitrogen derived from fertiliser in the total N of the above ground part of sugarcane plant crop for the experiments at the São Luiz and Santa Adélia Sugar Mills for the treatments 40, 80 and 120 kg/ha of N.

Analysing the participation of N fertiliser throughout the growth cycle of the plant cane (Figure 1), this participation proved to be low at harvest of the crop (around 10% of the total N accumulated by plant cane). This information, when analysed in an isolated way, may lead to over-hasty conclusions regarding the importance of nitrogen fertilisation in the nutrition of the plant cane.
and, to a lesser degree in ratoon cane. Since, in most studies with application of fertilisers labelled with $^{15}$N in sugarcane, evaluation is undertaken at harvest of the crop, a great deal of information and explanations regarding the effects of N fertiliser in plant nutrition are not addressed.

However, when the contribution of N fertiliser is evaluated throughout the plant cane cycle, there proves to be a contribution of approximately 40% of total N of the crop in the first stages of evaluation (Figure 1). What is the importance of this information regarding nutrition of the plant cane? The answer is in the accumulation of N fertiliser in the cell vacuoles in the form of $\text{NO}_3^-$ or assimilated as glutamate (Taiz and Zeiger, 2009), for later use.

In this sense, the plants, after absorbing the N fertiliser in the initial stages of growth, would enter in dormancy due to the beginning of the fall-winter seasons, characterised by climatic conditions adverse to plant development (low temperatures, lack of rain, water deficit and short days); with the spring, when the climatic conditions come to be favourable for the growth of sugarcane (beginning of rains and increase in temperature), the plants use this N reserve to help in their metabolism. Therefore, plants that received N fertiliser at the beginning of the crop cycle would have greater growth and development potential due to their greater reserve of N accumulated in the initial stages of growth. That way, in environmental conditions favourable to the development of the plant, the crop would respond in terms of productivity to the nitrogen fertilisation in comparison to the non-fertilised plants, even with the N fertiliser representing a small fraction of the total N (10 to 20%) of the plant when evaluated at harvest of the plant cane.

**Ratoon crop cycle**

After the harvest of the plant cane, the rates of N fertiliser were applied over the straw residue when the plants of the first regrowth were around 90 days of growth (October 8 and November 1, 2006 in the experiments at USL and USA, respectively). Later, in December 2006, the first estimate of the contribution (accumulation) of N fertiliser in the above ground part of the ratoon cane was undertaken. The results showed that, in this first evaluation time, the plants had absorbed practically all the fertiliser-N accumulated throughout the growth cycle of the crop; there was no statistical difference between the accumulated fertiliser-N in the plants (kg/ha) between the periods of evaluation within each treatment (Table 3).

**Table 3**—Estimate of the nitrogen in the plant derived from fertiliser (NDFF) during the cycle of the first regrowth in the São Luiz and Santa Adélia Sugar Mills experiments (2006/2007 harvest).

The accumulation of total N in the above ground part of ratoon cane (Table 4) in this work presented the same tendency of accumulation as in the plant cane; in other words, at the end of the maximum growth phase of the crop (May 2007) the plants had already accumulated a large part of the total N obtained at harvest.

L.S.D. = 38 CV = 30%

Equal capital letters in the line do not differ among themselves by the Tukey test at 5% probability. L.S.D.: least significant difference; CV: coefficient of variation; *June/July: June at the São Luiz Sugar Mill and July at the Santa Adélia Sugar Mill.

As indicated and discussed in the plant cane, in the initial growth stages of first regrowth cycle, the N coming from the nitrogen fertilisation (NDFF) was one of the main sources of N for the crop, emphasising that, in some treatments, it represented around 70% of the total N of the above ground part (Figures 2 and 3).

With the development of the ratoon cane, the fertiliser-N diminished its participation in the total N in the above ground part of the sugarcane, representing, on average, 30% of the total N at harvest.

It is to be emphasised that this contribution is significantly greater than that observed for fertilisation of the plant cane, which was in the order of 5 to 10% of the total N of the above ground part.

This probably relates to the higher mineralisation rates of soil organic carbon expected from tillage in the plant crop. Sampaio et al. (1984) found that the contribution of N from urea for the rates of 20 and 60 kg/ha of N was less than 10% of the total accumulated in the entire sugarcane plant.

Trivelin et al. (2002) obtained values of 11.5% for plant cane for the rates of N of 30, 60 and 90 kg/ha applied as urea. Gava et al. (2001) verified that the N in the plant coming from fertiliser...
represented 10 to 16% of the total accumulated N in the above ground part of the ratoon crop, while Trivelin et al. (1995) obtained a value less than 15% in ratoon cane at harvest.

Fig. 2—Nitrogen derived from the fertiliser (NDFF) in the total N of the above ground part of first ratoon crop in the experiment at the São Luiz Sugar Mill for the treatments 120-0 (the residual effect was evaluated from the dose of 120 kg/ha of 15N-urea on the plant cane and without fertilisation with N on the first ratoon); 0–50 (without fertiliser-N on the plant cane and 50 kg/ha of N with 15N-ammonium sulfate on the first ratoon); 120–50 (120 kg/ha of urea-N on the plant cane and 50 kg/ha of N with 15N-ammonium sulfate on the first ratoon); 0–100 (without N on the plant cane and 100 kg/ha of N as 15N-ammonium sulfate on the first ratoon); 120–100 (120 kg/ha of urea-N on the plant cane and 100 kg/ha N of 15N-ammonium sulfate on the first ratoon).
Fig. 3—Nitrogen derived from the fertiliser (NDFF) in the total N of the above ground part of first ratoon season in the experiment at the Santa Adélia Sugar Mill for the treatments 120–0 (the residual effect was evaluated from the dose of 120 kg/ha of $^{15}$N-urea on the plant cane and without fertilisation with N on the first ratoon); 0–50 (without fertiliser-N on the plant cane and 50 kg/ha of N with $^{15}$N-ammonium sulfate on the first ratoon); 120–50 (120 kg/ha of urea-N on the plant cane and 50 kg/ha of N with $^{15}$N-ammonium sulfate on the first ratoon); 0–100 (without N on the plant cane and 100 kg/ha of N as $^{15}$N-ammonium sulfate on the first ratoon); 80–100 (80 kg/ha of urea-N on the plant cane and 100 kg/ha of N with $^{15}$N-ammonium sulfate on the first ratoon) 120–100 (120 kg/ha of urea-N on the plant cane and 100 kg/ha N of $^{15}$N-ammonium sulfate on the first ratoon).

Conclusion

During the entire stage of growth of the ratoon cane, the contribution of fertiliser-N was greater than that of the plant cane, providing evidence that, in regrowth of sugarcane, in which there is little soil tillage, together with the maintenance of crop residues on the soil surface, the N fertiliser is one of the most important sources of the nutrient for the crop.

MOTS-CLES: Canne Récoltée en Vert, Urée Marquée avec $^{15}$N,
Paillis de Canne, Saccharum Spp.

Résumé

La fertilisation azotée en culture de canne à sucre est une pratique universellement utilisée pour atteindre des niveaux durables de productivité, à la fois en canne plantée et spécialement en repousse. Cependant, lors de l’évaluation à la récolte de l’azote de la plante provenant des engrais ($^{15}$N), on observe que cette contribution est de l’ordre de 20% de l’azote total mobilisé; ce qui pose des questions concernant l’efficacité de cette fertilisation. Aussi, des essais furent réalisés sur deux sites, avec de la canne à sucre mécaniquement récoltée en vert; localisés dans l’état de Sao Paulo, Brésil. La fertilisation azotée de la canne plantée (doses de 40; 80 et 120 kg/ha de N sous forme d’urée) et de la repousse (doses de 50 et 100 kg/ha sous forme de sulfate d’ammonium) fut marquée à l’aide de l’isotope stable $^{15}$N. En canne plantée, la contribution des engrais représentait 40% de l’azote total de la plante lors des étapes initiales de croissance, puis décroissait durant les stades de pré-maturité et maturité pour atteindre 10% à la récolte. En repousse, la contribution des engrais à la nutrition minérale fut plus efficace, avec 70% de l’azote total de la plante provenant des engrais dans les étapes initiales de croissance, spécialement pour les doses élevées en azote, puis diminua jusqu’à la récolte de la première repousse. Néanmoins, on remarqua que, pendant toute la croissance de la repousse, la contribution de l’azote de l’engrais fut plus élevée que celle de la canne plantée, de l’ordre de 30% de l’azote total de la plante. Ceci confirme que la fertilisation azotée de la repousse, avec peu ou pas de travail du sol, associé avec le maintien des résidus en surface, est une des sources d’azote les plus importantes pour la culture.
NITROGENO DERIVADO DEL FERTILIZANTE EN CAÑA DE AZUCAR

PALABRAS CLAVE: Caña Verde, $^{15}$N Urea Marcada, Residuos de Caña, Saccharum spp.

Resumen

La fertilización nitrogenada en el cultivo de caña de azúcar es una práctica universal utilizada para alcanzar niveles sostenibles de la productividad, tanto en la plantilla y sobre todo del segundo ciclo en adelante. Sin embargo, cuando se evalúa en la plantilla el N derivado del fertilizante ($^{15}$N) al momento de cosecha, se observa que esta contribución es del orden del 20% del N total, lo que da lugar a preguntas acerca de la eficiencia de la fertilización. Por lo tanto, se llevaron a cabo dos experimentos de campo en dos lugares cosechados mecánicamente y sin quema de la caña de azúcar en el Estado de São Paulo, Brasil. La fertilización con nitrógeno, tanto en la plantilla (40, 80 y 120 kg/ha de N como urea) y primera soca (50 y 100 kg/ha de N como sulfato de amonio), fueron marcados con el isótopo estable $^{15}$N. Se observó que el N de la fertilización nitrogenada representa hasta el 40% del N total de la caña en la plantilla en las etapas iniciales de su crecimiento, disminuyendo en las etapas de pre-madurez y madurez a niveles del orden del 10% en la cosecha. En las socas, la participación del fertilizante nitrogenado en la nutrición del cultivo fue más efectiva, constituyendo hasta el 70% del N total durante las etapas iniciales de desarrollo, especialmente cuando se aplicaron altas tasas de N, disminuyendo a través del ciclo de la primera soca. Sin embargo, se destaca que, durante todo el crecimiento de la soca, la contribución de los fertilizantes nitrogenados fue mayor que durante la plantilla, alcanzando el 30% del N total de la planta. Esto confirma que la fertilización con N en las socas, con poca o ninguna labranza del suelo, junto con el mantenimiento de residuos en la superficie del suelo, es una de las fuentes más importantes de N para el cultivo.
UTILISATION OF NITROGEN FROM TRASH BY SUGARCANE RATOONS

KEYWORDS: Sugarcane, Nitrogen, Residue, Trash, Organic Matter, Fertility of Soil, Nutrition, ^15^N.

Abstract

A LARGE AMOUNT of crop residue (dry leaves, stem pieces and tips) remains on the soil surface after mechanical harvesting of unburnt sugarcane. These residues are often referred to as straw or trash and are a source of nutrients for following crops. In order to evaluate the ability of sugarcane to recover the nitrogen (N) from this trash, three experiments were carried out in Santa Adélia (SA), São Martinho (SM) and São Luiz (SL) Sugarcane Mills located in São Paulo State, Brazil, in two consecutive crop seasons (2006 and 2007). Microplots (1.5 x 2.0 m), replicated four times in a randomised block design, were installed at the start of a 1st ratoon crop of the variety SP 81-3250. No fertiliser N was applied to the microplots. The field crop residues in the microplots were replaced with 10 t/ha DM of ^15^N labelled trash. The rate of trash-N and ^15^N abundances were 41, 41 and 51 kg/ha and 1.01, 0.83, and 1.00 atom % for SA, SM and SL experiments, respectively. The highest ^15^trash-N uptake was observed in the 1st ratoon crop in the SL experiment (4.3 kg/ha Trash-N), followed by SM and SA experiments (3.8 and 3.1 kg/ha of Trash-N). For the 2nd ratoon crop (2008), Trash-N recoveries could only be determined for the SA and SM experiments due to an accidental firing in the SL experiment. The SA experiment had the highest Trash-N uptake in the 2nd ratoon crop and was more than double the Trash-N recovery measured in the 1st ratoon crop. Nitrogen recovery from the trash on SM was 0.8 kg/ha of N, substantially lower than that observed in the 1st ratoon crop. After two crops (1st and 2nd ratoon crops), the total Trash-N recovered was 3.9 kg/ha (9.8%) and 9.6 kg/ha (23%), for SM and SA experiments, respectively.

Introduction

When sugarcane is mechanically harvested without previous burning, a considerable amount of dry leaves, pieces of stem and tip remains on the surface, forming a vegetable residue covering called trash or straw. This trash promotes changes in the nitrogen (N) cycle, mainly due to the immobilisation and mineralisation reactions mediated by microorganisms. In addition, these residues will serve as a source of nutrients for the soil macro and microflora as well as for the sugarcane crop (Wood, 1991).

The amount of sugarcane trash after an un-burnt harvest, can vary from 10 to 30 t/ha of dry matter and containing about 40 to 80 kg/ha of N (Oliveira et al., 2002; Vitti et al., 2007) which can
lead to an increase in the amount of organic matter and nutrients in the soil (Wood, 1991; Vallis et al., 1996).

The mineralisation of crop residues (trash) added to soil is mainly dependent on the quality (chemical composition) of crop residues as well as environmental factors such as temperature, humidity, and soil aeration. The quality of the trash is typically defined by the C:N ratio, contents of lignin, cellulose, hemicellulose, and polyphenols (Ng Kee Kwong et al., 1987, Oliveira et al., 2002). The organic complexes from the trash mineralisation, such as humic acid, accumulate in the soil because of their high degree of recalcitrance and resistance to microbial attack. Therefore, the components that control the kinetics of the transformation of the organic N to inorganic N in the organic matter are various and complex (Janssen, 1996).

The sugarcane trash, on average, contains 390 to 450 g/kg of carbon and 4.6 to 6.5 g/kg of N (Ng Kee Kwong et al., 1987; Oliveira et al., 2002), which indicates an average C:N ratio of 100. Under these conditions, a strong immobilisation of N from soil and a small net mineralisation in just one agricultural year is expected (Gava et al., 2005). Residues that present nitrogen content lower than 18 g/kg and C:N ratio above 20 usually enable immobilisation (Janssen, 1996; Jingguo and Bakken, 1997). Thus, the contribution of N from the trash to the crop mineral nutrition may be small, since the decomposition of these residues with high C: N ratio promotes a competition between roots and soil microorganisms for the N available in the system (Jingguo and Bakken, 1997).

In a study performed by Vitti et al. (2005) to assess the trash-\(^{15}\)N recovery in sugarcane second ratoon (3rd harvest), it was observed, after one year, that 73% of the total N present in the trash, remained in the trash, 22% in soil and only 4% was recovered by the plant. Despite the small contribution of N from trash to the crop nutrition in the first year of residence in the field, most of the N accumulated by sugarcane occurred in the last months before the harvest. Therefore, the largest contribution of N from trash may occur in the following crop seasons, since more than 20% of the nutrient remained in the soil, besides decreasing the C: N residue ratio over time.

In this way, the work presented here aimed to assess the utilisation of mineralised N from residual trash (trash-N) by the sugarcane crop, during the period after the harvest of the plant crop till the harvest of the 2nd ratoon (2007, 2008) using the \(^{15}\)N isotope tracer technique.

**Material and methods**

The experiment was conducted in three areas cultivated with sugarcane which were mechanically harvested without burning, located in São Paulo State, Brazil. The areas belonged to, respectively, the Santa Adélia (SA) (Latitude 21°15’S, Longitude 48°18’W), the São Martinho (SM) (Latitude 21°15’S, Longitude 48°18’W) and São Luiz Sugarcane Mills (SL) (Latitude 21°59’S, Longitude 48°02’W). The soil is an Arenic Kandiustults (Latosolso Vermelho distrófico) in SA, a Rhodic Eutrustox (Latosolso Vermelho eutrófico) in SM and a Typic Eutrustox (Latosolso Vermelho amarelo eutrófico) in SL, according to Soil Survey Staff (2003) and Embrapa (2006), respectively. The soil analysis was conducted in the three locations at 0-25 and 25–50 cm depth, after harvesting the plant-cane (Table 1).

The planting was performed in February for SL, March for SM and in April 2005 for SA, in which 17 to 20 buds/m of SP81-3250 sugarcane cultivar were distributed. In the bottom of the furrows we applied 120 kg/ha of K\(_2\)O as potassium chloride, 120 kg/ha P\(_2\)O\(_5\) as simple superphosphate and 80 kg/ha as urea.

After harvesting the plant-cane, the experiment was installed in randomised blocks with 4 replicates. Each experimental plot consisted of 12 rows, 15 metres long and 1.5 m row spacing. In October 2006, microplots (2 m length and 1.5 m width) were installed. Within the microplots, residual trash from the mechanical harvesting was replaced by trash labelled with the \(^{15}\)N isotope equivalent to 10 t/ha DM. The trash was coming from an experiment with nitrogen fertilisation employing \(^{15}\)N-fertiliser (urea enriched with 5.04% in \(^{15}\)N atoms) and presented \(^{15}\)N enrichment of
1.01% (SA), 0.83% (SM) and 1.00% (SL) in $^{15}$N atoms. The total amount of N present in the residues was equivalent to 41, 41 and 51 kg/ha for the 1st ratoon for SA, SM and SL respectively. Results from the 2nd ratoon (2008) for SL were not collected due to an accidental fire in the experimental area.

Table 1—Soil analysis at 0–25 and 25–50 cm depth, of the three experimental areas of São Luiz (SL), Santa Adélia (SA) and São Martinho (SM) Sugarcane Mills, performed after the first sugarcane harvest.

The 1st ratoon harvest was performed in July 2007 (SA and SL) and in August 2007 (SM). The above-ground parts of the plants located in 1 m of furrow in the centre of each microplot and beside each one of the microplots were harvested manually. The samples were separated into dry leaves, tips and stems. The mass of trash was determined directly in the field. All the material from the microplots was ground in a mechanical forage chopper.

After grinding and homogenising each wet sample, a subsample was taken, which was weighed and dried in an oven (72 hours at 65°C), and the dry mass and the moisture content of the material were determined. The dry material was ground in a Wiley mill and analysed by mass spectrometry for total N (%) and $^{15}$N abundance (% in $^{15}$N atoms).

The remaining rows of the plots were harvested by mechanical harvester. After the harvest of the 1st ratoon, the experimental plots and microplots were maintained. In the microplots, the unlabelled trash of the 1st ratoon overlapped the labelled trash-$^{15}$N of the plant-cane.

Nitrogen fertiliser was not used in the ratoon, so that the effect of the trash-$^{15}$N recovery could be isolated. The second ratoon crop was harvested in July 2008, and the procedure adopted was the same as the previous season. The nitrogen in the plant derived from trash (NPDS) and the N utilisation (NR) from the aerial part were calculated using the equations:

\[
NPDS = \frac{[(A - C) / (B - C)].NT}{100}
\]

\[
NR (%) = \frac{(NPDS / NAF)}{100}
\]

where: NPDS = N in the plant from the trash-$^{15}$N (kg/ha); NR = utilisation of trash-$^{15}$N by the aerial part of the plant (%); A = $^{15}$N abundance (atoms %) of the plant; B = $^{15}$N abundance (1.01%-SA, 0.83%-SM and 1.00%-SL atoms %) of the labelled trash; C = $^{15}$N natural abundance (0.366% of atoms); NT = N content of the plant (kg/ha); NAF = amount of N in the trash (kg/ha).

The results were submitted to analysis of variance and, when F was significant, the means were compared by Tukey test at 1% probability.

During the experimental period, the amount of rainfall and the average maximum and minimum temperature were measured in automatic stations installed near to the experimental areas (Figure 1).
Results and discussion

At the end of the 1st ratoon cycle, the above-ground plant components accumulated approximately 3.8, 3.0 and 4.3 kg/ha of N, which corresponds to a recovery of 9.5, 7.3 and 8.4% of nitrogen (^{15}N) in the initial crop residues for SA, SM and SL, respectively (Table 2). For the three areas, the results are similar to those presented by Ng Kee Kwong et al. (1987) and Gava et al. (2005), who observed from 5 to 14% of the N-total presented in the trash was recovered by above-ground parts of sugarcane. For the 2nd ratoon, the recovery of trash^{15}N in the field was 6.6 kg/ha (17.7%) for SA and 0.8 kg/ha (2.1%) for SM (Table 2).

The total recovery of trash-N by the sugarcane after two years was 3.9 kg/ha (9.6%) for SM and 9.6 kg/ha (23%) for SA, showing a small contribution to the nitrogen nutrition of sugarcane. Meier et al. (2006) showed that trash supplies N slowly and in small amounts to the succeeding crop, and N mineralisation from a single trash blanket is not important for sugarcane production in the wet tropics. Among the plant components, the largest recoveries of trash-N were observed in the
stems, regardless of nitrogen fertilisation, followed by the tip and dry leaf components. The greater allocation of N in the stem is due to the greater mass of this compartment in relation to the dry leaf and tip (Table 3).

Although the recovery for the 1st ratoon at SL site was not the largest one (8.4%), it presented the best results (4.3 kg/ha), probably due to the greater accumulation of total N present in the trash (51 kg/ha) in relation to the SA and SM areas (41 kg/ha).

For SA site, the trash-N recovery for the 2nd ratoon was double that observed in the 1st ratoon. This result was higher than those found by Ng Kee Kwong et al. (1987) and Gava et al. (2005). The greater utilisation by sugarcane of trash-N in the 2nd ratoon is mainly due to the decrease in the C: N ratio with the trash decomposition, favouring mineralisation instead of immobilisation. The mineralisation of residues depends, therefore, on the material C:N ratio, besides the quality of the residue (Oliveira et al., 2002) and the degree of partition and transfer (‘turnover’) in the soil of the mineralised nitrogen of vegetal residue (Myers et al., 1994). Those authors reported that during the decomposition of crop residues, there is a partitioning of N into the mineral N (soil and fertiliser) pool, N-humic pool and N-immobilised by the microbial biomass of the soil, as well as a continuous transfer (‘turnover’) of this N between the compartments. Jadhav (1996) observed, over time, that through the trash decarboxylation, CO₂ was released, keeping the N in the system, resulting in a decrease in C:N ratio from 120:1 to 20:1. This close relationship to the microorganisms C:N ratio (about 12:1) intensifies the mineralisation, increasing the N pool in soil from the trash decomposition, resulting in a greater N availability for the plants.

Table 2—Recovery from trash-N by the above-ground plant components (stem, tip and dry leaf), respectively, of the 1st and 2nd ratoon crops (2006/07 and 2007/08 seasons) for the Santa Adélia (SA), São Martinho (SM) and São Luiz (SL) sugarcane mill areas.

1 NPDS<sub>total</sub> = NP<sub>1</sub>*DS<sub>1</sub> + 2 NP<sub>1</sub>*±1DS<sub>1</sub> (Trivelin et al., 1994). Mean and standard deviation (m ± sm) of 4 replicates.
At the SM experiment site, there was a decrease in the utilisation of N in the 2\textsuperscript{nd} ratoon in relation to the 1\textsuperscript{st} ratoon. This is probably due to the reduced productivity of 2\textsuperscript{nd} ratoon in relation to the 1\textsuperscript{st} ratoon, resulting in a lower accumulation of total N in the above-ground plant material. On the other hand, most of the nitrogen mineralised in the 1\textsuperscript{st} ratoon cycle is located in the part of the trash which easily decomposes, linked to compounds such as sugars, cellulose, free amino acids, proteins, nucleic acids and nucleotides (Killham, 1994). Therefore, the N remaining in the trash for utilisation by the 2\textsuperscript{nd} ratoon crop is found in compounds more recalcitrant to microbial attack, such as lignin and polyphenols (Paul and Clark, 1996), impeding the mineralisation process. The trash-\textsuperscript{15}N recovery by the 2\textsuperscript{nd} ratoon may also be affected by the root system ageing since, during the course of the crop, the sugarcane roots consist of less fibrous roots and a lower proportion of the root hairs, which results in lower efficiency of nutrients and water absorption (Vasconcelos and Casagrande, 2008).

| Table 3—Production of dry matter and nitrogen accumulated in the above-ground plant components (stem, tip and dry leaf) for the 1\textsuperscript{st} and 2\textsuperscript{nd} ratoon crops for Santa Adélia (SA), São Martinho (SM) and São Luiz (SL) Sugar Mill. |

\(^{1}\) Mean and standard deviation (m ± sm) of 4 replicates.

The precipitation rates and the mean temperatures were also lower in the 2007/2008 period compared to 2006/2007 period, which may have affected the trash decomposition, since it is favoured by high temperatures and high humidity. It was noted by Stanford \textit{et al.} (1973) and Katterer \textit{et al.} (1998) that, in the range 5 to 35°C, the mineralisation rate doubles every 10°C of temperature increase.

In work done by Quemada and Cabrera (1997), in which the organic matter of \textit{Trifolium incarnatum} L. was placed on the soil surface, a decrease in mineralisation of about 20% was found, when the soil incubation temperature decreased from 28 to 20°C. In line with this reasoning, the higher recovery of the 2\textsuperscript{nd} ratoon in the SA can be explained, considering that it presented the most favourable conditions of temperature and humidity in relation to the 1\textsuperscript{st} ratoon (Figure 1).

When quantifying the trash-N recovery, it may be necessary to also take into account the translocation of N from the above-ground plant components to the root system mainly during the sugarcane maturation, as suggested by Vitti \textit{et al.} (2007). Therefore, the recovery may be greater than that presented here if the N in roots and rhizomes was accounted for. Vitti \textit{et al.} (2007) observed that the root system of sugarcane can be on average 1/3 of total N accumulated by shoots.
Although the sugarcane crop residues have presented low amounts of N available for uptake by the crop, the trash deposited in the soil in successive harvests can contribute to a greater accumulation of organic N in the soil, up to 79% of N can be retained in the soil, as observed by Robertson and Thorburn (2007). Studies conducted in Australia by Vallis et al. (1996) indicate that the sugarcane trash left on the soil surface for a period of 20 years may result in the reduction of up to 40 kg/ha in N fertilisation. Thus, the crop residues generated by mechanical harvesting without the use of fire to burn trash represent an important stock of nitrogen in the soil-plant system, and certainly they will contribute to a reduction in N rates used in ratoons cultivated in Brazil.

Conclusion

The trash-N recovery was significant in the two year period of this experiment, ranging from 7.5% to 9.5% and 2.2% to 17.7% in 1st and 2nd ratoons, respectively.

The lower utilisation of trash-N in the experimental site located in the São Martinho Sugarcane Mill area could be attributed to the less favourable weather conditions in relation to other areas, resulting in a lower mineralisation rate of the residues. The participation of trash-N in the sugarcane ratoons nutrition represented a small part of the total N. However, over many years, this N source may help in reducing N rates employed in the agricultural system as suggested in similar studies in other regions.

MOTS-CLES: Canne à Sucre, Azote, Résidus, Paille,
Matière Organique, Fertilité Des Sols, Nutrition, 15N.

Résumé
UNE GRANDE quantité des résidus de récolte (feuilles sèches, morceaux de tiges, et bouts blancs) restent à la surface du sol après la récolte mécanique de canne sans brûlage. Ces résidus, souvent appelés paille sont une source d’éléments nutritifs pour les récoltes suivantes. Afin d’évaluer la capacité de la canne à récupérer l’azote de ces pailles, trois expérimentations ont été conduites à Santa Adélia (SA), São Martinho (SM) et São Luiz (SL), sucreries situées dans l’état de São Paulo, Brésil, pendant deux campagnes consécutives (2006 et 2007). Des micro-parcelles (1.5 × 2.0 m) répétées 4 fois selon un dispositif en bloc randomisé, ont été installées en début de 1ère repousse de la variété SP 81-3250. Aucune fertilisation azotée n’a été appliquée dans les micro-parcelles et les résidus de récolte dans les micro-parcelles ont été remplacés par 10 t/ha de matière sèche de paille marquée avec de l’azote 15N. Les doses de N du paillis et d’abondance en 15N furent respectivement de 41, 41 et 51 kg/ha et fr 1.01, 0.83 et 1.00 de % d’atome pour les essays SA, SM et SL. La plus forte assimilation de 15N provenant des pailles a été observée dans la première repousse de l’expérimentation de SL (4.3 kg/ha de N-paille), suivie par les expérimentations de SM et SA (3.8 et 3.1 kg/ha de N-paille). En 2ème repousse, la récupération de l’azote provenant des pailles n’a pu être déterminée que pour les expérimentations de SA et SM, suite au feu accidentel survenu dans celle de SL. L’expérimentation de SA a eu le plus fort taux de prélèvement d’azote en provenance de la paille en 2ème repousse, soit plus du double de ce qui avait été mesuré en 1ère repousse. L’azote en provenance de la paille à SM a été de 0.8 kg/ha, soit bien plus bas que ce qui avait été observé en 1ère repousse. Après deux années de culture (1ère et 2ème repousse), la quantité totale de N en provenance des pailles a été respectivement de 3.9 kg/ha (9.8%) et 9.6 kg/ha (23%) pour SM et SA.
UTILIZACIÓN DEL NITRÓGENO A PARTIR DEL TRASH POR LAS CAÑAS SOCAS

PALABRAS CLAVES: Caña de Azúcar, Nitrógeno, Residuo, Trash, Materia Orgánica, Fertilidad del Suelo, Nutrición, 15N.

Resumen

Después de la cosecha mecánica de la caña en verde (sin quema), queda sobre la superficie del suelo una gran cantidad de residuos del cultivo (hojas secas, trozos de tallo y despunte). A estos residuos se los conoce frecuentemente como paja o trash y son una fuente de nutrientes para los cultivos subsiguientes. Con el objetivo de evaluar la capacidad de la caña de azúcar para recuperar nitrógeno (N) a partir de este residuo, se realizaron tres experiencias en los ingenios azucareros Santa Adélia (SA), São Martinho (SM) y São Luiz (SL), ubicados en el estado de San Pablo, Brasil, durante dos ciclos sucesivos de cultivo (2006 y 2007). Se trabajó con la variedad SP 81-3250, en la edad de primera soca, utilizando microparcels (1.5 × 2.0 m) en un diseño experimental de bloques al azar con cuatro repeticiones. En las microparcels no se realizó fertilización nitrogenada. El residuo de la cosecha en las microparcels fue remplazado por el equivalente a 10 t/ha (materia seca) de trash marcado con 15N. La tasa de trash-N y 15N fue 41, 41 y 51 kg/ha y 1.01, 0.83, y 1.00 átomo % para las experiencias en SA, SM y SL, respectivamente. La mayor absorción de 15N se observó en la soca 1 de la experiencia en SL (4.3 kg/ha de N del trash), seguida por las experiencias en SM y SA (3.8 y 3.1 kg/ha de N del trash). Para la edad de soca 2 (2008), la recuperación de N del trash solo pudo ser determinada para las experiencias en SA y SM, debido a un incendio accidental en la experiencia de SL. En la soca 2 la experiencia de SA presentó la más alta absorción de N del trash y fue más del doble de la recuperación de N del trash medida en la soca 1. La recuperación de N a partir del trash en SM fue de 0.8 kg de N/ha, sustancialmente menor que la observada en la primera soca. Después de dos ciclos de cultivo (1º y 2º soca) el total de N recuperado del trash fue 3.9 kg/ha (9.8%) y 9.6 kg/ha (23%), para las experiencias de SM y SA, respectivamente.
THE IMPACT OF REDUCED NITROGEN FERTILISER APPLICATION RATES ON NITROGEN LOADS TO SURFACE WATER

KEYWORDS: Nitrogen Replacement, Runoff, Fertiliser, Urea.

Abstract

NITROGEN losses to water from farming systems have the potential to negatively impact human and ecosystem health. Environmental damage to the Great Barrier Reef as a result of extra nitrogen inputs since European settlement is becoming increasingly apparent. Sugarcane is the dominant intensive landuse in Great Barrier Reef catchments, and consequently this industry’s nitrogen management practices are coming under increasing scrutiny and pressure to implement nitrogen management practices that reduce losses of nitrogen to the environment. An experiment was conducted in sugarcane on the Wet Tropical coast of Australia to measure nitrogen losses from two different rates of nitrogen fertiliser to surface water. Results show that substantial decreases in nitrogen application rate reduced nitrogen lost to surface water by 34%. Between 10 and 15 kg N/ha/y was lost in runoff water as total nitrogen, which is agronomically insignificant, but aggregated over the whole sugarcane industry, may be detrimental to the health of the Great Barrier Reef. For the sugarcane industry to reduce losses of nitrogen for improved water quality, reducing fertiliser rates is an appropriate management option that can deliver lower nitrogen contributions to downstream ecosystems.

Introduction

Nitrogen is an essential element for plant growth, providing good returns on investment in agricultural cropping systems (FAO, 2006). However, nitrogen can be mobile in the crop-soil system, and has been detected in water downstream of agriculture (e.g. Mitchell et al., 2001).

In Australia, elevated levels of nitrogen, likely to be originating from agricultural fertiliser use, have been detected in the rivers draining to the World Heritage listed Great Barrier Reef (Mitchell et al., 2001; Bramley and Roth, 2002). This extra nitrogen is a cause for concern, possibly causing degradation of the Great Barrier Reef (Brodie et al., 2005); and potentially lowering the reefs resilience to climate change (Wooldridge, 2009).

Sugarcane (Saccharum spp.) is by far the dominant cropping landuse in catchments draining to the Great Barrier Reef, occupying c. 380 000 ha (Canegrowers, 2009). In Australia, sugarcane receives annual nitrogen fertiliser applications of 150+ kg nitrogen per hectare (Calcino et al., 2000); however, not all of the applied nitrogen is used by the crop (Thorburn et al., 2003). Australian sugarcane is also grown with high water input from either high rainfall in the wet tropics or in supplementary or full irrigation in drier catchments. The majority of sugarcane grown in Great Barrier Reef catchments is grown on the coastal lowlands, floodplains and deltas close to estuaries,
creeks and river mouths. This proximity to the end of catchments means there are very short residence times for water draining from sugarcane farms to the Great Barrier Reef lagoon, providing little opportunity for in-river processes to remove nitrogen from the flow (Furnas and Mitchell, 2001). This unique combination of high fertiliser nitrogen input, high water input, proximity to the end of catchments and, by virtue of being the dominant landuse, means it is important to manage sugarcane to minimise nitrogen losses from the paddock to protect the sensitive ecosystems of the Great Barrier Reef.

Nitrogen losses from sugarcane production systems to ground water have been extensively investigated (e.g. Ng Kee Kwong and Deville, 1984; Ghiberto et al., 2009; Stewart et al., 2006; Bohl et al., 2000). While nitrogen lost to leaching is an economic imposition on the farm manager, the environmental consequences of this nitrogen on surface water are uncertain (Rasiah et al., 2005). The few studies of nitrogen losses in surface water suggest losses may be small, in the range of a few up to approximately 20 kg N/ha (Ng Kee Kwong et al., 2002; Bengtson et al., 1998) but, given sugarcane’s proximity to the Great Barrier Reef, virtually all nitrogen lost in surface water flow from cane lands will enter the reef lagoon (Furnas and Mitchell, 2001). Additionally, when these agronomically small nitrogen losses are aggregated across the entire sugarcane industry, they could be contributing a substantial increase in nitrogen flow to the Great Barrier Reef.

Furthermore, there is little evidence as to what contribution changing management practice may have on reducing nitrogen losses to surface water. For this reason, we measured nitrogen losses to surface water from two application rates of nitrogen fertiliser over two years to determine if nitrogen fertiliser application rate management can be a useful tool for reducing surface water nitrogen losses and ultimately benefit the Great Barrier Reef.

**Materials and methods**

Data were obtained from an experimental site in the Saltwater Creek catchment, in the Mossman district of north Queensland (approximately 16°S, 145°E). This district is in the wet tropics bioregion and receives an average annual rainfall of 2018 mm/year (Bureau of Meteorology, 2009); however, the experimental site receives on average approximately 750 mm more per annum according to the farmer (S. McDonald, pers. comm.). The experimental site has a well drained soil formed on alluvium, described as dark greyish brown silty clay loam A horizon and yellowish brown silty clay loam to light clay B horizon with moderate fine blocky structure (Murtha 1994). Soil organic carbon is 1.2% in the top 20 cm.

The site has been growing sugarcane continuously since the mid 1970s, with the sugarcane stool being ploughed out, the block cultivated and replanted to sugarcane in the same year every four to six years. The site has been harvested green with the residue retained since the early 1980s. The site was last planted in August 2000 with the cultivar Q174® and has been harvested in September of each subsequent year (achieving 64 tonnes/ha in 2001, 103 tonnes/ha in 2002, and 89 tonnes/ha in 2003).

The experimental program was initiated after the 2003 harvest (4th September 2003) with the site divided into six plots, each 13 rows wide (at 1.57 metre row spacing), a row length of approximately 175 metres, and a single row between each plot. One of two nitrogen rates was randomly assigned to plots, being either a) the normal nitrogen rate the farmer applies (N_farm), equalling 186 kg N/ha and b) a nitrogen rate based on replacing the nitrogen exported in the previous crop (N_repl), using a multiplier of yield in tonnes/ha (based on Thorburn et al., 2004), equalling 102 kg N/ha (a multiplier of yield in tonnes multiplied by 1.15 to determine rate in kg N/ha was used). All fertiliser was applied as urea on the surface trash on 28th October 2003.

On 28th and 29th October 2003, two of the plots (one from each treatment) were instrumented to record water runoff volume and automatically sample runoff water during events. Each plot had a 9 inch Parshall flume (extended to capture runoff from 11 rows) equipped with a
monitoring station including an ISCO automatic water sampler which could collect up to 24 samples and store at 4°C prior to collection, a stage recorder located in a stilling well, and a pluviometer. The stage recorders, sample data and pluviometer were connected to a Campbell CR10X data logger, linked via telemetry to download hourly for remote monitoring. A ridge ran across the plots, with not all surface water running towards the sampling stations. Each plot was surveyed using total station surveying gear, with the Nfarm rate draining an area of 3300 m² with a slope of 0.65%, and the Nrepl rate draining an area of 2600 m² and a slope of 0.33%.

Over the 2003/04 wet season, water samples were collected after each triggered sampling event and retained frozen before being transported and analysed for total nitrogen.

During events, the Parshall flume stage height was recorded every minute, with stage height being converted to discharge for all of the stage data recorded over the six month wet season. Some corrections were necessary to the raw stage data when there was ponding of water in the base of flumes after small rainfall events. Flow weighted TN was calculated for each monitored event.

**Results**

The 2003/04 wet season’s first runoff event was in the beginning of December 2003, and there were 20 monitored events through to the end of May 2004 (Figure 1). A total of 2868 mm of rain was recorded during this period (Figure 1). There were two distinct periods of heavy rainfall during the 2003/04 season, with 492 mm falling between 29th February 2004 and 3rd March 2004 and 465 mm falling on the 18th and 19th of March 2004. Flood events occurred during these two events where runoff water below the flume backed up into the flume, meaning accurate measurement of runoff discharge was not possible. Estimates of runoff discharge during these periods were made.

Runoff coefficients varied between the events from 1 up to 76% of rainfall being monitored as runoff water. The total runoff coefficients for the two plots had a high level of agreement, with 23.9% for the Nfarm plot and 24.9% for the Nrepl plot.
The calculated event mean concentrations for the first events were the highest for the year (9.75 mg/L in the N_farm treatment and 3.87 mg/L in the N_repl treatment). Both treatments showed a steady decline in event mean concentration after the first event down to 0.93 mg/L in the N_farm treatment and 0.42 mg/L in the N_repl treatment. Calculated N loads (kg/ha) for total nitrogen delivery to surface water are presented in Table 1. TN loads are highest in the high runoff events, even though they have lower event mean concentrations.

**Table 1**—Loads of total nitrogen (TN) lost to surface water for all monitored events in the 2003/04 wet season from two rates of nitrogen fertiliser application.

</table>

There was no significant difference between the two fertiliser treatments in yield (average 74 tonnes/ha), the amount of nitrogen in the above ground biomass (73 kg N/ha) or the amount of nitrogen exported from the plots (48 kg N/ha). There was, however, a significantly lower surplus (fertiliser nitrogen minus exported nitrogen) with the N_farm treatment having a surplus of 136 kg N/ha and N_repl a surplus of 57 kg N/ha.

**Discussion**

The most important finding in this paper is the confirmation that nitrogen losses from sugarcane to surface water can be reduced by lowering the nitrogen fertiliser application rate. Importantly, in these trials, the nitrogen fertiliser application rate was not too low to negatively impact on cane yield. Losses of total nitrogen to surface water from a sugarcane production system were reduced approximately 33% when fertiliser application rate was reduced from the growers normal rate of 186 kg N/ha to a nitrogen replacement rate of 102 kg N/ha.

The recorded total nitrogen losses to surface water over the 2003/04 wet season were 15 kg/ha when the N_farm application rate was used and 10 kg/ha with the N_repl application rate. These losses of nitrogen to surface water seem to be small (8 to 10% of applied nitrogen), and would not cause any significant agronomic impact, reflecting the findings of Ng Kee Kwong *et al.* (2002), who measured small losses of nitrogen to surface water and described the losses they found as ‘agronomically insignificant’. While this may be so, this contribution of nitrogen from sugarcane production to surface water may be contributing to the degradation of the Great Barrier Reef when
aggregated over the entire Australian sugarcane industry. Given the importance of nitrogen in surface water in Great Barrier Reef catchments, the 33% reductions reported here from lowering the nitrogen application rate could be highly environmentally significant.

There was a 38 day time lag between fertilisation date and the first event, probably allowing sufficient time for the urea fertiliser to hydrolyse and be immobilised into the soil organic matter. The first event did have the highest event mean concentration of total nitrogen, and this concentration reduced through the season.

Walton et al. (2000) investigated using tracer (KBr) losses to determine loss processes from sugarcane (KBr acts in a similar way to nitrate in water). Their study used rainfall simulation equipment, with simulated rainfall applied as soon as practical after tracer application. They reported high losses of the tracer and concluded nitrate losses from sugarcane to surface water could be significant. Comparing the results of Walton et al. (2000) with Ng Kee Kwong et al. (2002) and the results presented here suggests the time lag between fertiliser application and the first runoff event is a major determinant of the total nitrogen loss potential from sugarcane. This is consistent with the review of Daniels et al. (1998), who stated the amount, intensity and timing of the first runoff event after chemical application is the important determinant of losses.

In conclusion, we have shown that lowering N application rates will reduce N losses from sugarcane to the environment. Currently, losses of nitrogen in Great Barrier Reef catchments are too high (Brodie and Mitchell, 2005), and this study shows conclusively lower nitrogen fertiliser application rates will reduce the nitrogen load from sugarcane production systems to the Great Barrier Reef. The nitrogen replacement method (Thorburn et al., 2004) of determining nitrogen application rate is appropriate for determining lower application rates that achieve the dual goals of maintaining yield and benefiting downstream ecosystems.

Résumé

LES PERTES d'azote des systèmes de culture dans l’eau ont potentiellement un impact négatif sur la santé de l’homme et l’écosystème. Les dommages environnementaux sur les récifs de la Grande barrière dus aux apports supplémentaires d'azote consécutif à l’établissement des européens devient de plus en plus apparent. La canne à sucre est culture intensive dominante autour des captages de la grande barrière, et par conséquent les pratiques de gestion azotée de cette industrie sont de plus en plus examinées minutieusement et pressées d’établir des pratiques de gestion azotée qui réduisent les pertes en azote vers l'environnement extérieur. Un essai a été mené en canne à sucre sur la côte tropicale humide de l'Australie afin de déterminer les pertes d'azote vers les eaux de surface causées par deux apports différents d'engrais d'azoté. Les résultats montrent que les diminutions substantielles d’apports d’engrais azoté ont réduit de 34 % les pertes d’azote vers les eaux de surface. Entre 10 et 15 kilogrammes N/ha/an sont perdus par ruissellement, ce qui est agronomiquement insignifiant. Cependant, agrégés au niveau de l'industrie sucrière, ces pertes peuvent être nuisible à la santé de Grande Barrière.La diminution des apports d’azote est une stratégie appropriée qui peut améliorer la qualité de l'eau et entrainer des charges inférieures d'azote vers les écosystèmes en aval.
EL IMPACTO DE LAS DOSIS REDUCIDA DE NITRÓGENO DE FERTILIZANTES EN LOS NIVELES DE NITRÓGENO EN LAS AGUAS SUPERFICIALES

Resumen

La pérdida de nitrógeno desde los sistemas agrícolas hacia el agua tiene potencial para impactar negativamente sobre la salud humana y los ecosistemas. Daños ambientales en la Gran barrera de coral como resultado de las aportaciones de nitrógeno extra desde la colonización europea se está convirtiendo cada vez más evidente. La caña de azúcar es el intensivo uso de la tierra dominante en la Gran Barrera de Coral de las cuencas, y en consecuencia de este sector las prácticas de manejo de nitrógeno se encuentran bajo escrutinio cada vez mayor y la presión para implementar prácticas de manejo del nitrógeno, que reducir las pérdidas de nitrógeno al medio ambiente. Se realizó un experimento en la caña de azúcar en la costa tropical húmedo de Australia para medir las pérdidas de nitrógeno a partir de dos tipos diferentes de fertilizantes de nitrógeno a las aguas superficiales. Los resultados muestran que un descenso sustancial en la tasa de aplicación de nitrógeno reducido nitrógeno perdido en las aguas superficiales un 34%. Entre 10 y 15 kg N / ha / año se perdió en las aguas de escorrentía como nitrógeno total, que es insignificante punto de vista agronómico, sino agregados sobre la industria de la caña de azúcar entera, puede ser perjudicial para la salud de la Gran Barrera de Coral. Para la industria de la caña de azúcar para reducir las pérdidas de nitrógeno para mejorar la calidad del agua, la reducción de las tasas de abono es una opción de gestión apropiadas que pueden entregar las contribuciones más bajas de nitrógeno a los ecosistemas aguas abajo.
INFLUENCE OF BIO-ETHANOL DISTILLATION RESIDUE ON WATER QUALITY OF AN UNDERGROUND DAM

KEYWORDS: Bio-ethanol, Sugarcane, Vinasse.

Abstract

BIO-ETHANOL made from sugarcane is considered clean energy since the carbon accumulated in the plant is obtained from the atmosphere so that there is no net CO₂ flux when the biomass-energy is burned. In Okinawa, where the major sugarcane production takes place in Japan, a project for making bio-ethanol from molasses is being conducted. However, wasted liquid, called vinasse, that is 15 times as much as the distilled ethanol, is generated during the distillation, which is certainly a problem when creating sustainable energy. This vinasse is extremely dark brown and contains highly concentrated macro- and micro-nutrient elements, so it could be used as a liquid fertiliser. However, effects of the application of the vinasse on a soil are unknown. In addition, in Miyakojima in Okinawa, where the cultivated land area is limited and depends on an underground dam as a main water source, the sugarcane growers are anxious about the influence of colour especially and nitrate contamination of ground water by applying vinasse to their fields. We examined how the application of vinasse affects the ground water by analysing the drainage through a soil column after the application of 500 mL of vinasse and diluted vinasse over a 29-day period. From the ionic analysis for the nitrate concentration of the drainage of the each column, the potential for nitrate contamination in the underground dam by applying the diluted vinasse is of little concern. By the fact that application of the genuine vinasse caused the highly colored drainage, and with respect to possible salinity, we propose that the amount and times of diluted vinasse application as a fertiliser be limited.

Introduction

Japan imports about 80% of its energy. The Ministry of Economy, Trade and Industry and the Ministry of the Environment in the Japanese Government launched a project for producing bio-ethanol from the materials which do not conflict with food, such as dumped foodstuffs, extra-lumber for architecture and molasses.

The amount of the bio-ethanol made in Japan in 2005–2006 was about 30 kL, and a lot of effort is needed to accomplish the short term goal, 1.5 million kL/year, by 2015.

In Miyakojima Island in Okinawa, the area of sugarcane is around 8400 ha and the total amount of the production of sugarcane is approximately 300 kt.

In this island, producing bio-ethanol from molasses is being worked on as a part of the project. About 6000 t/year of molasses is made, and most of it has been transported to the main island of Japan for use as food for livestock. In the distillation process, ethanol is refined out of the residue, called vinasse.
In Miyakojima Island, at the refinery, 15–20 litres of vinasse for each litre of ethanol are produced, while using conventional technologies, 10–13 litres is produced in Brazil (Rocha et al., 2007). The vinasse in Miyakojima is an extremely dark, brown-coloured liquid, of acid nature, which has highly concentrated chemical components.

Returning vinasse to the farm as a partial or total substitute for mineral nutrients is thought to be a possible solution for disposal of the vinasse (Rocha et al., 2007).

However, since an underground dam supplies domestic water for the people in Miyakojima, sugarcane growers are concerned about the influence of the vinasse on it. In addition, nitrate contamination to the underground dam is also a concern.

The objective of this study is to assess the impact of diluted or non-diluted vinasse application on the groundwater by analysing drainage infiltrated through soil.

For the analysis, a column study was conducted and the turbidity, pH, EC and anions in the drainage were measured.

**Materials and methods**

**Soil sample and vinasse material**

The soil we used in this experiment was located in the experimental field in the University of the Ryukyus. The soil is low alkaline red clay soil and is widely spread in the Okinawa main island and in the other small separated islands, including Miyako Island.

The vinasse from the experimental bio-ethanol producing facility in Miyako Island had been applied to a column study. The vinasse is dark brown colored and, has highly concentrated chemical elements (Table 1).

| Table 1—Chemical properties of the vinasse used in this experiment. |
|-------------|-------|-----|-----|------|-----|-----|-----|-----|
|              | Na    | Mg  | P   | S    | K   | Ca  | Cl  | NO₃⁻ | pH  |
| Vinasse      | 603   | 2709| 180 | 4164 | 23  | 1564| 1082| 0    | 4.1 |

**Column study**

A total of 5 columns were made from polyvinyl chloride (PVC) pipe with inside diameter of 18.2 cm, length of 105 cm and a drain-hole with 1.5 cm diameter at the side 1 cm above the bottom of the column.

The bottom of the column was closed by the square PVC board which allowed the column to stand still. Twenty centimetre length tubes were fixed into the drain-hole, connecting the column and the flask which collects the drainage sample coming through the column.

The column was filled with mixed soil, 4 of 5 columns were saturated with water to compare buffer effects of soil with and without water, which was expected to allow the components of the vinasse to move more freely and remained for 24 hours to let the water drain by gravity.

The depths of the soil in the each column were equal to 96 cm. The photographs of the column just before the application are shown in Figures 1 and 2.

We set up 4 series of vinasse applications with 3 different concentrations of vinasse and 1 control (water) versus saturated soil columns, and a vinasse versus an unsaturated soil column.

Table 2 shows a tested series of column study. The different concentrations of vinasse were: a raw vinasse and diluted vinasse by 10% and 2%, and 500 mL of water poured into the column by hand. Sample-collections and applications were performed every morning. Samples were reserved in the refrigerator at 4°C.

Fig. 1—The prepared columns.

Fig. 2—The flask collecting the drainage from a column.

Measurements of the drainage water properties

For each drainage sample, we measured turbidity, pH, EC and anions. Anion contents measured were limited to nitrate, chloride and sulfate among the column c, d and e. pH and electrical conductivity were measured by turbidity sensor, pH sensor and EC meter respectively.

For the determination of anion contents in the drainage sample, each sample was filtrated through a membrane filter with a 5 mL plastic syringe to a vial of 500 µL volume and measured by ion chromatography.

The drainage of Column A was dripped for the first time at the 16th application (8 litre), while the other columns were obtained from the beginning of the application.

Results

The chemical properties of the drainage from the each column are shown in Figure 3. In each analysis, there was little variation detected up to the 15th application. After that point, the turbidity and EC of the drainage from columns A and B (applications of genuine vinasse) drastically escalated with each additional application. However, the drainage from columns C and D showed no change in turbidity and less increase in EC than for the raw vinasse.

Only when raw vinasse was applied was there a drop in pH of the drainage to approximately 6.5. In columns C, D and E, nitrate and sulfate concentrations in the drainage showed little fluctuation, and the highest density was found in Column E followed by D, then C at the 29th application. On the other hand, the chloride concentration in the drainage from columns C and D increased although the latter showed only a little gain (Figure 4).
Fig. 3—Chemical analysis of the drainage collected from 5 columns, each alphabets (A, B, C, D, and E) correlates with column codes in Table 2.

Fig. 4.—Anion analysis of the drainage from 3 columns (C, D and E).
Discussion

Effects on ground water quality

Though the present study gives the extreme results of unusual day-to-day applications of vinasse as a fertiliser, only applying the raw vinasse to the soil has the potential to cause observable effects on the turbidity and pH of the underground water.

Besides, by applying the raw vinasse to an unsaturated column continuously, both electric conductivity and pH reached the same levels as the application of the raw vinasse to a saturated column. It suggests that whether soil is wet or not, applying the raw vinasse has a potential to contaminate the underground dam once it reaches the limitation of soil capacity as a buffer.

However, considering the depth of the soil layer down to the underground dam, the fact that it took 16 applications (8 litres equivalent to 308 mm) for the raw vinasse to infiltrate the unsaturated soil thoroughly is an important consideration.

Application of a limited amount or times of a diluted vinasse may not directly affect the turbidity or pH of the underground dam. Since an increase of nitrate and sulfate ions in the drainage was not detected, the contamination of nitrate to the underground dam is of less concern.

However, the constant applications of vinasse on the soil increased the electric conductivity of the drainage, which suggests possible inhibition of the growth of crops by the application of vinasse.

The concentration of chloride and EC are highly correlated \((r = 0.94)\) and when the 10% diluted vinasse was applied continually, the concentration of chloride reached more than 1200 mg/L at the 29th application.

Consequently, salinity should be considered when determining how much the vinasse should be diluted and how many times it should be applied as a fertiliser.

Résumé

Le bio-éthanol fabriqué à partir de la canne est considéré comme une énergie propre puisque le carbone accumulé dans la plante est obtenu à partir de l’atmosphère de telle sorte qu’il n’y a pas de flux net de CO2 quand la biomasse-énergie est brûlée. A Okinawa, zone principale de production de canne à sucre au Japon, un projet de fabrication de bio-éthanol à partir des mélasses a été réalisé. Cependant, un déchet liquide appelé vinasse, 15 fois plus important en quantité que le bio-éthanol, est généré pendant la distillation, ce qui entraîne un problème environnemental lors de la création d’énergie durable. Cette vinasse brun foncé, est fortement concentrée en micro et macro éléments et pourrait être utilisée comme engrais liquide. Cependant, les effets de l’application des vinasses sur le sol ne sont pas connus. De plus, à Miyakojima (Okinawa), où la surface en terre cultivable est limitée et dépend d’un barrage souterrain comme principale ressource en eau, les planteurs de canne sont inquiets à propos de la coloration et de la contamination en nitrates de la nappe phréatique après application de vinasse dans les champs. Ainsi, nous avons étudié comment l’application de vinasse affecte la nappe phréatique en analysant le drainage à travers une colonne de sol après application de 500 ml de vinasse pure et de vinasse diluée pendant 29 jours. A partir des analyses de concentrations en nitrates des eaux drainées de chaque colonne, le potentiel de contamination en nitrates dans le barrage souterrain en appliquant de la vinasse diluée est un problème mineur. Du fait que l’application de vinasse entraîne un drainage fortement coloré et une possible salinité, nous proposons que les quantités et fréquences d’apports de vinasse diluée comme engrais soient limitées.
INFLUENCIA DEL RESIDUO DE LA DESTILACIÓN DE BIOETANOL EN LA CALIDAD DEL AGUA DE LA PRESA SUBTERRÁNEA

PALABRAS CLAVE: Bioetanol, Caña de Azúcar, Vinaza.

Resumen
EL BIOETANOL producido de caña de azúcar es considerado como energía limpia, dado que el carbón acumulado en la planta se obtiene de la atmósfera, de tal manera que no hay flujo neto de CO₂ cuando se consume la energía de la biomasa. En Okinawa, donde se produce la mayor parte de la caña de azúcar en Japón, se efectúa un proyecto para producir bioetanol a partir de melaza. Sin embargo, de esto se genera el residuo líquido denominado vinaza, cuyo volumen es 15 veces más que el del etanol destilado, lo cual representa un problema en la producción de energía sostenible. La vinaza posee un color marrón muy oscuro y contiene altas concentraciones de macro y micronutrientes, por lo que puede utilizarse como fertilizante líquido. No obstante, los efectos de la aplicación de la vinaza sobre el suelo se desconocen. Además, en Miyakojima, Okinawa, donde el área para cultivo es limitada y depende de la presa subterránea como principal fuente de agua, los productores están preocupados por la influencia que tengan, especialmente el color y contaminación con nitrato en el agua subterránea, por la aplicación de vinaza en sus campos. En el presente trabajo se examinó cómo la aplicación de vinaza afecta el agua subterránea, por medio del análisis del drenaje a través de una columna de suelo, después de la aplicación de 500 ml de vinaza y vinaza diluida, por un período de 29 días. Del análisis iónico para determinar la concentración de nitrato del drenaje de cada columna, muestra que el potencial de la contaminación con nitrato de la presa subterránea es de poca importancia cuando se aplica vinaza diluida. Dado que la aplicación de la vinaza sin diluir provoca una coloración fuerte en el drenaje y, posiblemente salinidad, se propone que se limite la cantidad y frecuencia de aplicación de vinaza diluida como fertilizante.
UTILISATION OF SILICON FROM METALLURGY SLAG BY SUGARCANE

By

R.T.X. SOUSA, G.H. KORNDÖRFER* and D.R.B WANGEN

KEYWORDS: Silicate, Soluble Si, Silicon Recovery, Accumulated Si.

Abstract
SUGARCANE is a species that accumulates silicon (Si) and has the ability to respond to silicon fertilisation, especially in soils where this element is scarce. Metallurgy slags constitute a source of Si in soils where this crop is grown. The objective of this paper was to study the value of metallurgy slag as a source of Si for sugarcane. A randomised block experimental design was adopted, in a 2×4 factorial combination represented by two sugarcane cultivars (SP81-3250 and RB86-7515) and four Si rates of slag providing 0, 100, 200, and 400 kg/ha. The application of metallurgy slag (silicate) increased the available soil Si content as well as the status of available Si and the Si content in sugarcane leaves. The amount of Si from the applied silicate accumulated by the above-ground part of sugarcane ranged between 23 and 56% in varieties RB86-7515 and SP81-3250, respectively. On average, 39% of the Si absorbed by the above-ground part of sugarcane came from the applied fertiliser (silicate).

Introduction
At present, the importance of sugarcane has been highlighted as a source material for the production of sugar and more particularly because it constitutes a basic input for the production of ethanol. Brazil stands out in the world scenario as the largest producer of sugarcane (Brazil. Ministério da Agricultura e Pecuária, 2007). However, many sugarcane areas in the country are characterised by significantly weathered soils, and therefore have small amounts of soluble or available silicon (Si) available to crops.

Sugarcane is considered a Si-accumulating crop. Several studies (Pereira et al., 2004; Carvalho-Pupatto et al., 2003; Berni and Prabhu, 2003) have demonstrated that grasses respond favourably to silicon fertilisation, especially when grown in soils deficient in ‘available’ Si.

Si provides many benefits to sugarcane including increased photosynthetic efficiency and resistance to the attack of pests and diseases, higher tolerance to water stress during periods of low soil moisture (Korndörfer and Datnoff, 1995), relief from damage caused by frosts and improved plant architecture (Savant et al., 1999), among others.

Such benefits result in improved sugarcane quality and increased sugarcane productivity. According to Kingston et al. (2005), the beneficial effects of Si in sugarcane clearly indicate that this element should be treated as an integral part of the fertilisation practices associated with sugarcane cultivation.

The metallurgy slags from iron steel production are basically composed of calcium and magnesium silicates. So long as they do not contain heavy metals in their composition, they can satisfactorily meet the requirements of a good Si source for agricultural use, such as: high soluble Si content, easy mechanised application, balanced ratios and amounts of calcium (Ca) and magnesium (Mg), low cost, and low soil contamination potential with heavy metals (Korndorfer et al., 2004a).
Although the agricultural use of industrial residues such as metallurgy slags is not very common in Brazil in spite of the high quantities available, their use as a source of Si for plants has been studied and in many parts of the world (Prado and Fernandes, 2001).

Considering that part of Si absorbed/accumulated by plants comes from the soil and another part comes from Si applied in the form of fertiliser, our aim in this study was to evaluate varietal differences with regard to Si absorption and the amount of accumulated Si in the above-ground part that is derived from metallurgy slag.

**Material and methods**

The experiment was conducted in an experimental area of Universidade Federal de Uberlândia, in Uberlândia city, Brazil, simulating a field situation, during the period from August 15, 2007 to May 2, 2008.

A randomised block experimental design was adopted, in a 2×4 factorial combination represented by two sugarcane cultivars (SP81-3250 and RB86-7515) and four rates of Si (0, 100, 200, and 400 kg/ha), with four replicates (Table 1).

The metallurgy slag (CaSiO$_3$) employed had the following physical and chemical characteristics: powder formulation, CaO: 42%, MgO: 12%, SiO$_2$: 23%, total Si 11.2% (determined by colorimetry after extraction with hydrochloric acid and hydrofluoric acid, according to methodology described by Korndorfer et al (2004b), P$_2$O$_5$: 0.4%, K$_2$O: 0.2%, SO$_4$: 4.4%, Fe: 8.5%, Mn: 1.4%, Mo: 0.4 mg/kg; and Zn: 0.1 mg/kg. Each experimental plot consisted of a plastic tank (200 L capacity), filled with 200 kg of soil where three sugarcane stools were planted.

The soil used in the pots was taken from the 0–20cm of a soil classified as typic Dark Red Dystrophic Latosol with the following chemical characteristics: organic matter = 13 g/dm; pH in CaCl$_2$ 0.01 mol/L (1:2.5) = 5.2; P mehlich = 2.7 mg/dm; K = 1; Ca = 7.0; Mg = 3.0; H + Al = 31.0 all exchangeable in mmol/dm; and V (base saturation) = 27%, (Embrapa, 1999). The amount of soil soluble Si, 4.3 mg/dm, was determined according to a methodology described by Korndorfer et al (2004b), using CaCl$_2$ 0.01 mol/L as extractant.

Before the sugarcane seedlings were transplanted to the tanks (permanent site), pre-established quantities of limestone were applied (Table 1), with physical and chemical characteristics similar to those found in the slag used (TNP 85%, CaO = 42%, and MgO = 12%). Both Ca and Mg were balanced, that is, all pots received identical quantities of Ca and Mg.

All treatments received 100 kg N/ha as ammonium sulfate, 300 kg P$_2$O$_5$/ha as single superphosphate, 300 kg K$_2$O/ha as potassium chloride, 80 kg/ha of a cocktail (FTE – BR12) containing 9% Zn, 1.8% B, 2% Mn, 0.8% Cu, 0.1% Mo, and 3% Fe, as recommended by Boletim Técnico N° 100 (1996).

</tbody>
</table>

The amount of soil used in each tank was divided into two portions of 100 kg each. The nutrients (both macro and micro) were incorporated in to one of those parts. Next, the soil was placed in the bottom of the tank. The treatments, the limestone and the slag were incorporated into
the second portion of soil, which was then placed in the pot, over the first portion. This procedure was adopted to achieve a uniform distribution of nutrients in the entire tank, leaving the limestone and the silicate in the first soil layer only. Water was added in the next step, with about 32 L applied per pot; this is the quantity required to reach approximately 70% of field capacity. The amounts of slag and limestone used in each treatment are presented in Table 1.

Three pre-germinated (one month old) cuttings of sugarcane were planted in each tank on September 13. Two kg/ha boric acid were applied per pot on December 10, 2007 (87 days after transplanting). On December 17, 2007, after nitrogen deficiency was detected, we applied 200 kg/ha N in the form of ammonium sulfate (20% N). On December 21, 2007 we again applied 2 kg/ha boric acid. Leaves (first leaf from the apex to the base at the TVD or Top Visible Dewlap) were collected in January 2008 for Si analysis according to methodology described by Korndorfer and Ramos (2008). Soil samples were taken on the same day for determination of available or soluble Si.

Since a high infestation of sugarcane spittlebugs was observed in the overall experiment, the insecticide thiamethoxan 250WG was applied on March 13, 2008 at a rate of 2.5g of active ingredient per 4 L water. The sugarcane was harvested eight months after planting. At harvest, the plants were divided into leader shoot (heart + leaves) and stalks and then weighed.

The plant material was ground separately and dried in a forced air circulation oven at 65°C to constant weight. After drying, the material was placed in properly identified plastic bags. Si accumulation by the plants was determined as a function of dry matter yield and on Si content in the tissues of the various plant parts.

Si determinations were made according to analytical procedures described by Korndorfer et al. (2004a). After harvest, soil samples were taken from each pot for determination of soluble Si analysis according to Korndorfer et al. (2004a) and for determination of pH and exchangeable Ca and Mg analysis according to Embrapa (1999). The qualitative results were submitted to analysis of variance and means were compared using Tukey’s test at 5% significance. The quantitative results were submitted to polynomial regression analysis. The SISVAR software was used in the statistical analysis (Ferreira, 2000).

**Results and discussion**

Si content in the soil showed an increasing trend with increasing rates of slag at 120 and 260 days after application (Figure 1).

![Graph showing the relationship between Si content and Si rates](image)

The data showed that, at 120 days, indicated Si content increased by 18, 56, and 72% relative to the control, for doses of 100, 200, and 400 kg Si/ha, respectively. At 260 days, soil Si contents in the treatments that received 100, 200, and 400 kg/ha Si were 2, 8, and 50% higher than the control, indicating that nine months after application, the slag continued to supply Si to the soil although at smaller quantities with the lower rates of 100 and 200 kg Si/ha.
By comparing the soil Si results at 120 and 260 days after slag application, a significant reduction can be noted in available Si contents in the soil (Figure 1). Such difference can be explained in part by Si extraction by the sugarcane (Table 2). Si contents in the plants increased from 12.31 to 17.46 g per pot when the Si dose applied was 400 kg/ha, corresponding to an increase of approximately 70% in the amount of Si extracted by the above-ground part of sugarcane (Table 2).

The increased Si contents in the soil caused by the application of slag resulted in increased amounts of Si accumulated in the above-ground part of sugarcane (Table 2).

The silicon mean recovery from slag (mean of two sugarcane cultivars) was 39.4%, varying from 25.8 to 56.6% depending on the Si rate used (Table 2). Considering the fact that the soil under study had low clay (sandy soil), low organic matter and low water retention capacity, the interaction of the slag particles with the soil solid phase was smaller, which can explain the low reactivity of the slag (silicate) applied. This result agrees with those reported by Korndörfer et al. (1999), who studied the effect of calcium silicate as a source of Si on upland rice crop in four soils representative of the savanna region and found greater recovery of this element in soils with higher clay contents.

* Absorbed Si from the fertiliser = Si accumulated in the above-ground part – Si accumulated by the control;
** Recovery Index (%) = (absorbed Si from the fertiliser/applied Si) × 100

Cultivar SP81-3250 had the highest Si recovery capacity (Recovery Index equal to 55.8%), which means that of all absorbed Si more than one half came from the fertiliser. The difference between recovered Si amounts was approximately 60%, which gives variety SP81-3250 a greater capacity of utilising Si from the fertiliser (slag) when compared with variety RB86-7515 (Figure 2).
In general, cultivar SP81-3250 proved superior to RB86-7515 for its capacity to accumulate Si in the top leaves, lower leaves, and stalks, which resulted in greater accumulation of this element in the whole above-ground part of the plant (Table 3).

The mean contents of Si accumulated in the top leaves, lower leaves, stalks, and the whole above-ground part of cultivar SP81-3250 were 80%, 29%, 23%, and 24% higher, respectively, than the values accumulated by variety RB86-7515 (Table 3).

The mean Si contents accumulated in the leaves, stalk, and the whole above-ground part increased linearly with Si doses applied (Figures 3a, 3b, and 3c).

This fact reinforces the importance of Si use in sugarcane fertilisation to obtain greater resistance against pests, diseases and drought susceptibility.

The foliar diagnosis performed at 87 days after planting the seedlings showed that variety RB86-7515 had a higher incidence of B deficiency symptoms when compared with variety SP81-3250 (Table 4).

CV: 10% LSD (cultivar): 0.05 LSD (mean): 0.03

*Means followed by the same letter in the line are not significant by the Tukey test at 5% significance.
***LSD = least significant difference.

**Means followed by the same letter in the line are not significant by the Tukey test at 5% significance.
****LSD = least significant difference.

*** Report made 87 days after seed transplanting.
The two sugarcane cultivars did not differ from each other for Si content in the top leaves and lower leaves in any of the doses applied (Table 4). However, the mean Si concentrations increased from 0.33 to 0.37% in the top leaves and from 0.94% to 1.28% with the highest rate of 400 kg/ha.

Regardless of cultivars, Si concentration in the top leaves and the lower leaves increased linearly with doses of this element (Figures 4a and 4b). When the control is compared against the highest Si dose (400 kg/ha), the mean values of increase in Si concentration in the top leaves and lower leaves were 36 and 12%, respectively.

Variety SP81-3250 had a significantly higher (14% higher, on average) Si content in stalks compared to variety RB86-7515 (Table 4). Considering only the two highest Si doses (200 and 400 kg/ha), cultivar SP81-3250 concentrated 15 and 22% more Si in stalks, respectively, than RB86-7515 (Table 4).

Silicon deposition in stalks may increase sugarcane resistance to lodging (Ma and Takahashi, 2002). This trait is particularly important in mechanised green cane harvest. The selection of varieties with high Si uptake potential could minimise damping-off problems in mechanised harvest.

The mean Si content in stalks of both sugarcane varieties increased linearly with Si doses applied to the soil (Figure 4c). Plants grown in the presence of 400 kg/ha Si had 60% more Si in stalks than control plants.
Si deposition in stalks could also increase sugarcane resistance to the attack of pests such as the stalk borer, *Eldana saccharina* (Lepidoptera: Piralidae) (Keeping and Meyer, 2005).

**Conclusions**

a) The silicate application increased the soil content of available Si and the Si content in sugarcane leaves.

b) The amount of Si from the applied silicate accumulated by the above-ground part of sugarcane ranged between 23 and 56% in varieties SP81-3250 and RB86-7515, respectively.

c) On average, 39% of the Si absorbed by the above-ground part of sugarcane came from the applied fertiliser (silicate).

Résumé

LA CANNE à sucre est une espèce qui accumule le Silicium (Si) et a la capacité de répondre à de la fertilisation à base de Silicium, spécialement dans les sols où cet élément est rare. Les scories de métallurgie constituent une source de Si pour les sols où la canne à sucre est cultivée. L’objectif de ce papier est d’étudier la valeur des scories de métallurgie comme source de Si pour la canne à sucre. Un essai factoriel 2×4 en blocs randomisés fut réalisé. Cet essai comprenait 2 variétés (SP81-3250 et RB86-7515) et 4 doses (0, 100, 200, et 400 kg/ha) de Si provenant de scories. L’épandage des scories de métallurgie (silicate) augmenta la teneur en Si assimilable du sol aussi bien que le statut en Si assimilable et la teneur en en Si des feuilles. La quantité de Si accumulée par les parties aériennes de la canne à sucre variait respectivement de 23 à 56% dans les variétés RB86-7515 et SP81-3250. En moyenne, 39% du Si absorbé par les parties aériennes provenait de l’engrais appliqué (silicate).

UTILIZACIÓN DE SILICIO PROVENIENTE DEL DESECHO DE LA METALURGIA, POR LA CAÑA DE AZÚCAR

PALABRAS CLAVE: Silicato, Si soluble, Recuperación de Silicio, Si Acumulado.

Resumen

LA CAÑA de azúcar es una especie que acumula silicio (Si) y tiene la habilidad de responder a la fertilización con silicio, especialmente en suelos donde este elemento es escaso. Los desechos de la metalurgia constituyen una fuente de Si en suelos donde se planta este cultivo. El objetivo de este trabajo era estudiar el valor del desecho de la metalurgia como fuente de Si para la caña de azúcar. Se empleó un diseño experimental de bloques al azar, en una combinación factorial 2×4, representada por dos variedades de caña de azúcar (SP81-3250 y RB86-7515) y cuatro dosis de Si proveniente del desecho, que proporcionaran 0, 100, 200 y 400 kg/ha. La aplicación del desecho de la metalurgia (silicato) incrementó el contenido de Si disponible en el suelo, así como el estado de disponibilidad de Si y el contenido de Si en las hojas de la caña de azúcar. La cantidad de Si del silicato aplicado acumulada en la parte aérea de la planta osciló entre 23 y 56% en las variedades SP81-3250 y RB86-7515, respectivamente. En promedio, 39% del Si absorbido por la parte aérea de la planta provinio del fertilizante aplicado (silicato).
SUGAR PRODUCTION: INTEGRATION AMONG SUGAR, ALCOHOL, RESIDUE CYCLING AND SUSTAINABILITY—A REPORT ON THE 2009 AGRONOMY WORKSHOP

By

KEYWORDS: Productivity, Trash Management, Green Manuring, Irrigation, Fertilisation, Weed Control.

Abstract

The 2009 Agronomy Workshop was held from 24 to 28 May 2009 in Uberlandia, Brazil. It was attended by some 70 participants with 22 of them travelling overseas from 13 different countries. The workshop was a success with 33 oral presentations (and 16 posters) spread under the following five specific themes: new technologies for sustainable sugar cane production, ratoon yield decline and its management, modelling sugarcane growth and production, soil and plant residue management, and the challenge of environmental pressure and strategy for the sugarcane grower. The workshop was also an opportunity to gain an insight into the sugar industry in Brazil, in particular the cultural practices adopted and the status of research and development in the country. The workshop has served as a reminder to technologists that optimising sugarcane production requires high quality seed to establish the plantation and the adoption of an integrated approach to the management of the crop. This integrated approach to optimise or enhance productivity includes the adoption of the most suitable technology in irrigation, fertilisation, weed management and crop protection. Though it is accepted that a sustainable sugarcane production system lies in soil organic matter conservation, particularly through green-cane harvesting, the management of the residues to avoid loss in productivity still needs to be researched. There will be no universally applicable residue-management system, and each system will need to be tested under the specific conditions prevailing locally. With the rising demand for higher fibre cultivars for cogeneration and ethanol synthesis, research and development in sugarcane agronomy will be increasingly focussed towards optimising the partitioning of the biomass in favour of fibre. The workshop has also created awareness that research and development initiatives will not attain the objective of enhanced productivity if social and organisational constraints impacting negatively on agronomic practices at field level are not addressed.

Introduction

The 2009 ISSCT Agronomy Workshop was held from 24 to 28 May 2009 at the Plaza Convention Centre in Uberlandia, Brazil. The workshop was very well organised with three institutions collaborating closely (the Federal University of Uberlandia, the Society of Sugar Cane Technologists of Brazil and APTA) to make the attendance worthwhile and interesting to the participants. However, with the world economy in recession, the response by sugarcane technologists to the workshop was understandably below expectation as, of the 70 participants, only 22 of them were from overseas from 13 different countries.

The workshop nevertheless was an excellent opportunity for the participants from overseas to acquire an overview of the sugar industry in Brazil, in particular the cultural practices and the status of research and development in the country. The constraints to the sugar industry worldwide
at the beginning of this 21st century are wide ranging and, in agronomy, they tend to be the same in all countries. Those constraints to the viability and sustainability of the sugarcane production systems cannot be resolved by research and development in just one specific discipline in agronomy. Instead an integrated approach is warranted and accordingly the theme of the workshop *Sugar production: Integration among sugar, alcohol, residue cycling and sustainability* was chosen to cover the spectrum of interests in agronomy.

Following the opening of the workshop by the Mayor of the City of Uberlandia and a very enlightening keynote address on ‘*Perspective for the sugar cane production in Brazil and in the world*’ by Dr Roberto Rodrigues, a former Minister of Agriculture of Brazil, the scene for discussion and interaction among the technologists was set by 33 oral presentations (and 16 posters) spread under the five following specific themes.

- New technologies for sustainable sugarcane production.
- Ratoon yield decline and its management.
- Modelling sugarcane growth and production.
- Soil and plant residue management.
- Challenge of environmental pressure and strategy for the sugarcane grower.

The discussion after each presentation was positive and lively, demonstrating the interest and willingness of the participants to share and exchange their know-how. A report on the presentations and discussions is given in the sections below.

Report and discussion

**Optimum sugar cane productivity**

One factor that is often overlooked and yet is the basis of a successful sugarcane crop is the necessity for high quality seed cane, particularly free from diseases. Attention to the central role which high quality seed cane plays in reducing costs and bringing out the real productive potential of sugarcane varieties grown was demonstrated in Tucuman, Argentina. Here one of the constraints to sugarcane production was the lack of nurseries guaranteeing high quality seed cane availability and purity, with the result that commercial plantations have widespread high RSD incidence levels (>50%) which may cause production losses of 50%. It also emerged from the workshop that once high quality seed is planted, an integrated approach to the management of the sugarcane crop must be adopted to optimise productivity. In this context, work in Thailand showed that while dual-row planting raised cane yields by 26–31% in plant cane and by 12–24% in first ratoon, dual-row planting with green manuring increased cane yields by 47–48%, while irrigation with recommended fertiliser and dual-row planting caused cane yields to rise by as much as 64–72% without the quality of the cane juice being affected.

It was also evident that to optimise productivity, the most appropriate technology or agronomic management system must be chosen. Thus, though many different irrigation systems are available and can be adopted, work done in Brazil demonstrates that drip irrigation conserves water and energy, thereby further increasing the profitability of the sugarcane production system particularly when varieties showing a better yield potential under the drip irrigation system are grown. The results obtained in Brazil showed a rise in sugarcane production of some 30 tonnes cane per hectare under drip irrigation, with different responses being obtained among the varieties tested.

Further avenues to optimise the profitability and sustainability of the sugarcane production systems that were presented at the workshop were:

- **Use of a foliar biofertiliser consisting of mesophilic, cellulolytic, ammonifying and nitrifying fungi and yeasts and containing low quantities of NPKCa and micronutrients.** Studies in Argentina showed that 10 L/ha of this foliar biofertiliser was an effective substitute for half the dose of N traditionally supplied by synthetic sources, that is 120 kg N/ha as urea instead of 240 kg/ha.
Adoption of leguminous green manure not only to provide nitrogen to the crop but also to improve the fertility of the soil by gradually increasing the organic matter content in the soil and to hinder the development of the weed population. Work in Brazil showed that sunhemp decreased the incidence of light and thermal amplitude on the ground, thereby hindering the germination of weeds. In field trials, while the control without green manure gave cane yields of 135.5 t/ha, treatments with pigeon pea and *Crotalaria juncea* produced 158.8 and 157.0 t cane/ha, respectively. Studies of different rotation systems with leguminous crops in Brazil further showed that the best rotation system for sugarcane in that country was a two-year soybean cultivation as opposed to fallow, one-year soybean cultivation and one or two years with *Crotalaria*.

Adoption of a weed management strategy based on the critical period of competition between weeds and sugarcane. Weed control in sugarcane in Mauritius has traditionally been achieved by two or even three herbicide applications per cropping season and is often complemented by manual weeding. With the adoption of a new strategy based on the initial period of weed control which started at least 6 weeks after planting or harvest and which ended 14–20 weeks later, there was a saving of at least one herbicide application per season. Further savings in herbicide costs were achieved by adoption of mechanical weeding during the first 12–16 weeks after planting and in ratoon by promoting the adoption of green-cane trash blanketing.

Controlling prevalence of pests. Harvest age has been presented as being critical to production of sugarcane in South Africa, a 12, 18 or 24 month cycle being practised depending on the environment. Data were presented to show that lower yields were obtained for the 18-month cane as a result of *Eldana* damage associated with aging of the sugarcane along the coast. High yields with aging cane can only be achieved by planting appropriate varieties that have good *Eldana* resistance. In the control of pests, the merit of silicon to induce sugarcane resistance to insects such as spittlebugs was demonstrated in Brazil.

Management of trash residues

It was clear at the workshop that soil organic matter conservation and build up in the soil are most critical for a sustainable sugarcane production. Data presented from Argentina showed that a trash-blanket treatment led to a significantly higher crop yield (83.5 tonnes cane/ha) as compared with a treatment without residue retention (53.7 tonnes/ha). It was, however, also evident from the presentations and discussion at the workshop that one system of trash-residue management could not fit all situations. The management of the residues from green-cane harvesting still needs to be researched and tested under specific local conditions to avoid drawbacks such as prevalence of pests like the spittlebug, or slower shoot appearance and lower tillering rate as a result of lower temperature under the trash blanket causing ultimately a reduced sugarcane yield as was observed for instance in Brazil. It was reported that a 100% trash cover of the soil gave for instance 83 tonnes cane/ha as opposed to 91 tonnes/ha and 96 tonnes/ha in trash management systems covering respectively, 66% and 33% of the soil surface. Under the temperate climatic conditions of Louisiana, burning the trash as soon as possible after harvest was even shown to give consistently better yields than when the mulch was left on the field after harvest or mechanically removed by a hay bailer.

New technologies

The workshop was an opportunity to present progress or refinements in new technologies that can be applied in sugarcane agronomic management systems. Biomass estimates inferred from remote sensing techniques were shown to be well correlated with gross cane yields obtained from field measurements in Louisiana. The yield variations within field were sufficiently large to justify a precision agriculture approach in the management of the crop. In this context, the suitability of mapping soil pH and electrical conductivity in a 25–ha fallow sugarcane field to assist producers in developing lime variable rate application in sugarcane was demonstrated. Progress in modelling sugarcane growth has been achieved with an up-to-date Canegro model modularised and
incorporated into the DSSAT4.5. Though room for improvement exists, the model was shown to perform fairly well when simulations were compared with experimental data.

In the investigation of the sugarcane root system, particularly root length density which, though a key factor for sugarcane water and nutrient uptake, is difficult to measure, a technique was presented based on root intersection counting with a 0.5 m x 0.5 m mesh grid on a soil profile and modelling the root length density from the root intersection counting. This new method is 10-fold, less time consuming than the core sampling method and has the merit of not needing the export of soil samples. Using the technique developed, studies in Brazil have provided evidence that sugarcane root development in ratoon is not affected by the changes in soil management practices, namely from conventional tillage (soil cultivation and disking twice at planting) to minimum tillage (soil cultivation with one disking at planting) and to no tillage (only disking at planting).

**Initiatives required**

The workshop in Brazil moreover has the merit of drawing attention to the need for broadening the research base in the agronomy of sugarcane. Current research on sugarcane is focused on contemporary cultivars which are designed to have low to moderate fibre levels and high sucrose and fermentables for sugar or ethanol production. A shift in paradigm is now occurring with the higher demand for high fibre cultivars for electricity cogeneration or for conversion of cellulose and hemicellulose to ethanol and syngas. The impact which this shift in paradigm has on biomass partitioning in sugarcane will need to be studied from all angles in agronomy. Preliminary results from Australia showed that, though cultivars did not generally result in significant difference in total biomass production or in the yield of the vegetative components, significant differences, however, occurred among the cultivars in the partitioning of the dry matter to fibre and soluble sugar equivalents. Research in such areas as fertilisation, cultural operations and irrigation needs to be pursued to optimise the partitioning of the biomass depending on market economies which will include consideration of price for products, processing costs and conversion efficiency. Work done in Japan has in this context indicated that high biomass cultivars may require more nitrogen and potassium than conventional sugarcane varieties.

Progress in research and development of sugarcane initiatives focussed only on the economic and environmental pillars of sustainability would not suffice to achieve the objective of higher productivity. Indeed it emerged at the workshop that less tangible factors such as trust, communication and coordination between growers and contractors or other stakeholders are equally important and should not be ignored. These factors have a direct impact on agronomic practices at field level as demonstrated in a study in South Africa where, in spite of climate, soils and terrain being well suited to sugarcane production, the reality over the past 10 years or more had been a persistent decline in yields and land abandonment. The study confirmed the occurrence of numerous improper practices at field level such as lengthy harvest to crush delays, poorly controlled burning, improper weed and fertiliser management, the root causes of which could all be traced back to social and organisational constraints at the local community levels rather than to lack of knowledge.

**Conclusions**

The workshop has been a success due to a large extent to the effort made by the local organising team led by Professor Gaspar Korndorfer. Research-wise, the workshop provided the opportunity to gauge the progress accomplished in sugarcane agronomy during the three years since the preceding workshop was held in Thailand in 2006. If there is no doubt that profitable and sustainable sugarcane production lies most importantly in soil organic matter conservation, particularly through green-cane harvesting, it is also clear that more effective techniques for incorporating the residues into the soil than current available methods remain a research challenge in many sugarcane growing areas of the world. The incidence of some negative results on productivity arising from trash blanketing has also served to emphasise that one solution could not fit all situations and each research finding requires testing under the specific local conditions prevailing in each country or state.
The workshop has also reinforced the awareness that the sugar industry in the world has common goals in agronomy, namely the search for alternatives to mineral fertilisers through research on green manuring and on biofertilisers, more efficient means of pest control, a more effective irrigation system and weed management so as to minimise production costs. However, the research and development in agronomy will not attain the desired goal of higher productivity if impeding factors such as trust and coordination among the stakeholders are not simultaneously addressed.

PRODUCTION SUCRIÈRE: INTÉGRATION ENTRE SUCRE, ALCOOL, RECYCLAGE DES RÉSIDUS ET DURABILITÉ – UN RAPPORT SUR L’ATELIER 2009 D’AGRONOMIE

Par

K.F. RENE NG KEE KWONG

Institut de Recherche de l’Industrie Sucrière de Maurice

RNKKwong@msiri.intnet.mu

MOTS-CLÉS: Productivité, Gestion de la Paille, Légumineuses, Irrigation, Fertilisation, Contrôle des Mauvaises Herbes.

Résumé

L’ATELIER DE travail 2009 en agronomie a eu lieu du 24 au 28 mai 2009 à Uberlândia, Brésil. Il a réuni quelque 70 participants dont 22 venaient de 13 pays différents d’outre-mer. L’atelier de travail a été un succès avec 33 présentations orales (et 16 posters), répartis sous cinq thèmes spécifiques: les nouvelles technologies pour la production durable de canne à sucre, la baisse de rendement en repousses et sa gestion, la modélisation de la croissance de la canne à sucre et de la production, la gestion des résidus du sol et de la plante, et le défi de la pression environnementale et de la stratégie pour le producteur de canne à sucre. L’atelier de travail a procuré l’occasion d’avoir un aperçu de l’industrie sucrière brésilienne, en particulier les pratiques culturales adoptées et l’état de la recherche et du développement dans ce pays. L’atelier de travail a également été l’occasion de rappeler aux technologues que l’optimisation de la production cannière requiert avant tout des semences de bonne qualité pour l’établissement des plantations et l’adoption d’une approche intégrée dans la gestion de la culture. Cette approche intégrée repose sur l’adoption de la technologie la plus adaptée en irrigation, fertilisation, contrôle des mauvaises herbes et protection de la culture. Bien qu’il soit admis que la viabilité du système de production de canne à sucre se trouve dans la conservation de la matière organique du sol, en particulier avec la récolte de la canne en vert, la gestion des résidus afin d’éviter la perte de productivité doit encore être étudiée. Il n’y aura pas d’application universelle du système de gestion des résidus, chaque système devant être testé selon les conditions locales spécifiques. L’atelier de travail a conscientisé les participants sur le fait qu’avec l’augmentation de la demande pour des variétés à forte teneur en fibre pour la cogénération, et la production de l’éthanol, le paradigme dans la recherche et le développement de la canne à sucre est appelé à se déplacer vers l’optimisation de la partition de la biomasse en faveur de la fibre. L’atelier de travail a également créé une prise de conscience que la recherche et les initiatives de développement n’atteindront pas les objectifs fixés de l’amélioration de la productivité si les contraintes sociales et organisationnelles ayant un impact négatif sur les pratiques agronomiques au niveau des champs ne sont pas résolues.
PRODUCCIÓN DE AZÚCAR: INTEGRACIÓN ENTRE AZÚCAR, ALCOHOL, UTILIZACIÓN DE RESIDUOS Y LA SUSTENTABILIDAD – INFORME SOBRE EL TALLER DE AGRONOMÍA 2009

Por

K F RENE NG KEE KWONG
Instituto de Investigación de la Industria Azucarera de Mauricio

PALABRAS CLAVE: Productividad, Manejo de Trash, Abono Verde, Irrigación, Fertilización, Control de Malezas.

Resumen
El TALLER de Agronomía 2009 se llevó a cabo del 24 al 28 de mayo de 2009 en Uberlandia, Brasil. Asistieron a él 70 participantes, de los cuales 22 habían cruzado el océano, arribando desde 13 países diferentes. El taller fue un éxito, con 33 presentaciones orales (y 16 pósteres) que versaron en los siguientes cinco temas específicos: nuevas tecnologías para una producción sustentable de azúcar, la disminución del rendimiento de la caña soca y su manejo, el uso de modelos para el crecimiento de la caña y su producción, el manejo del suelo y residuos de la planta y el desafío de la presión ambientalista y estrategias para el productor cañero. El taller también constituyó una oportunidad para reflexionar acerca de la industria azucarera en Brasil, en particular en lo que concierne a las prácticas culturales adoptadas allí y el estatus de la investigación que se lleva a cabo en el país y su desarrollo. El taller ha servido para recordarles a los tecnólogos que, para optimizar la producción de caña de azúcar, se requiere la utilización de semilla de alta calidad para establecer la plantación y la adopción de un enfoque integral del manejo del cultivo. Este enfoque integral para optimizar y aumentar la productividad involucra la adopción de las tecnologías más adecuadas para la irrigación, fertilización, control de malezas y protección del cultivo. Aunque se acepta la idea de que un sistema de producción de caña de azúcar sustentable se basa en la conservación de la materia orgánica del suelo, particularmente mediante la cosecha de caña en verde, se necesita aún investigar sobre manejo de residuos para evitar pérdidas en la productividad. No existe ni existirá un sistema de manejo de residuos universalmente aplicable, y cada sistema necesitará ser evaluado en las condiciones locales predominantes. Con la demanda creciente de cultivares con mayor contenido en fibra para la cogeneración y síntesis de bioetanol, la investigación y desarrollo de la agronomía de la caña de azúcar estará cada vez más focalizada en optimizar la partición de la biomasa a favor de la obtención de fibra. El taller también ha logrado que se tome conciencia de que si no se trabaja sobre las limitaciones sociales y organizativas que impactan negativamente en las prácticas agronómicas a nivel del campo, las iniciativas en investigación y desarrollo para aumentar la productividad no lograrán su cometido.
SUCCESSFUL SITE-SPECIFIC FERTILISATION WITH ORGANIC BY-PRODUCTS

By

EGBERT SPAANS¹ and OSCAR NÚÑEZ²

KEYWORDS: Organic Fertilisation, Site-Specific Management, Sugarcane, Waste Management.

Abstract
RAPIDLY increasing fertiliser prices are having a strong impact on the economics of sugarcane production. To control production costs, fertiliser applications are reduced and thus productivity is compromised. At the same time, pressure for proper management of organic, agro-industrial by-products is increasing as environmental regulations are becoming stricter. This situation provides for a unique, win-win opportunity to substitute expensive, synthetic fertilisers with readily available, organic by-products. At San Carlos Mill in Ecuador, we are using all the filter cake and vinasse from our own operation, and purchasing chicken manure from a large-scale chicken firm, in a site-specific fertilising schedule. The 17 845 ha plantation is divided into 1382 lots, and nutrient requirements are calculated for each lot individually based on soil and leaf analyses, cane variety, expected production, climate, and soil type. In 2008, we applied 49 249 t of filter cake and 13 023 t of chicken manure on 1506 and 2050 ha, respectively, of mainly plant cane. The organic by-products were applied fresh and supplemented with synthetic fertiliser where needed. Cane-tissue analyses and harvest data show that cane fertilised with organic by-products had similar growth and nutrient-uptake patterns, and recorded similar cane and sugar yields, compared to the cane that received only synthetic fertiliser, while fertilisation cost was reduced by up to 25%. In 2009, we have added the vinasse from the distillery to our fertilisation program and envisage purchasing only urea in the near future since, with the use of by-products, we are self-sufficient in P and K.

Introduction
Sugarcane removes large amounts of nutrients from the soil. Subirós Ruiz (2000) reports a wide range of values for nutrient uptake found in the literature, with an average value of 1.09 kg N, 0.24 kg P₂O₅ and 1.90 kg K₂O per tonne of cane (tc). Differences can be attributed to cane variety and nutrient availability in the soil.

As sugarcane is harvested, all the nutrients in the stalk are removed from the field; when cane is burned, additional nutrients are lost to the atmosphere (Núñez and Spaans, 2007). In order to avoid loss of soil fertility and maintain productivity of the land, these nutrients need to be returned to the soil. Since the green revolution, synthetic fertilisers have been the primary nutrient source, because; i) they are highly concentrated reducing storage, transportation, and application costs; ii) their nutrient content is well-known and uniform; and iii) once dissolved in the soil solution, they are readily available for plant uptake. Moreover, they were less expensive on a per kg nutrient basis compared to organic fertilisers.

Since 2004, however, synthetic-fertiliser prices have tripled and it appears that they will not be reduced in the near future (Figure 1). These high fertiliser prices have an enormous economic impact on sugarcane producers, as fertilisation is one of the principal components of the crop-management budget.
At the San Carlos Mill in Ecuador (2°13’14.61” S and 79°24’32.23” W), interest has always existed in the use of organic by-products from the factory as nutrient sources for the cane crop. However, manipulation and transport of the by-products used to be much more expensive compared to the use of conventional, synthetic fertilisers, as large quantities of organic products are needed because their nutrient content is relatively low.

Organic by-products that could serve as nutrient sources include filter cake (high P and medium N content), boiler ash (high P and K content), and vinasse (high K content). At the San Carlos Mill, filter cake and vinasse have been mixed with the irrigation water for the sugarcane crop since 1985, and the area that received this irrigation water (Sector 3, 3064 ha), has increased production ever since.

Prior to 1985, Sector 3 produced on the average 1 tc/ha less than the rest of the plantation (14,781 ha). After 1985, its productivity started to increase gradually and, since 1990, it has recorded 8 tc/ha more than the rest of the plantation, corresponding with a 12% productivity increase. Moreover, Sector 3 receives only N-fertiliser as soil analyses indicate high values of P and K, resulting in a lower production cost than other sectors that receive N, P and K fertilisers.

In accordance, Morris et al. (2007) reported that applying 246 t/ha of mill mud on a sandy soil one time before planting increased fresh cane and sucrose yields by 200% compared with low fertilisation treatments and 26% compared with adequate fertiliser treatments (two year average). Soil P and K also increased with this application of mill mud.

However, over that same period, sucrose recovery from Sector 3 has dropped from 0.4 kg sucrose/tc above, to 4.7 kg sucrose/tc below the average of the rest of the plantation. We attribute this to K build up in the soil from the vinasse to levels above 0.4 cmol/kg which result in reduced crystallisation of sucrose in the factory (Körndorfer, 1990). Another interesting observation is that, although P and K levels in the soil are much higher, the organic matter content in the soil is the same in Sector 3 compared to the rest. We suspect that the organic matter from the filter cake, that remains on the soil surface as the irrigation water infiltrates, is being burned at harvest. That would also explain why, in spite of receiving the same N application, foliar levels of N in the sugarcane of...
Sector 3 are similar to those of the rest of the plantation, since the N of the organic matter of the filter cake is also lost during the burning of the cane.

These results from an unreplicated field experiment provided practical evidence that filter cake and vinasse do break down in the soil and liberate nutrients to the soil. In field experiments in South Africa, Roth (1971) reported that the filter cake treatments, on average, gave highly significant increases in biomass yield when compared with the control but they also depressed sucrose content in cane. The results showed that bacteria, actinomycetes, fungi, and nematodes are closely associated with the increasing stability of the soil aggregates. The fungi in the control samples were only present in the form of spores or chlamydospores, and there was no pronounced mycelial network. By using different methods, it was possible to show that filter cake-treated soil had a very active mycelial network which was able to hold separate soil particles together.

The soils of Sector 3 have become quite rich in P and K and could sustain a healthy crop for many years even without receiving any more filter cake, vinasse or synthetic P and K fertilisers; in fact, the elevated K levels in the soil could be affecting sucrose recovery. In order to use these precious by-products in the rest of the plantation, however, they would have to be brought up-slope since irrigation is gravity fed, hence requiring a completely different application method.

As a response to the high fertiliser prices, in 2008 all the filter cake produced in the factory of San Carlos Mill and chicken manure purchased from a third party, were applied to mainly plant cane but also to ratoon cane, in P deficient soils. The objectives of this paper are to present the logistics of these commercial-scale operations, the model that was developed to incorporate the nutrients contained in the by-products into the fertilisation program, and the crop response and cost-benefit analysis of this operation.

**Site-specific, organic fertilisation**

The chicken manure was purchased from Ecuador’s largest chicken producer and the filter cake came from our own factory. Chemical analyses of the organic by-products used in the San Carlos Mill are presented in Table 1.

The chemical composition of the by-products was periodically monitored to control their quality. The results from the filter cake are rather constant (Table 1). The chicken manure was also constant and any variation in nutrient content was most likely due to the cleaning cycles of the floor of the chicken barn.

Those from the vinasse fluctuated between 7 and 10 probably depending on the molasses–cane juice mix that is used in the distillery. Note that vinasse data are shown for reference purpose, since vinasse was not incorporated into the site-specific fertilisation program until 2009, and field evaluations are not available yet.
The efficiency of organic by-products depends on the availability of its nutrients, which in general is much higher for animal by-products than for vegetative material, because animal by-products can be considered an end-product of an optimum decomposition of vegetative material. Once applied to the soil, the decomposition rate depends on the microbial activity, which accelerates under conditions of medium-high temperatures, humidity and biodiversity.

Composting is usually recommended before applying organic by-products, mainly to control the decomposition process and obtain a higher quality product, but also to kill pathogens by the high temperatures generated during the composting process, and to reduce weight and water content and therefore transportation costs. Composting, however, is expensive both in investment of machinery and infrastructure, as well as in operation. We prefer to have the decomposition occur in the soil, stimulating biological activity where it is most needed and where liberated nutrients and leachates are immediately available for plant-uptake. Both filter cake and vinasse are exposed to high temperatures in the factory, so they should not contain pathogens. Chicken manure could contain animal-based pathogens, which we did not expect to affect the cane crop. In conclusion, we chose to apply the by-products directly to the soil without any prior treatment.

In our model to calculate fertiliser rates, we assumed conservative values for nutrient availability of the by-products, because we did not want to compromise cane production. Moreover, the sudden jump in synthetic fertiliser prices forced us to skip the experimental stage and to go straight to a commercial-scale application, and fortunately economic returns of the project were favourable enough that we could be conservative. Since filter cake is a raw vegetative material, the rate of release of both N and P was estimated at 50% in the first year and 25% in the second year. The remaining 25% would stay in the stable, humic fraction in the soil. The chicken manure was assumed to liberate 75% of its N and P in the first year, with 25% remaining in the humic fraction of the soil. Potassium does not form an integral part of the carbon structures because it does not form covalent bonds; instead, it only forms ionic bonds which do not require microbial breakdown, but only water for it to become available as K⁺ for plant uptake. We assumed an availability of 75% of the K in all by-products in the first year; the other 25% would be leached or maintained in the soil.

Taking into account these efficiencies, the practical, equivalent NPK-value can be calculated (Table 1). With respect to the practical value of filter cake, note that $8.75 is available in the first year and $3.60 the following year.

The plantations of the San Carlos Mill are divided into 1382 lots with an average size of 12.91 ha (Spaans and Núñez, 2006). On every lot, soil analysis is done immediately after harvest, and leaf analysis is done at 3.5, 5.5, 8.5 and 10.5 months after harvest. Soils are neutral, neither saline nor sodic, and rich in Ca and Mg. Therefore only urea, DAP and KCl are used in the fertilisation program. Based on soil and leaf analyses, cane variety, expected production, soil type and climate, the amount of N, P₂O₅ and K₂O that needs to be applied in every lot is being calculated.

On commercial lots, applications were made of either filter cake at a rate of 30 t/ha or chicken manure at a rate between 8–10 t/ha. The amount of by-product applied to a lot, multiplied by its nutrient content (see Table 1) and multiplied by the release rate discussed above, was subtracted from the total nutrient requirement of that lot. The difference was then applied separately by conventional means with synthetic fertilisers.

As a consequence of the site-specific management and the large number of lots, many different combinations of NPK application rates are used. Table 3 shows the most common nutrient requirements on San Carlos lots, and possible scenarios of how these nutrients were applied with by-products, synthetic fertiliser, or a combination of the two.

To evaluate the effect of the filter cake applications, in 2008 six pairs of commercial lots with plant cane were selected, such that within each pair both lots had the same soil type, planting
date, and cane variety; however, one lot was fertilised with synthetic fertiliser only and the other with a by-product and supplemented with synthetic fertiliser where needed. To evaluate the chicken manure application, seven pairs were selected in the same way. On every one of the selected lots, crop growth was monitored monthly by measuring stalk height and diameter on the same 10 plants in five sites within the lot; population was measured on the same five sites, counting the number of stalks present in 15 m. In addition, Crop-log data (Clements, 1970) in every lot were collected on plant tissue at 3.5, 5.5 and 8.5 months after crop-start date. During the harvest of 2009, cane yield and sucrose yield data of each lot were obtained from the commercial data.

Field operations

In order to process filter cake directly and without water, the filters were relocated outside the factory and the filter cake now falls directly into a dump truck. The filter-cake truck was then weighed on the same scales used to weigh the cane trucks, allowing for precise monitoring of filter cake production in the factory, an additional advantage of the project. The truck then proceeded to the field and dumped the filter cake on one side of the lot, where it accumulated until the total amount was deposited. Chicken manure was provided directly from the chicken barns to the mill by truck.

In the field, one front-loader lifted up the by-product from the ground and put it into a spreader. The spreader is a V-shaped wagon with a conveyor belt on the bottom that is driven by a hydraulic pump. The wagon has a volume of approximately 7 m$^3$ and can store 4 t of chicken manure or 6 t of filter cake. The team consisting of one front-loader, three 110 HP tractors each hauling a spreader and one supervisor could cover about 2.1 ha/h.

In plant cane, the equipment that makes the furrow also applied the synthetic fertiliser (where needed) in one single operation. Then either the chicken manure or the filter cake was applied in the furrow, the cane was planted on top of and in direct contact with the by-product, and then the furrow was closed and irrigation water applied. In ratoon cane, by-products were applied right after harvest in a separate operation. Then, the conventional equipment was used that in one single operation incorporates synthetic fertiliser, cultivates the inter-row, and reforms the furrow. Although the cultivation incorporates the by-products, these will never be placed as close to the roots of the cane stool as in plant cane. Therefore, in the selection of where to apply by-products, preference was given to plant cane.

Results and discussion

In 2008, 49 249 t of filter cake was applied to 1506 ha and 13 023 t of chicken manure to another 2050 ha, substituting 187 t of urea, 616 t of DAP and 314 t of KCl. Organic by-products contain all three macro nutrients in a more or less fixed proportion, and it is rare that their proportion matches exactly the sugarcane nutrient requirements of a lot. Thus, the amount of by-product to be applied in any lot can be calculated according to two strategies. One is fulfilling the requirement of all three nutrients, which inherently implies that two of the three nutrients will be applied in excess.

The other strategy is to apply only the amount necessary to fulfil the requirement of one nutrient, and complement the requirement of the other two with synthetic fertiliser. The second choice takes full advantage of the value of the organic by-product according to Table 1; however, a second application with synthetic fertiliser is needed. With the first choice, fertilisation is done in one operation, but the economic values reported in Table 1 will not be reached. Obviously, the optimum strategy will depend on the cost of acquisition, transport, and application of synthetic fertiliser and by-products.

Field evaluations

The evolution of stalk height and diameter throughout the growing season followed a normal pattern in all of the six pairs of lots for the filter cake evaluation (Figures 2 and 3), as well as in the seven pairs of lots for the chicken manure evaluation.
Fig. 2—Stalk height to the top visible dewlap of sugarcane fertilised with filter cake (♦) or synthetic fertiliser only (■). Each datum is an average of 300 plants. The data from the cane fertilised with chicken manure and its synthetic comparison (not shown) followed a similar pattern.

Fig. 3—Stalk diameter at the base of sugarcane fertilised with filter cake (♦) and synthetic fertilisers only (■). Each datum is an average of 300 plants. Data from the cane fertilised with chicken manure and its synthetic comparison (not shown) followed a similar pattern.

Detailed agronomic data for all evaluations from the pairs of lots are shown in Table 2. No significant differences in any of the agronomic parameters were found between the organically fertilised and the synthetically fertilised cane (Tukey test; P ≤ 0.05).
The Crop-log values (Table 2) for leaf-N and sheath-K levels at 3.5, 5.5 and 8.5 months after planting and P content of the stalk at 5.5 months, indicate that nutrient absorption occurred at normal rates for both organic fertilisations as compared to synthetic fertilisations. Since roughly the same amounts of nutrients were applied within each pair (organic-synthetic) of comparative lots, the data suggest that the liberation of nutrients from the organic by-products occurred at a sufficiently high rate to keep up with the instantaneous nutrient requirement of the crop, at any time. This is remarkable as no composting or any other pretreatment of the by-products was done.

One of the concerns of using organic fertiliser is the slow release of N and thus continuous N availability in the soil, possibly hampering the maturing of the crop. The data presented in Table 2, however, show that the decline of N content of the leaves as the cane develops follows a similar pattern in the organically compared to the synthetically fertilised cane.

We should bear in mind that the prime objective was not to improve crop production, but to substitute expensive synthetic fertiliser with readily available organic by-products to reduce costs. The results so far indicate that the assumptions in our model to quantify this substitution are valid.

In addition to the plant cane evaluations, we did similar observations on four pairs of ratoon cane lots. No significant differences (Tukey test; P ≤ 0.05) were found in any of the agronomic parameters between the ratoon cane fertilised with chicken manure compared to the cane fertilised with synthetic fertiliser.

| Table 2 | Growth indicators, Crop-log and yield data (average ± std) of sugarcane fertilised with filter cake and chicken manure, each compared with its synthetic fertiliser control fields. For growth indicators, n = 300 plants for filter cake evaluation, and n = 350 plants for chicken manure evaluation. Crop-log data are from five random plants selected in each lot, and cane and sucrose yield data were obtained from the commercial harvest of the entire lots. None of the agronomic parameters were significantly different (Tukey test; P ≤ 0.05), neither for the filter cake vs. its synthetic comparison, nor for the chicken manure vs. its synthetic comparison. |
In 2009, vinasse application was added as a component of the fertilisation program. To reduce transportation cost, 13 km of PVC pipes were installed in the ground to transport vinasse at a rate of 20 L/s to strategic sites in the field, where small ponds lined with double-plastic layers serve as buffers that can store up to 1 day of vinasse.

From these ponds, vinasse was mixed with the irrigation water at a rate of approximately 1:100. In lots that might drain into natural creeks, vinasse was not used for irrigation; instead vinasse was applied directly with a 12 m³ tanker hauled by a 140 HP tractor. Considering previous experiences in Sector 3 and the immediate availability of the K⁺ ion as discussed above, we expect that the vinasse will substitute KCl and that K uptake by the crop will be normal. So far, the logistics prove to be satisfactorily; field evaluation data, however, are not available yet.

**Cost/benefit analysis**

The cost/benefit analyses of possible nutrient requirements are presented in Table 3. The greatest savings using organic nutrient sources occurred when P and K requirements were high, because DAP and KCl were, in 2009, more expensive than urea. Fertilisation costs could be reduced by up to 25% with organic by-products, with the additional advantages of; i) incorporating organic material into the soil; ii) properly managing organic by-product, and iii) adding, in general, more P and K than necessary due to the difficulty of exactly matching the N-P-K proportion with organic by-products and fine tuning the amounts applied. Although not considered in Table 3, filter cake application is expected to save an additional $108/ha in the following year when the remaining nutrients will be released.

The use of organic by-products becomes less profitable when P and K requirements are lower, as the cost/benefit compared to synthetic fertilisers is reduced.

Costs and benefit will vary from one mill to another, depending on transportation cost and distance, chicken manure prices and efficiency in field logistics. Application costs ranged from US$27 (chicken manure) to US$33/ha (filter cake).

Transportation cost of the chicken manure was included in the price (US$28/t) as it was transported from the chicken barn directly to the lot, while transport of the filter cake from the mill to the lot averaged US$1.80/t. Investment in the spreaders (3), tractors (3) and front-loader (1) are in the order of US$220,000, which was paid back within the first year of the project. Application and transportation costs in Ecuador are relatively low due to highly subsidised fuel prices ($0.28/L diesel).

**Table 3**—Fertiliser rates and cost/benefit analysis for some of the most typical nutrient requirements calculated for San Carlos cane plantations. For every nutrient requirement, three possible scenarios are presented; using synthetic fertilisation (first row), chicken manure (second row) or filter cake (third row). As can be seen, chicken manure and filter cake fertilisations may require additional synthetic fertiliser depending on the rate applied and the specific nutrient requirement of the lot.

Conclusions

Organic by-products were successfully incorporated into the fertilisation program at San Carlos Mill in Ecuador. Organic nutrient application was fully mechanised and optimised so that by-products could substitute synthetic fertiliser in a wide range of nutrients requirements.

Due to high fertiliser prices, the cost-benefit of this project was extremely positive, but even at much lower fertiliser prices, the use of by-products is still profitable. Moreover, their contribution to the production system is not limited to providing N, P and K, but also in micro nutrients and valuable organic matter that improves soil structure and stimulates biological activity in the soil.

A field of one hectare that produces 80 t of cane produces about 2.4 t of filter cake which corresponds to 30 kg of P₂O₅, which, in turn, is similar to the amount of P extracted from the soil by that same crop. Thus, returning filter cake back to the soil completes the nutrient cycle for P and can as such be considered a sustainable practice.

The same is true for vinasse, which is the sink for all the K that was present in the cane juice. From a theoretical point of view this is logical, as the export products from the industry (sugar and ethanol) contain only C, H and O; all nutrients are removed in the process and evacuated as by-products. Requisite for the sustainability argument, however, is that the by-products are being returned to all fields that are being harvested, even the distant ones where transport costs are higher, including the fields of cane farmers that sell their cane to the mill.

We envisage that the only synthetic fertiliser that we will need in the future will be urea; DAP and KCl will be substituted entirely with filter cake and vinasse; if not, there are still other products such as chicken manure and boiler ashes to complement the fertilisation program.

MOTS CLES: Fertilisation Organique, Gestion Adaptée au Site, Canne à Sucre, Gestion Des Déchets

Résumé

L’AUGMENTATION rapide des prix des engrais à un fort impact sur l’économie de la production de canne à sucre. Pour contrôler les coûts de production, les applications d’engrais sont réduites et la production est ainsi compromise. En même temps, l’incitation à bien gérer les sous produits agro-industriels organiques augmente du fait des lois environnementales qui deviennent de plus en plus strictes. Cette situation est une occasion unique de remplaces les engrais minéraux coûteux par des sous produits organiques facilement disponibles. À L’usine de San carlos, en Equateur, toutes les écumes et les vinasses produites, ainsi que les fientes de poules achetées à une société d’élevage sont utilisées dans un schéma de fertilisation adapté aux parcelles. Les 17845 ha de la plantation sont divisés en 1382 lots. Les besoins en éléments minéraux sont calculés pour chaque lot à partir des analyses de sol et des analyses foliaires: de la variété; de la production espérée; du climat et du type de sol. En 2008, nous avons épandu 49349 T d’écumes et 13023 T de fientes de poulet sur 1506 et 2050 ha respectivement, en majorité sur des cannes plantées. Les sous produits organiques furent appliqués en frais et complémentés avec des engrais minéraux quand il y en avait besoin. Les analyses de plantes et les résultats de récolte montrent que les cannes fertilisées avec des sous produits organiques avaient des croissances, des dynamiques de mobilisation, des rendements en canne et en sucre similaires à ceux des cannes fertilisées uniquement avec des engrais minéraux., alors que les coûts de fertilisation étaient réduits de 25%. En 2009, de la vinasse provenant de la distillerie a été ajoutée au programme de fertilisation et des achats uniquement d’urée sont envisagés dans un futur proche puisque avec l’utilisation des sous produits, les plantations sont autos suffisantes en P et en K.
UNA FERTILIZACIÓN DE SITIO ESPECÍFICO EXITOSA
CON SUBPRODUCTOS ORGÁNICOS

PALABRAS CLAVES: Fertilización Orgánica,
Manejo de Sitio Específico, Caña de Azúcar, Manejo de Desechos.

Resumen

EL RÁPIDO AUMENTO de los precios de los fertilizantes está causando un fuerte impacto en la economía de la producción de caña de azúcar. Para controlar los costos de producción se reduce la aplicación de fertilizantes y en consecuencia se compromete la productividad. Al mismo tiempo está aumentando la presión para un manejo apropiado de los subproductos orgánicos agroindustriales a medida que las regulaciones ambientales se vuelven más estrictas. Esta situación ofrece una oportunidad única para sustituir los caros fertilizantes sintéticos por subproductos orgánicos fáciles de conseguir. En el ingenio San Carlos en Ecuador, se está utilizando toda la cachaza y la vinaza proveniente de la fábrica y comprando estiércol de pollo a una firma productora de pollos en gran escala, lo cual se utiliza en un esquema de fertilización de sitio específico. Las 17 845 ha plantadas están divididas en 1382 lotes, y los requerimientos de nutrientes son calculados individualmente para cada lote en base a análisis de suelo, análisis foliares, cultivares, producción esperada, clima y tipo de suelo. En 2008 se aplicaron 49249 t de cachaza y 13023 t de estiércol de pollo en 1506 y 2050 ha, respectivamente, principalmente en caña planta. Los subproductos orgánicos se aplicaron frescos y suplementados con fertilizantes sintéticos donde fue necesario. Los análisis de tejidos de la caña y los datos de cosecha mostraron que la caña fertilizada con los subproductos orgánicos presentó similares patrones de crecimiento y absorción de nutrientes, y registró similares rendimientos de caña y azúcar, que la caña que recibió solamente fertilizantes sintéticos, mientras que el costo de fertilización se redujo hasta un 25%. En 2009, se incluyó la vinaza proveniente de la destilería al programa de fertilización y se prevé para el futuro próximo la compra solamente de urea, ya que con el uso de estos subproductos se será autosuficiente en P y K.
SPRAY VOLUME FOR THE CONTROL OF WEEDS IN SUGAR CANE

By

hhramos@iac.sp.gov.br

KEYWORDS: Herbicides, Pesticide Application Technology, Imazapic, Droplet.

Abstract

The objective of this work was to evaluate the efficacy of different volumes of water for the application of imazapic in sugarcane and its effect on soil coverage and operational capacity. The minimum possible volumes applied by the sprayer (70 to 80 L/ha), 100, 150, 200 L/ha were compared to the processing plant’s standard (250 or 300 L/ha) in commercial fields with areas varying between 8 and 10 ha, at three periods within the crop season. During the applications, the parameters for operational capacity analysis were analysed. Soil coverage was evaluated by means of water-sensitive sampling and quantification through image analysis. Weed control was evaluated, on a visual basis, up to 150 days following application. All the treatments were efficient in controlling weeds up to 150 days following the treatments. The surface ranged from 8.34 to 51.81% and the gain in operational performance from 4.18 to 29.80%. Thus, imazapic applied with spray volumes from 70 L/ha, with a soil coverage of 8.34%, efficiently controlled the weeds in sugarcane when applied either at the beginning, in the middle, or at the end of the crop season, providing gains up to 29.80% in the application operational performance.

Introduction

By definition, pesticide application technology is the use of scientific knowledge to provide the correct usage of the biologically active product in the target, as required, in an economic way with minimal contamination of other areas (Matuo, 1990). Although it involves knowledge in different areas, the application technology is often restricted to the adoption of a spray volume per hectare, or at most to a volume associated with a specified droplet size. When technicians or producers are asked why they are using so many litres per hectare, the answers are often ‘I do not know’ or ‘because this is the most used one’. The volumes that have been used are almost never based on preliminary coverage, deposition and control evaluations or tests. Despite the little importance that has been assigned to it, the volume of water for pesticide application is currently one of the main items involved in the operating cost of phytosanitary treatments.

Sugarcane is not exempted from this rule. Despite the large areas and quality of the sprayers that have been used, particularly by the processing plants or big producers, the most commonly used volumes for herbicide application are pre-established, regardless of all the involved factors, and range from 200 to 300 L/ha. The fact that the application volume (L/ha) does not directly influence the biological result, once the amount of water per unit of area has been determined to facilitate the distribution of the active substance over the target surface (soil, straw or plant), with the necessary coverage, is simply not considered in the set up process. The reduction of the spray volume used for herbicide application will increase the equipment operating capacity, and can thus be an essential tool in reducing the application costs, besides the environmental gain associated with a decrease in water consumption. Proving the latter has been the objective of PROVAR – Programa de Valorização da Água em Pulverizações Agrícolas, a partnership between the Engineering and Automation Center of the Agronomic Institute (CEA/IAC), BASF S.A. and the sugarcane processing plants of the State of São Paulo.
Material and methods

The trials were conducted in commercial fields of six partner processing plants in the State of São Paulo: Buriti, Colorado, Santa Elisa Vale, Pedra, São Martinho and Cruz Alta. In all trials, the spraying equipment was similar to that used for commercial application, and was calibrated to deliver the following volumes: as little as possible applied by the sprayer (70 to 80 L/ha), 100, 150, 200 L/ha and the processing plant’s standard (250 or 300 L/ha). The standard conditions, as well as the treatments used in each of the trials, are described in Table 1.

While establishing the treatments, the type of spraying nozzle and the class of the droplet size were kept unchanged and compared to the standard adopted by the processing plants. Only the flow and the working pressure of the nozzles were changed to adjust to the different volumes. The lowest pressure considered in the establishment of the minimum application volume was 1.5 bar as, with pressures close to 1.0 bar, failures are likely to occur in spraying once it is very close to the anti-dropping device opening pressure; the latter will prevent the system from working appropriately and, thus, negatively affecting the quality of the application. Furthermore, nozzles using 100 mesh sieves were not considered as they could increase the risk of retaining products in the filters, affecting the operational efficiency.

(1) C = Coarse, VC = Very Coarse and XC = Extremely Coarse

The applications were conducted in the Beginning (June–July), Middle (August–September) and End (October–November) of the crop season and the environmental conditions were monitored, but not controlled, in an attempt to represent the real application conditions. During spraying, the temperature ranged between 20–35, 18–39 and 21–35°C, the relative humidity between 19–65, 15–80 and 15–87%, and the wind speed between 0.3–6, 0.1–7.1 and 0.4–4.4 m/s, respectively to
Beginning, Middle and End applications. Imazapic (Plateau) was standardised as the herbicide to be used in all the areas, so that it did not constitute a source of variation, with doses ranging between 140 g/ha and 240 g/ha, according to the soil texture and weeds population.

Each treatment, represented by a spraying volume, was established in a commercial stand with approximately 10 hectares of cane harvested either in green (application over straw) or after burning (application over the soil).

In trials carried out at the beginning of the crop season, for each treatment, an untreated area was maintained without application with a width corresponding to the extension of the spraying boom by 10 m length. In the other trials, 3 similar areas were maintained untreated, in order to evaluate the weeds that were present.

In order to allow a soil coverage analysis and subsequently relate it to the control, 6 water-sensitive paper leaves were placed under the spray boom in the treated area, 3 of them were placed under the right boom and 3 under the left sprayer boom.

After spraying, the papers were stored into paper bags duly identified and forwarded to the laboratory for coverage analysis. In the laboratory, the water-sensitive papers were digitised through a 'scanner' and the images obtained were analysed with the image analysis IDRISI software, in order to determine the coverage percentage from colour contrast, in compliance with the method developed and evaluated by Firveda et al. (2002).

To assess the efficacy of the different treatments on weed control, untreated and selected sampling points were assigned total or specific coverage percentage scores for the species at 30, 60, 90, 120 days after the application; and, where possible depending on the culture size, also at 150 days after the application.

The scores were individually assigned by each of the 3 duly-trained observers. Five sampling points were randomly chosen, by walking between an untreated area and the other within the parcel, following the W pattern.

The observers attributed a general coverage percentage score between 0 to 100% for the weed population observed in the parcel, 0 corresponding to the absence of infestation and 100% to total area infestation (general coverage related to the observed area). Subsequently, five species were identified in the parcel and a visual grading of specific frequency was assigned to the individual weeds, the sum of the five grades reaching 100%. The data collected were used for the calculation of the percentage control. The control scores were submitted to variance analysis according to the design proposed and, when significant differences were observed, the averages were compared by Tukey test at 5% probability.

During the entire operation, in order to allow the economic comparison based on the adoption of the different volumes that have been considered, the times related to refilling the sprayer with the spray solution, carrier manoeuvres, emptying the spraying tank, the time required to move from refilling to the application areas were collected, in addition to the measurement of the stand’s length.

The gain in operational capacity, calculated based on the time required to spray one ha, was analysed considering the following formula proposed by Matuo (1990):

\[
t = \frac{10000 + 10000 \cdot TV + d \cdot v + Tr \cdot V}{Vp \cdot L \cdot C \cdot L \cdot Vd \cdot Ca \cdot Ca}
\]

where:

- \( t \) = Time required to spray 1 hectare (min/ha).
- \( Vp \) = Spraying speed (m/min).
- \( L \) = Width of the spraying area (m).
Tv = Turn time (min).
C  = Length of the treatment area (m).
D  = Total covered distance in each refilling (m).
V  = Spraying volume (L/ha).
Vd = Forward speed for refilling (m/min).
Ca = Tank capacity (L).
Tr = Time for tank refilling (min).

Results and discussion

A sample of the surface coverage obtained by each of the different treatments is shown in Figure 1.

According to data obtained (Table 2), soil coverage ranged from 8.34 to 51.81%, and the coverage of the control could be compared with the other treatments.

Table 2—Coverage means obtained from the water-sensitive papers in the different treatments, processing plants, and application timing.

(1) C = Coarse, VC = Very Coarse and XC = Extremely Coarse  
(2) Mean coverage of Beginning, Middle and End phases

The visual control evaluations have not shown significant differences for any of the considered volumes, application timing or processing plant. Thus, soil coverage up to 8.34%, such as those obtained in the coverage evaluation, was sufficient to reach the maximum efficacy of the herbicide.

It should be noted that imazapic is a high solubility herbicide and, therefore, has high redistribution capacity in soil solution and penetration in straw. It may be that such coverage would not be applicable to some very low solubility herbicides.

The mean operational data of the three application times are described in Table 3.

The operational capacities at the three timings of application, considering the mean data obtained from each processing plant, are presented in Table 4.

The operational capacities were not very different between the processing plants, except for Cruz Alta and Pedra where the ready-to-use spray-mixture system has already been adopted, with considerably reduced filling and filling moving times.

In all of them, the operational capacity gain was significant, ranging between 4.18 and 29.80%.

Conclusions

The results showed that imazapic (Plateau) applied with spray volumes from 70 L/ha efficiently controlled weeds in sugarcane when applied at the beginning, middle or end of crops. As the level of control was not adversely affected, the adoption of lower water volumes may represent reduced application operating costs for the processing plants, ranging from 4.18 to 29.80% of the total invested amount.

MOTS-CLÉS: Herbicides, Technique d’Application des Pesticides, Imazapic, Gouttelette.

Résumé
L’OBJECTIF de ce travail était d’évaluer l’efficacité de différents volumes de bouillie pour l’application d’imazapic en canne à sucre, ainsi que leur taux de couverture du sol et les aspects opérationnels. Les quantités minimum applicables par le pulvérisateur (70 à 80 l/ha, 100, 150 et 200 l/ha) ont été comparées aux volumes standards qui sont de 250 à 300 l/ha; les essais ont été conduits sur des parcelles de cultures commerciales de 8 et 10 ha à trois périodes de la saison culturelle. Au cours des applications, les paramètres de la pulvérisation ont été analysés. La couverture du sol a été évaluée grâce à des papiers hydrosensibles traités par analyse d’image. La maîtrise des mauvaises herbes a été estimée par des contrôles visuels jusqu’à 150 jours après l’application. Tous les traitements ont été efficaces sur l’enherbement jusqu’à 150 jours après l’application. Les surfaces couvertes variaient de 8.34 à 51.81% et les performances de l’opération étaient améliorées de 4.18 à 29.80%. Ainsi, l’imazapic appliqué avec une bouillie à 70 l/ha avec une couverture du sol de 8.34% a maîtrisé efficacement les mauvaises herbes en canne à sucre que l’application soit effectuée au début, au milieu ou à la fin de la saison de culture, en apportant un gain de performance atteignant 29.80%.

VOLÚMEN DE PULVERIZACION PARA EL CONTROL DE MALEZAS EN CAÑA DE AZÚCAR

Resúmen
EL OBJETIVO de este trabajo fue evaluar la eficacia de diferentes volúmenes de agua para la aplicación de imazapic en caña de azúcar, y su efecto en la cobertura del suelo y en la capacidad operativa. Se compararon volúmenes de aplicación, en tres diferentes periodos dentro de la estación de crecimiento, entre el mínimo posible aplicado por la pulverizadora (70 a 80 l/ha), 100, 150 y 200 L/ha, con los estándares utilizados en el cultivo (250 o 300 L/ha) en lotes comerciales con superficies de entre 8 y 10 ha. Durante las aplicaciones, se analizaron los parámetros para el análisis de capacidad operativa. Se evaluó la cobertura del suelo a través de muestreo hidro-sensible que fue evaluado utilizando análisis de imágenes. Se evaluó el control de malezas, en forma visual, hasta 150 días después de la aplicación. Todos los tratamientos fueron eficientes para el control de malezas hasta los 150 días. La cobertura tuvo un rango de 8.34 a 51.81% y la ganancia en desempeño operativo varió de 4.18 a 29.80%. De este modo, imazapic aplicado con volúmenes de aplicación de 70 L/ha, con una cobertura de suelo de 8.34%, controló eficientemente las malezas en caña de azúcar tanto en aplicaciones al inicio, mitad o final del periodo de crecimiento, generando ganancias de hasta 29.80% en la capacidad operativa de la aplicación.
USE OF ORGANOMINERAL FERTILISERS ON SUGARCANE PRODUCTIVITY IN A TYPIC HAPLUSTOX SOIL

KEYWORDS: Alternative Fertiliser, Organomineral, Organic Matter, Sugarcane.

Abstract

The association of organic manure with mineral fertiliser, called organomineral fertiliser, combines the benefits of organic manure through the improvement of the physical, chemical and biological soil qualities with the efficiency of the mineral fertiliser provided by its high solubility and ready availability of nutrients in the soil solution. The objective of this study was to evaluate the efficiency of organomineral fertiliser in sugarcane productivity in a dystrophic soil. The statistical design was a randomised block with seven treatments and four replicates. The treatments consisted of a control (without fertilisation), three rates of a ternary chemical fertiliser providing 50, 100, 150 kg/ha each of K₂O and P₂O₅ and 10, 20, 30 kg N/ha, three rates of an organomineral fertiliser providing 50, 100, 150 kg/ha of K₂O and P₂O₅ and 7.5, 15, 22.5 kg N/ha. Lime was broadcast over the total area, 30 days before planting at the rate of 2.0 tonnes per hectare and the fertilisers were applied in the furrows at planting. The variety of cane used was SP81 3250. The results obtained from this study showed that fertilisation with organomineral fertiliser or conventional chemical fertiliser, in dosages that provided 100 and 150 kg/ha of K₂O and P₂O₅ produced the same yields of sugarcane. In relation to the technological traits, the two sources of fertiliser applied in the same dosages promoted the same values for Pol % cane and ATR (Total Recoverable Sugar). For fibre % cane, a difference was observed. The treatments with the doses of 50 and 100 kg/ha of K₂O and P₂O₅ in chemical form and 150 kg/ha of K₂O and P₂O₅ as organomineral form promoted the lowest levels of fibre % cane.

Introduction

The use of new technologies in sugarcane fertilisation has become necessary in the face of the expansion of the sugarcane growing areas on sandy soils with natural low soil fertility. In these soils, nutrient leaching and volatilisation, especially potassium and nitrogen, can be a problem due to the low CEC, and may decrease sugarcane yield. Under these conditions, the integrated use of organic and mineral forms of fertilisers, named organomineral fertilisers, may be more beneficial, as the organic fertilisation will lead to an improvement of the physical, chemical and biological qualities together with the proven efficiency of mineral fertilisation.

The addition of organic matter to soils is known to improve soil physical characteristics resulting in reduced soil bulk density, improved water holding capacity as a result of the aggregation of particles of sand, silt and clay by organic matter (Alves, 1997).

The organic material applied or existing in soil can also provoke modifications in its chemical properties such as nutrient furnishing, toxicity amendment, pH, CEC, and humus content (Kiehl, 1985).

The objective of this work was to evaluate the efficiency of organomineral fertilisation on sugar yield compared with mineral fertilisation on Typic Haplustox.
Materials and methods

The assay was conducted in the town of Altinópolis, SP- Brazil, on Typic Haplustox, the chemical analysis of which is in Table 1.

The cane variety used was SP813250, with the following characteristics: high agricultural yield, high sucrose content, good tillering, medium maturation and tolerant to the main diseases.

</table>

The organomineral fertiliser used has the formulation of 3% of N, 12% of P₂O₅ and 12% of K₂O with minimal warrant of 25% of dry matter, due to the Brazilian Legislation. The mineral fertiliser had 4% N, 20% P₂O₅ and 20% K₂O.

The experimental plots were made up of five rows of sugarcane, spaced 1.4 m apart, 10 m in length. The assay planting was performed in March of 2007 and the crop was harvested in August of 2008.

Cane yield was evaluated through weighing in the useful area of each plot, and the technological characteristics by removing ten stalks from each plot for determination of fibre % cane, Pol % cane and ATR kg/t.

The F test was used to evaluate the effect of the treatments on the investigated variables and Scott-Knott test at the level of 10% of probability for comparison between means.

Results and discussion

Cane yield

The average results for cane yield are presented in Table 3. The treatment which was not given any chemical or organomineral fertilisation had lower cane yield (TCH), indicating nutrient
shortage and the need for nutrient mineral complementation, characteristic of dystrophic soils in nutrient furnishing for crops. This agrees with Raij et al. (1996) who recommended a dose of 120 kg/ha of P₂O₅ and K₂O to soils with low content of K₂O and P₂O₅.

In the treatments which were given doses of 100 and 150 kg/ha of P₂O₅ and K₂O, either in the chemical or organomineral form, the yield means obtained were equal to one another and higher than the other treatments.

It can be observed that the nitrogen rates were low. However, they did not affect significantly the yield of cane. This can be explained by the edaphoclimatic conditions found in Brazil where the plant cane has shown low response to nitrogen fertilisation, mainly due to a better efficiency of biological fixation and other biotic factors that improve the use of nitrogen from the soil by plant.

When applying two sources of fertilisation, one strictly mineral and the other which possesses organic matter, promoting similar yield, it is advisable to choose the source which adds organic matter, since it promotes improvements in the physical, chemical and biological properties of soil. It will also contribute to future increases in agricultural yield.

</tbody>
</table>

Technological characteristics

The average values obtained for the technological characteristics are presented in Table 3. As far as the chief technological characteristics are concerned, one can observe that use of fertilisation in the organomineral and chemical form, both at the same dosages of nutrients, promoted values statistically equal for contents of Pol % cane and total recoverable sucrose % cane.

Nevertheless, for the contents of fibre % cane, a difference can be noticed among the treatments. To a treatment which was given no source of fertilisation, the fibre content was higher than the other treatments, brought about by the decreased yield, causing less accumulation of sugars and hence an increased proportion of fibre in the stalks.

For the treatments which received doses of 150 kg/ha of K₂O and P₂O₅ in the organomineral form and 100 and 50 kg/ha of K₂O and P₂O₅ in the mineral form, there was decreased fibre content, when compared with the other treatments.

As yield is increased, promoted by the efficiency of fertilisation, a greater accumulation of photoassimilates (sucrose) occurs, to the detriment of fibre content.

Conclusions

The organomineral fertiliser provided the same agricultural and technological yield in sugarcane as the mineral fertiliser in plant cane.
So, it is suggested that the study of organomineral fertiliser and its effects on long-term productivity be the subject of future studies.

Résumé

L'association d'engrais organique avec de l'engrais minéral, appelée engrais organominéral, combine les avantages de l'engrais organique par l'amélioration des qualités physiques, chimiques et biologiques du sol avec l'efficacité de l'engrais minéral due à sa solubilité élevée et à la disponibilité rapide des éléments minéraux dans la solution de sol. L'objectif de cette étude était d'évaluer l'efficacité de l'engrais organominéral sur la productivité de la canne à sucre dans un sol dystrophique. Un dispositif statistique en blocs randomisés avec sept traitements et quatre répétitions a été utilisé. Les sept traitements étaient composés d'une témoin (sans fertilisation), trois doses d'engrais chimique ternaire fournissant respectivement 50, 100 et 150 kg/ha de K₂O et P₂O₅, et 10, 20, 30 kilogrammes de N/ha, et enfin de trois doses d'engrais organominéral fournissant respectivement 50, 100 et 150 kg/ha de K₂O et P₂O₅, et 7.5, 15 et 22.5 kilogrammes de N/ha. Ces engrais ont été appliqués dans le sillon à la plantation. De la chaux a été épandue en surface, 30 jours avant la plantation, à la dose de 2.0 tonnes par hectare. La variété de canne utilisée était la SP 81/3250. Les résultats ont montré, qu’aux doses de 100 et 150 kg/ha de K₂O et de P₂O₅, l'engrais organominéral et l'engrais chimique conventionnel produisaient les mêmes rendements de canne à sucre. En ce qui concerne la qualité technologique, les deux types d'engrais appliqués aux mêmes doses ont donné les mêmes valeurs de Pol % de canne et d’ATR (sucre récupérable total). Par contre, des différences ont été observées pour la fibre % canne. Les traitements avec des doses de 50 et 100 kg/ha de K₂O et P₂O₅ sous forme chimique et celui avec une dose de 150 kg/ha de K₂O et de P₂O₅ sous forme organominérale ont produit les teneurs en fibre % canne les plus basses.
USO DE FERTILIZANTES ORGANOEMINERALES EN LA PRODUCTIVIDAD DE LA CANA DE AZÚCAR EN UN SUELO TÍPICO HAPLUSTOX

PALABRAS CLAVE: Fertilizante Alternativo, Organomineral, Materia Orgánica, Cana de Azúcar.

Resumen
La asociación de abono orgánico con fertilizante mineral, comúnmente denominada fertilizante organomineral, combina los beneficios del abono orgánico en el mejoramiento de las propiedades físicas, químicas y biológicas del suelo, con la eficiencia del fertilizante mineral, la cual es producto de su alta solubilidad y disponibilidad inmediata de nutrientes en la solución del suelo. El objetivo del presente estudio era evaluar la eficiencia del fertilizante organomineral en la productividad de la caña de azúcar en un suelo distrofico. La evaluación se realizó con un diseño experimental bloques al azar con siete tratamientos y cuatro repeticiones. Los tratamientos consistieron de un testigo (sin fertilización), tres dosis de un fertilizante químico triple, para proveer 50, 100 y 150 kg/ha de ambos K₂O y P₂O₅ y 10, 20, 30 kg N/ha, tres dosis de un fertilizante organomineral para proveer 50, 100 y 150 kg/ha de ambos K₂O y P₂O₅ y 7.5, 15 y 22.5 kg N/ha. Se aplicó cal en todo el área 30 días antes de la siembra, en una dosis de 2 toneladas por hectárea y los fertilizantes se aplicaron en el surco al momento de la siembra. Se plantó la variedad SP81-3250. Los resultados del estudio demuestran que la aplicación de fertilizante organomineral o el convencional químico, en dosis que provean 100 y 150 kg/ha de K₂O y P₂O₅, produjo los mismos rendimientos para caña de azúcar. Respecto a los caracteres tecnológicos, las dos fuentes de fertilizante, aplicadas en la misma dosis, produjeron los mismos valores de Pol% cana y ATR (Total de azúcar recuperable). Se observó una diferencia en cuanto a porcentaje de fibra en cana. Los tratamientos con dosis de 50 y 100 kg/ha de K₂O y P₂O₅ en forma química y 150 kg/ha de K₂O y P₂O₅ en forma organomineral produjeron menor porcentaje de fibra en cana.
PERSISTENCE OF HERBICIDES APPLIED TO SUGARCANE DURING THE RAINY SEASON IN BRAZIL

KEYWORDS: Weed Management, Pre-Emergence Control, Cane Trash.

Abstract

This research aimed to study the persistence of herbicides in soil after the rainy season, evaluated by weed control in sugarcane. A split-plot design was used with main-plots consisting of six sugarcane rows (37.5 m²) and sub-plots one cane row (7.5 m²). Seeds of Ipomoea quamoclit, Ipomoea hederifolia, Merremia cissoides, Panicum maximum and Brachiaria decumbens were sown in the sub-plots while the main-plots consisted of ten herbicide treatments as follows: an untreated control, imazapic (147 g/ha), imazapic (98 g/ha) + sulfentrazone (600 g/ha), sulfentrazone (800 g/ha), tebuthiuron (1000 g/ha), amicarbazone (1400 g/ha), flumioxazin (125 g/ha), diuron (1066 g/ha) + hexazinone (134 g/ha) + imazapic (98 g/ha), amicarbazone (840 g/ha) + isoxaflutole (82.5 g/ha), imazapic (98 g/ha) + isoxaflutole (85 g/ha). During the 120 days following spraying, 698.7 mm of rainfall was observed, the average minimum and maximum temperature being 21.9 and 30.6°C respectively. The herbicides that best resisted this weather had a satisfactory control on the species studied in the following descending order: amicarbazone (91.2% control), imazapic (90.8%), imazapic + sulfentrazone (89.6%), amicarbazone + isoxaflutole (89.2%), imazapic + isoxaflutole (85.6%), diuron + hexazinone + imazapic (84.4%), tebuthiuron (76%), sulfentrazone (70.8%), flumioxazin (19.2%).

Introduction

Concerning Ipomoea spp., the usual method of control is chemical, which, according to Siebert et al. (2004), is conducted in pre-emergence in early spring. During that period, the more intense rainfall associated with high temperatures may cause faster degradation of residual herbicides in soil (Viator et al., 2002). The persistence of some herbicides in the soil is extremely variable. Some herbicides may be degraded within days, while others may persist for several months or years; however, the time they remain active in the soil depends on edapho-climatic conditions (Silva et al., 1999). Within this context, the objective of this work was to study the persistence of herbicides during bad weather in the rainy season, by assessing their control over weeds in sugarcane.

Material and methods

The experiment was established in a commercial sugar cane plantation in its 3rd ratoon, Brazil; the cane variety was SP84-2025 and it was planted at a row spacing of 1.50 m. The soil type is Red Latosol, clay textural class with 49.9% clay, 36.6% sand and 13.5% silt.

The experimental design was a split-plot scheme, with the main-plots composed of 5 sugarcane rows of 5 m length, representing an area of 37.5 m², and the sub-plots by each row with 7.5 m² of area. Herbicides were assigned to the main plots: Untreated; imazapic (147 g/ha); imazapic (98 g/ha) + sulfentrazone (600 g/ha); sulfentrazone (800 g/ha); tebuthiuron (1000 g/ha);
amicarbazone (1400 g/ha); flumioxazin (125 g/ha); diuron (1066 g/ha) + hexazinone (134 g/ha) + imazapic (98 g/ha); amicarbazone (840 g/ha) + isoxaflutole (82.5 g/ha) + imazapic (98 g/ha) + isoxaflutole (85 g/ha). The weed species assigned to the sub-plots: *Ipomoea quamoclit*, *Ipomoea hederifolia*, *Merremia cissoides*, *Panicum maximum* and *Brachiaria decumbens*.

The seeds were sown in the interrows of each plot. During sowing, the cane straw was removed, the seeds were sown and the straw returned to the plots. The amount of seeds used was related to the germination test provided by the seed supplying company, so that each species provided 100 plants in the usable area of each main-plot. Herbicide application was performed in pre-emergence of the weed species and sugarcane with pressurised backpack equipment regulated at 200 kPa pressure and 250 L/ha spray volume.

At 70, 90 and 120 days after application (DAA), herbicide control over the weeds sown was assessed. The methodology used was assigning percentage scores to the coverage of weeds in the main-plot area, with 0 for no infestation and 100% for total infestation. Those scores were used for assigning control based on the calculation: \( ctr = 100\% \times \text{specific coverage} \).

The control scores were submitted to an analysis of variance according to the design proposed, and the averages were compared by Tukey test at 5% probability.

**Results and discussion**

The herbicides applied were possibly exposed over the straw for at least 15 days as, at the end of that period, an accumulation of 26.1 mm rain was recorded, possibly enough for herbicides to be leached through the straw layer and reach the soil. However, during that period, the 8.7°C oscillation between minimum and maximum temperature and the sunlight fell directly over the herbicide.

At 120 DAA, in addition to flumioxazin (125 g/ha), herbicides sulfentrazone (800 g/ha), tebuthiuron (1000 g/ha) and diuron (1066 g/ha) + hexazinone (134 g/ha) + imazapic (98 g/ha) also had an unsatisfactory level of control on the infesting weed communities. All species had lower controls by the herbicides when compared to those in the previous assessments, especially against the grasses.

However, when looking closer at the level of control by each herbicide treatment, it was observed that all herbicides provided unsatisfactory control for some species; herbicide imazapic (147 g/ha) had unsatisfactory control only for *B. decumbens*, imazapic (98 g/ha) + sulfentrazone (600 g/ha) on *M. cissoides*, sulfentrazone (800 g/ha) on *M. cissoides*, *P. maximum* and *B. decumbens*; tebuthiuron (100 g/ha) on *P. maximum* and *B. decumbens*; amicarbazone (1400 g/ha) on *I. quamoclit* and *B. decumbens*, flumioxazin (125 g/ha) unsatisfactory control for all the species, diuron (1066 g/ha) + hexazinone (134 g/ha) + imazapic (98 g/ha) on *I. quamoclit*, *M. cissoides* and *B. decumbens*; amicarbazone (840 g/ha) + isoxaflutole (82.5 g/ha) on *I. hederifolia* and imazapic (98 g/ha) + isoxaflutole (85 g/ha) on *I. quamoclit* and *B. decumbens*.

**Conclusions**

One hundred and twenty days after application, during which 698.7 mm rain were recorded with averages of 21.9 and 30.6°C as minimum and maximum temperature respectively, the herbicides that resisted the bad weather had an average control over the species studied in the following order: sufficient control: imazapic, amicarbazone, imazapic + sulfentrazone, imazapic + isoxaflutole amicarbazone + isoxaflutole; doubtful control: diuron + hexazinone + imazapic, tebuthiuron; insufficient control: sulfentrazone; and very bad control: flumioxazin.

**Résumé**

CETTE ÉTUDE avait pour but de déterminer la persistance des herbicides dans le sol après une saison des pluies en évaluant les mauvaises herbes contrôlées dans des cultures de canne à sucre. Un dispositif en split-plot fut utilisé avec des parcelles principales de six lignes de canne (37.5 m²) et des sous parcelles d’une ligne de canne (7.5 m²). Des graines d’*Ipomoea quamoclit, Ipomoea hederifolia, Merremia cissoides, Panicum maximum* et *Brachiaria decumbens* furent semées dans les sous parcelles tandis que les parcelles principales étaient composées des dix traitements herbicides suivants: un témoin non traité, imazapic (147 g/ha), imazapic (98 g/ha) + sulfentrazone (600 g/ha), sulfentrazone (800 g/ha), tebuthiuron (1000 g/ha), amicarbazone (1400 g/ha), flumioxazin (125 g/ha), diuron (1066 g/ha) + hexazinone (134 g/ha) + imazapic (98 g/ha), amicarbazone (840 g/ha) + isoxaflutole (82.5 g/ha), imazapic (98 g/ha) + isoxaflutole (85 g/ha). Pendant les 120 jours suivant la pulvérisation, nous avons observé 698.7 mm de pluies, des températures moyennes minimum et maximum de 21.9°C et 30.6°C. Les herbicides qui ont le mieux persisté furent dans l’ordre décroissant: amicarbazone (avec un contrôle de 91.2% des mauvaises herbes), imazapic (90.8%), imazapic + sulfentrazone (89.6%), amicarbazone + isoxaflutole (89.2%), imazapic + isoxaflutole (85.6%), diuron + hexazinone + imazapic (84.4%), tebuthiuron (76%), sulfentrazone (70.8%), et enfin flumioxazin (19.2%).
PERMANENCIA DE HERBICIDAS APLICADOS A CANA DE AZUCAR DURANTE LA EPOCA LLUVIOSA EN BRASIL

PALABRAS CLAVE: Control de Malezas, Control Preemergente, Trash de Cana.

Resumen

El objetivo de la presente investigación era estudiar la permanencia de los herbicidas en el suelo después de la época lluviosa, evaluados de acuerdo al control de malezas en cana de azúcar. Se utilizó un diseño de parcelas divididas, con una parcela grande de seis surcos de cana (37.5 m$^2$) y una parcela pequeña de un surco (7.5 m$^2$). Se sembraron semillas de Ipomoea quamoclit, Ipomoea hederifolia, Merremia cissoides, Panicum maximum and Brachiaria decumbens en la parcela pequeña, mientras la parcela grande consistió en diez tratamientos con herbicidas, de la siguiente manera: un testigo sin aplicación, imazapic (147 g/ha), imazapic (98 g/ha) + sulfentrazone (600 g/ha), sulfentrazone (800 g/ha), tebuthiuron (1000 g/ha), amicarbazone (1400 g/ha), flumioxazin (125 g/ha), diuron (1066 g/ha) + hexazinone (134 g/ha) + imazapic (98 g/ha), amicarbazone (840 g/ha) + isoxaflutole (82.5 g/ha), imazapic (98 g/ha) + isoxaflutole (85 g/ha). Durante los 120 días después de la aplicación, se tuvo una precipitación de 698.7 mm, con temperatura mínima promedio de 21.9 y máxima promedio de 30.6°C. Los herbicidas que mejor soportaron estas condiciones presentaron un control satisfactorio de las especies bajo estudio, en el siguiente orden descendente: amicarbazone (91.2% de control), imazapic (90.8%), imazapic + sulfentrazone (89.6%), amicarbazone + isoxaflutole (89.2%), imazapic + isoxaflutole (85.6%), diuron + hexazinone + imazapic (84.4%), tebuthiuron (76%), sulfentrazone (70.8%), flumioxazin (19.2%).
PRODUCTIVITY OF UDULTS UNDER SUGARCANE AS INFLUENCED BY THE PROPERTIES OF THEIR TEXTURAL B HORIZON

By

A.L. PÁDUA JUNIOR and M.S. SCARPARI

IAC/ Centro de Cana-de-Açúcar/Fundag,
C.P. 206 – CEP: 14001-970 – Ribeirão Preto, SP – Brasil
alceulinares@iac.sp.gov.br

KEYWORDS: Sugarcane, Udults, Soil, Textural B Horizon.

Abstract

Studies to qualify the production environment have been undertaken to explore the productive potential of the soil, and consequently find the most favourable environment for sugarcane production. The surface and sub-surface characteristics of the soil, correlated with climate, allow the exploration of the genetic potential of sugarcane varieties. In the state of São Paulo (Brazil), there are extensive areas of Udult with sugarcane plantations. However, these Udults possess different water availabilities due to differences in clay content between the A and B horizons and the position where the textural B horizon (Bt) begins in the soil profile, thus influencing sugarcane productivity. Udults with Bt horizon beginning at 40, 60, or 80 cm were analysed. Soil samples were obtained in 0–20 cm, 20–40 cm and in the Bt horizon for determination of physical properties, such as clay content and available water capacity. The correlation of the productivity data with morphological characteristics such as the textural gradient of the Udults led to the conclusion that Udults with Bt horizon beginning at around 40 cm depth showed better conditions for water and nutrient absorption by the roots and consequently better sugarcane productivity.

Introduction

The production environment can be qualified by associating soil classification with climate information. Pedological characteristics can be used to obtain productivity increases of sugarcane through proper and rational soil exploration.

Prado (2007) defines the production environment as an association of surface and subsurface soil characteristics correlated with regional climate. The state of São Paulo accounts for a large amount of sugarcane production in Brazil and large areas are used.

Regarding soils with high occurrence, extensive areas of Udults (EMBRAPA, 2006) are used for sugarcane production. The Udults have morphological characteristics, namely an elevated textural gradient between the surface A horizon and the subsurface textural B horizon (Bt), and pedological characteristics, namely the position where the Bt horizon begins in the soil profile, that affect the water flux and storage in the soil.

This creates a wide variety of production environments in the same region. This work shows that the Udult heterogeneity, such as the textural differences between A and Bt horizons and the initial position of the Bt soil horizon, causes differences in the production environments of sugarcane.

Material and methods

The productivity data were acquired from sugarcane industries in the regions of Catanduva, Quatá, Porto Ferreira and Itapira, all located in the state of São Paulo. The soils studied were
Udults, with Bt horizon beginning at 40, 60 or 80 cm. Samples were obtained for granulometric analysis and determination of available water capacity (AWC) at 0–20 cm, 20–40 cm depth and in Bt horizon, which occurs at variable depth in the soil profile.

Results and discussion

Table 1 shows the productivity of the Udults in the four regions under study. Sugarcane productivity was observed to be lower where the Bt horizon starts at a greater depth, as described by Prado et al. (2008).

This indicates that Udults with Bt horizon beginning at about 40 cm showed better conditions for water and nutrient absorption by roots and consequently better productivity for sugarcane.

In the four regions studied, Udults with Bt horizon beginning around 40 cm showed the highest productivities, independent of the subsurface chemical condition.

Table 1—Sugarcane productivities (average of 5 analyses) in Udults with Bt horizon starting at different depths.

</tbody>
</table>

In Table 2, results of the granulometric analysis show that soil water storage is better where the difference in clay percentage between A and Bt horizons is larger. The high textural gradient in the Udults was thus one of the responsible factors for the highest sugarcane productivities.

</tr>
</tbody>
</table>

*CC = field capacity
*PWP = permanent wilting point
*H = depth of Bt horizon
*AWC = L of water/cm of Bt horizon considering the depth of 100 cm

Conclusions

The Udults with Bt horizon beginning at around 40 cm and with a high percentage of clay in the beginning of this horizon had higher productivity, due to the elevated water retention and availability in the soil profile.
Through correlation of productivity data with morphological and pedological characteristics of the Udults, it was possible to conclude that soils with Bt horizon beginning at 40 cm had an environment that was more suitable for production as they allowed better water and nutrient absorption by the roots and, consequently had the highest sugarcane productivity.

MOTS-CLES: Canne à Sucre, Udults, Sol, Horizon Textural B.

Résumé

Des études de caractérisation de la production environnementale ont été entreprises afin d’inventorier le potentiel productif du sol, et donc de trouver l’environnement le plus favorable pour la production de canne à sucre. Les caractéristiques surfaciques et pédologiques du sol, corréllées au climat, permettent d’explorer le potentiel génétique des variétés de canne à sucre. Dans l’état de São Paulo (Brésil), il existe des surfaces importantes d’Udults cultivées en canne à sucre. Cependant, ces Udults possèdent des disponibilités différentes en eau liées aux différentes teneurs en argile entre les horizons A et B et à la position où l’horizon textural B (Bt) commence dans le profil de sol, influençant ainsi la productivité de la canne à sucre. Des Udults avec des horizons Bt commençant à 40, 60 et 80 cm ont été analysés. Des échantillons de sol ont été prélévés entre 0–20, 20–40 cm et dans l’horizon Bt afin de déterminer les propriétés physiques, telles que la teneur en argile et la réserve en eau disponible. La corrélation entre la productivité et les caractéristiques morphologiques des Udults telles que leur gradient textural montre que les Udults avec un horizon Bt à environ 40 cm de profondeur présentent les meilleures conditions d’absorption en eau et éléments minéraux pour les racines et par conséquent la meilleure productivité en canne à sucre.
PRODUCTIVIDAD DE UDULTS BAJO EL CULTIVO DE CAÑA DE AZÚCAR, INFLUENCIADOS POR LAS PROPIEDADES DE SU HORIZONTE B TEXTURAL

PALABRAS CLAVE: caña de azúcar, Udults, suelo, horizonte B textural

Resumen

Se han realizado estudios para calificar el ambiente de producción con el fin de explorar el potencial productivo del suelo y, consecuentemente, encontrar el ambiente más favorable para la producción de la caña de azúcar. Las características de la superficie y sub-superficie del suelo correlacionadas con el clima permiten la exploración del potencial genético de las variedades de caña de azúcar. En el estado de São Paulo (Brasil) hay áreas extensivas de Udults con plantaciones de caña de azúcar. Sin embargo, estos Udults poseen diferentes disponibilidades de agua, debido a diferencias en el contenido de arcillas entre los horizontes A y B, y la posición en que comienza el horizonte B textural (Bt) en el perfil, lo cual influye la productividad de la caña de azúcar. Se analizaron Udults con horizonte Bt a los 40, 60 y 80 cm. Se obtuvo muestras de suelo de 0–20 cm, 20–40 cm y del horizonte Bt para determinar propiedades físicas tales como contenido de arcilla y capacidad de disponibilidad de agua. La correlación de los datos de productividad con características morfológicas como el gradiente textural de los Udults, condujo a concluir que los Udults con un horizonte Bt que comienza alrededor de los 40 cm de profundidad, muestran mejores condiciones para la absorción de agua y nutrientes por las raíces y, consecuentemente, una mejor productividad de caña de azúcar.
SILICON AMENDMENT IN THE PRODUCTIVITY OF FOUR SUGARCANE VARIETIES IN BRAZIL

By
F.L.F. DIAS¹, R. ROSSETTO¹,
M.G.A LANDELL¹ and A. MENDES²

¹IAC/APTA – Instituto Agronômico de Campinas,

KEYWORDS: Silicon, Sugarcane
Productivity, Economy, Variety.

Abstract
SILICON is a beneficial element for some crops. The low rates of available silicon in tropical soils, together with the large amount of silicon extracted by sugarcane, emphasises the importance of this work which reports on the responses of four sugarcane varieties to excoriates of metallurgy applied as a silicon source. The soil in the experiment was an Oxisol, medium texture, previously cultivated with pasture and it has a low level of soluble silicon (less than 3 ug/cm³). A split plot trial comprised four sugarcane varieties as the main plots: RB867515—high productivity; SP81-3250—rich and high productivity; RB72454 and SP83-2847—wide adaptability varieties. The sub plots were two treatments comprising a control (no silicon) and a plot receiving 940 kg/ha of Agrosilício containing 23% SiO₂. The fertilisers were applied at the bottom of the furrows at planting. The measured parameters were fibre, purity, Pol, reducing sugars (AR) and total recoverable sugars (ATR), and cane yield (t/ha). The economic analysis was conducted on plant cane. We observed different productivity for varieties due to silicon application in the first harvest. The varieties RB72454 and SP83-2847 were more responsive, and there were economic gains from silicon application. The economical gains in the second period of harvest were lower, with no statistical differences between treatments.

Introduction
In the past 10 years, Brazil has become the world's leading exporter of sugar, accounting for 30% of world exports of the product. Brazilian ethanol produced from sugarcane is both more economical and more efficient in terms of carbon dioxide balance (GHG emissions) than gasoline.

This aspect is reflected in the fact that Brazil is now responsible for half of world exports of the product.

There has been major expansion of sugarcane planted areas in the west of São Paulo, Minas Gerais, Mato Grosso, Mato Grosso do Sul and Goias states. Many of those areas, for example the west of São Paulo and Goias states, are usually deficient in Si with marginal soils that are sandy and with low fertility.

Although silicon is not considered an essential element for plant nutrition, scientific research has showed its involvement in structural, physiologic and biochemical aspects.

Some benefits have been ascribed to silicon application, such as: more tolerance to water stress, resistance to lodging in rice and cane, productivity increase and improvement in the product quality. Lima Filho et al. (1999) emphasised the need for silicon in tropical and subtropical soils. In general, tropical soils have lost available silicon by intensive leaching due to...
climatic conditions and some agricultural practices like intensive cultivation and continuous monoculture.

There is a lack of information in the literature concerning differences between sugarcane varieties in response to silicon application.

Sugarcane uptakes more silicon than potassium and nitrogen. Therefore, the low rate of available silicon in verified (or controlled) plants in Oxisols, plus the great silicon extraction accumulated by sugarcane biomass, emphasise the objectives of this paper.

Our main objective was to verify the response of four different sugarcane varieties in productivity, Pol, purity, reducing sugars (AR) and total recoverable sugars (ATR).

**Material and methods**

Field trials were initiated in May, 2007 at Moema sugar-mill production area, in the district of Orindiuva, São Paulo, Brazil, on an Oxisol of medium texture, 3 mmolc/dm³ of soluble silicon to study the productivity of sugarcane varieties following the application of silicon fertiliser in two planting seasons namely July and November 2008.

The experiment used a split plot design with four main treatments, namely sugarcane varieties RB867515, RB72454, SP81-3250 and SP83-2847.

The sub-plot treatment comprised the control (without silicon) and the treated plot receiving 940 kg/ha of ‘Agrosilício’ that is a silicon fertiliser produced by EXCELL company containing 23% of total silicon and 43% of soluble silicon.

Silicon fertiliser was applied in the planting furrow. In each plot, 500 kg/ha of 13-20-25 (N-P₂O₅-K₂O) was applied in the furrow.

The plots were replicated four times in a randomised block design. Each sub plot consisted of 10 cane rows 8 m long and spaced at 1.40 m.

The plots were weighed with a dynamometer to determine cane yield (t/ha). Pol, fibre, purity, reducing sugars (AR) and total recoverable sugars (ATR) were determined in ten stalks collected in each plot according to CONSECANA, (1999).

We also calculated the economic revenue (mean ATR/ha) = mean productivity of the varieties-treatment with silicon – mean productivity of the varieties-treatment without silicon; productivity (%) = (mean productivity of the varieties-treatment with silicon/mean productivity of the varieties-treatment without silicon * 100; Relative revenue for the productivity earnings = productivity * ATR (month reference August of 2008 = U$0.0999 and month reference November of 2008 = U$0.1206); cost fertilisers = function of the applied dose and adopted product. Liquidate relative = relative revenue – cost of the fertilisers (U$40.00/ha).

Statistical analyses of variance were performed using SAS software, and means were compared with Tukey’s test with P = 0.05%. The graphs were produced with the Office/Excel software.

**Results and discussion**

In Table 1 we show the results of the first evaluation time. The varieties showed differences such as: Pol cane, purity, reducing sugars (AR) and total recoverable sugars (ATR).

The varieties RB72454 and SP83-2847 are considered varieties with wide adaptability to low soil fertility and restrictive conditions of climate. RB867515 and SP81-3250 require more nutrients; however, there was no statistical difference in yield between varieties. Silicon promoted just a few changes in Pol% and ATR. Silicon application promoted increments in stalk productivity near 5 t/ha (132.61-127.36).

In the second harvest period (Table 2), which differed from the first period because there were no constraints in water and thermal climate parameters, there was no response for silicon application in stalk yield.
Increases in productivity were observed for variety RB867515 in the second harvest, but variety SP81-3250 maintained the same productivity in both harvests. These varieties should be harvested in the second harvest period. However, the varieties RB72454 and SP83-2847 should be harvested in the middle of the harvest period. There was no interaction between variety and silicon.

Table 1—Variance analysis and comparison among averages for Pol, fibre, purity, reducing sugars (AR), total recoverable sugars (ATR), and stalks productivity harvested on July 2008.

Table 3 shows the calculations of economical income concerning the use of silicon. The largest incomes as well as the relative balances were positive for silicon application in the first period of harvest. However, in the second harvest period, the incomes were not so impressive, resulting in little economical return per hectare. As an example, the agricultural area in a sugar mill is around 20 000 hectares.

In this case, it is possible with use of silicon to obtain profits of US$548 400.00 (20 000 hectares multiplied by US$27.42 with silicon, Table 3).
Table 3—Absolute contributions and relative balances obtained for varieties vs silicon and silicon in the experiment harvested in August (Time 1) and November (Time 2).

(–Si) and (+Si): without silicon and with silicon, respectively.

Silicon use provided gains in productivity for all varieties in this experiment. The increase was around 7% in the first period of harvest and of 3% in the second time. The varieties RB867515 and SP81-3250 were more responsive in the first evaluation time, showing 8.40 and 7.90% respectively in ATR gains.

For the second period of harvest, the varieties RB72454 and SP83-2847 were more responsive showing 6.08 and 3.54% respectively in ATR gains.

MOTS CLES: Silicium, productivité de la canne à sucre, économie, variété

Résumé
Le silicium est un élément bénéfique pour de nombreuses cultures. Les faibles teneurs en silicium disponible dans les sols tropicaux associées aux grandes quantités de silicium mobilisées par la canne à sucre, accentuent l’importance de cette étude qui relate la réponse de quatre variétés de canne à sucre à des scorces de métallurgie appliquées comme source de silicium. Le sol de l’essai était un Oxisol de texture moyenne, avec un précédent pâturage et ayant une faible teneur en silicium soluble (moins de 3 μg/cm³). Un essai en split plot comprenait quatre variétés de canne à sucre comme parcelles principales, RB867515, productivité élevée; SP81-3250 – riche et productivité élevée; RB72454 – large adaptabilité; et SP83-2847 – rustique. Les sous parcelles comprenaient un témoin sans silicium et un traitement recevant 940 kg/ha d’Agrosilício contenant 23% de SiO₂. Les engrais ont été épandus au fond du sillon à la plantation. Les paramètres mesurés furent la fibre, la pureté, le Pol, les sucres réducteurs (AR), les sucres totaux extractibles (ATR) et le rendement (t/ha). L’analyse économique fut réalisée sur la canne plantée. Selon les doses de silicium, différentes productivités ont été observées pour les variétés de canne. Les variétés RB72454 et SP83-2847 ont montré les réponses les plus élevées avec des gains économiques dus à l’application de silicium. Les gains économiques sur la seconde récolte furent plus faibles avec aucune différence statistique entre traitements.
ENMIENDA DE SILICIO EN LA PRODUCTIVIDAD DE CUATRO VARIEDADES DE CANA DE AZUCAR EN BRASIL

PALABRAS CLAVE: Silicio, Productividad de Cana de Azúcar, Economía, Variedad.

Resumen
El silicio es un elemento benéfico para algunos cultivos. El bajo contenido de silicio en los suelos tropicales, aunado a la gran cantidad de silicio que la caña de azúcar extrae, enfatiza la importancia de este trabajo, que reporta las respuestas de cuatro variedades de caña de azúcar a la aplicación de residuos de metalurgia como fuente de silicio. El suelo en que se plantó el experimento era un Oxisol, de textura media, previamente cultivado con pasto y con bajo nivel de silicio (menos de 3 ug/cm³). Se utilizó un diseño de parcelas divididas con las variedades de caña como parcela grande- RB867515 – productividad alta; SP81-3250 – productividad alta y rica; RB72454 – amplia adaptabilidad y SP83-2847 – una variedad rustica. Las parcelas pequeñas fueron dos tratamientos: un testigo (sin silicio) y una parcela donde se aplicó 940 kg/ha de Agrosilicio que contiene 23% SiO₂. Los fertilizantes se aplicaron en el fondo del surco en el momento de la siembra. Los parámetros evaluados fueron fibra, pureza, Pol, azúcares reductores (AR) y total de azúcar recuperable (ATR) y rendimiento de cana (ton/ha). Se realizó un análisis económico en soca. Se observó diferencia en la productividad de las variedades debidas a la aplicación de silicio en la primera cosecha. Las variedades RB72-2454 y SP83-2847 tuvieron mejor respuesta y presentaron ganancias económicas con la aplicación de silicio. Las ganancias económicas en la segunda cosecha fueron menores, sin diferencia estadística entre tratamientos.
THE DSSAT4.5 CANEGRO MODEL: A USEFUL DECISION SUPPORT TOOL FOR RESEARCH AND MANAGEMENT OF SUGARCANE PRODUCTION

KEYWORDS: Crop Model, Biomass, Sucrose Mass, Leaf Area Index, Simulation.

Abstract

THE NEW DSSATv4.5 Canegro model allows users to combine the latest advances in sugarcane modelling with the latest DSSAT functionality to address production and research problems. The objectives of this poster are to (1) describe the main features of the model, (2) report on its accuracy of simulating biomass, cane and sucrose yields in different parts of world, and (3) highlight potential applications in sugarcane research and management. The model uses daily weather data to simulate canopy development, interception of radiation, biomass accumulation and partitioning. It simulates the effect of water stress and lodging on photosynthesis, growth and sucrose storage. Eighteen cultivar parameters are used to simulate genetic control of crop response to environmental factors. Simulated green leaf area index, aboveground biomass, stalk mass and sucrose mass were compared with observed data from Australia, Brazil, South Africa, Thailand and Zimbabwe. The model performed remarkably well for these widely different cropping situations and cultivar types. In some cases, the simulated biomass accumulation rates declined too rapidly in winter leading to an underestimation of yields. This needs further investigation. The DSSATv4.5 Canegro model is now easily accessible and may be applied, after thorough testing, to support research and management world-wide.

Introduction

The new DSSAT v4.5 Canegro model allows users to combine the latest advances in sugarcane modelling with the latest DSSAT (Jones et al., 2003) functionality to address production and research problems.

The objectives of this poster are to (1) describe the main features of the model, (2) report on its accuracy of simulating biomass, cane and sucrose yields in different parts of world, and (3) highlight potential applications in sugarcane research and management.

Model description

The DSSAT v4.5 Canegro plant module (Singels et al., 2008) uses soil properties, weather data, management inputs and genetic parameters to simulate the daily growth and development of sugarcane crops.
The duration of phenological phases (germination, tiller production, tiller senescence and stalk elongation) are simulated using the thermal time (TT) concept.

Tiller population and numbers of green and dead leaves on the primary tiller are calculated using TT. The product of leaf size, tiller population and leaf number provides total and green leaf area index (GLAI).

Interception of photosynthetically active radiation is calculated using Beer’s law. Biomass accumulation is calculated following the radiation use efficiency approach but also accounting for respiration.

Partitioning of biomass to different plant components, including stalk sucrose, is calculated using a source-sink approach and accounts for physiological age, temperature and water stress.

Water stress is calculated following the CERES approach (Jones and Kiniry, 1986) of process-specific soil water deficit factors.

Water stress affects rates of transpiration, photosynthesis, growth and sucrose storage. The model uses 18 cultivar parameters to simulate genetic control of crop growth and development to environmental factors.

**Model testing**

The model was tested using experimental data from Australia, Brazil, South Africa, Thailand and Zimbabwe (see Table 1).

The model was calibrated for cultivars other than NCo376 by adjusting the values of some cultivar parameters so that simulations of phenological, tiller and leaf development and of biomass partitioning followed observations closer.

Simulation accuracy was quantified using the root mean square of the deviations between simulated and observed values, expressed as a percentage of the mean observed value (RMSE).

Visual comparisons of simulations with experimental data showed that the model performed remarkably well for most of these widely different cropping situations and cultivar types.

RMSEs for GLAI, biomass, stalk dry mass and sucrose mass ranged from 11 to 45, 14 to 26, 13 to 34 and 7 to 34% respectively (see Table 1).

The large errors are ascribed to incomplete cultivar calibration or to apparent model shortcomings.

The study highlighted areas that may require refinement:

- The simulation of tiller appearance and senescence does not adequately account for the dynamic effects of planting density and radiation transmission through the canopy. This leads to inaccurate predictions of GLAI at times.

- Observations from several data sets (South Africa, Australia, Brazil) suggest that the simulated reduction in the rate of biomass accumulation due to decreased temperature is too drastic. Further investigation into this aspect is required.

**Model applications**

Sugarcane crop models have many applications in research and management of sugarcane production. These include:

1. climate change impact studies (Marin et al. 2009);
2. exploring ideotypes for given environments;
3. forecasting crop yield and quality (Bezuidenhout and Singels, 2007); and
4. supporting irrigation management (Singels and Smith, 2006).

The inclusion of an up-to-date Canegro model into the DSSATv4.5 package makes sugarcane modelling more easily accessible and should enhance sugarcane research and management. However, local testing is necessary before the model can be applied with confidence.

Résumé

LE NOUVEAU modèle Canegro DSSATv4.5 permet aux utilisateurs de combiner les dernières avancées en modélisation de la canne à sucre avec les toutes dernières fonctionnalités de la plateforme DSSAT pour résoudre des problèmes de recherche et de production. Les objectifs de ce poster sont (1) de décrire les caractéristiques principales du modèle, (2) de montrer sa capacité à simuler la biomasse, et les rendements en canne et en sucre dans différentes parties du monde, et (3) d’exposer les applications potentielles en gestion et recherche sur la canne à sucre. Le modèle utilise des données climatiques journalières pour simuler le développement du couvert, l’interception du rayonnement, l’accumulation de biomasse et sa partition. Il simule l’effet du stress hydrique et de la verse sur la photosynthèse, la croissance et le stockage du saccharose. 18 paramètres variétaux sont utilisés pour simuler le contrôle génétique de la réponse des plantes aux

EL MODELO CANEGRO DSSAT4.5: UNA HERRAMIENTA UTIL EN LA TOMA DE DECISIONES EN INVESTIGACION Y GESTION DE LA PRODUCCION DE CANA DE AZUCAR

PALABRAS CLAVE: Modelo de Cultivo, Biomasa, Producción de Sacarosa, Índice de Área Foliar, Simulación.

Resumen

El nuevo modelo Canegro DSSATv4.5 permite a los usuarios combinar los últimos avances en modelación de caña de azúcar con la funcionalidad de DSSAT para abordar problemas en investigación y producción. Los objetivos del presente poster son (1) describir las funciones principales del modelo, (2) reportar su precisión para simular rendimientos de biomasa, caña y azúcar en diversas partes del mundo y (3) resaltar aplicaciones potenciales en gestión e investigación en caña de azúcar. El modelo utiliza datos diarios de clima para simular el desarrollo del follaje, la intercepción de la radiación, así como la acumulación y partición de biomasa. Además simula el efecto del estrés hídrico y acáme en la fotosíntesis, crecimiento y almacenamiento de azúcar. Se utilizaron 18 parámetros del cultivar para simular el control genético de la respuesta de la planta a los factores ambientales. Se comparó el índice de área foliar, biomasa aérea, cantidad de tallos y sacarosa con datos de Australia, Brasil, Sudáfrica, Tailandia y Zimbabwe. El modelo funcionó notablemente bien para estas diversas condiciones de cultivo y tipos de cultivares. En algunos casos, los índices de acumulación de biomasa decrecieron muy rápidamente en invierno, lo cual causó una subestimación de los rendimientos. Es necesario continuar la investigación en ese aspecto. Actualmente el modelo Canegro DSSATv4.5 es fácilmente accesible y, luego de cuidadosas pruebas, puede aplicarse a nivel mundial para apoyar la investigación y gestión.
N AND K FERTILISATION OF SUGARCANE RATOONS HARVESTED WITHOUT BURNING

KEYWORDS: Green Cane, Sugarcane Nutrition, Potassium, Nitrogen.

Abstract
THE CURRENT production capacity of Brazilian sugarcane is mainly based in the State of São Paulo, which accounts for approximately 60\% of national production. São Paulo state has environmental regulations prohibiting the burning of sugarcane before harvesting. The residue layer left on the soil surface can interfere with fertilisation, by recycling some nutrients and also making fertiliser incorporation more difficult. In order to verify if N and K rates recommended for the burnt cane ratoon system are different from green cane, in this paper we report the response of sugarcane ratoons to different nitrogen and potassium fertiliser application rates in green cane systems. Fifteen experiments were established in several regions of São Paulo State, Brazil. All the experiments had crop residue (trash) from plant cane remaining on the soil surface since sugarcane was mechanically harvested without burning. Fertilisers were applied over the trash at the rates of: 0, 60, 120 and 180 kg/ha of N and 0, 70, 140 and 210 kg/ha of K\textsubscript{2}O. Each experiment was harvested after 12 months of growth. Our results showed significant responses to N application in 14 experiments, and significant responses to K fertilisation in 7 experiments. Nitrogen and K\textsubscript{2}O application rates that produced optimum cane yields were: N = 148 kg/ha and K\textsubscript{2}O = 125 kg/ha; however, economically profitable rates were N = 120 kg/ha and K\textsubscript{2}O = 70 kg/ha. Productivity gains did not offset costs when rates were higher than 120 kg/ha of N and 70 kg/ha of K\textsubscript{2}O. Sugarcane residues contributed mainly to sugarcane potassium nutrition.

Introduction
A great challenge facing the sugarcane industry in Brazil these days is to improve overall productivity, decrease production costs and improve sustainability. Sugarcane production systems in São Paulo State, Brazil, have experienced several modifications over time, especially due to new environmental regulations prohibiting crop burning. The sugarcane crop is now mechanically harvested without burning resulting in great amounts of residue on the soil surface. After several years of residue application, the trash layer can interfere with fertilisation, since residues make fertiliser incorporation more difficult. Our objective in this experiment was to update sugarcane fertilisation recommendations regarding N and K application in sugarcane ratoons harvested without burning. Fifteen experiments were established in the state of São Paulo, Brazil. Productivity responses were verified across differing rates of N and K application.

Material and methods
Fifteen experiments were carried out in diverse regions in São Paulo State, Brazil, including the main sugarcane production environments (named A, B, C, D and E). The production
environments are defined by soil fertility status and the ability to store water for sugarcane crop. So, it is expected that sugarcane cultivation in environment A will achieve high productivity. In environment E, productivity is expected to be very low. In São Paulo state, sugarcane is grown mainly in environments B, C and D (Prado et al., 2008).

In addition, areas with different soil potassium levels were selected (Figure 1). The experiments were installed primarily in the first and second ratoon crops, with one of the trials implemented in third ratoon. All the experiments were established following mechanical harvest without burning. Table 1 presents the description of the 15 sites.

Fig. 1—Potassium (mmol c/dm³) in soil samples for each experiment.
The experiments were planted in a factorial design with 16 treatments placed in randomised blocks with four replications. Plots consisted of 5 rows of sugarcane 10 metres long, with between-row spacing of 1.4 and 1.5 m. N and K fertility treatments were:

- Nitrogen – 4 rates (0, 60, 120 and 180 kg/ha of N);
- Potassium – 4 rates (0, 70, 140 and 210 kg/ha of K₂O).

The fertiliser sources were ammonium nitrate and potassium chloride. Each experiment was harvested following 12 months of growth. The plots were weighed with a dynamometer to determine cane yield (t/ha).

Statistical analyses of variance for a factorial design was performed using SAS, and Tukey means separations were calculated with P = 0.05. Productivity responses were also estimated by SAS.

Results and discussion

Cane yield results for each fertilisation treatment from all 15 sites are presented in Table 2. Results differed among locations; however, this was expected since different production environments, sugarcane varieties and crop longevity were studied. Higher cane yields were measured in experiments carried out in environments classified as B or C, as well as in the younger ratoons.

Based on the results, it can be established that soil classification and water storage capacity are very important to predict cane productivity. Chalita (1991), determined that the soil level of potassium critical for cane growth in the State of São Paulo, Brazil, was 1.2 mmol c/dm³ for first ratoon cane. Our experiments show that lower cane productivities were obtained in soils when potassium levels were < 1 mmol c/dm³ of K. Average yields at each location can be observed in Figure 2. Higher productivity locations were: Araras, Iracemápolis, Guaira 2, Piracicaba, Ribeirão Preto, Sertãozinho and S. Rita.

Fig. 2—Average cane yield at each location.
Statistical analyses of cane yield responses indicated that nitrogen significantly increased cane yield in 14 experiments and potassium increased cane yield in 7 trials. Thornburn et al. (2002) estimated that N application rates for sugarcane harvested without burning should be 60 kg per ha higher than burnt cane.

Higher N doses are required following green sugarcane harvest because the water storage capacity is higher and, consequently, the biomass accumulation can be increased. Also, there is a need to compensate for soil nitrogen immobilisation in the crop residue. These were the main reasons for cane yield responses to nitrogen in 14 of the 15 locations.

Sugarcane production systems with crop burning are considered highly responsive to potassium fertilisation in both the plant cane and ratoon crops (Rossetto et al. 2004). However, in green cane systems, the crop residues can add substantial amounts of K.

Oliveira et al. (2002) estimated that remaining trash can recycle approximately 65 kg/ha of K2O. The potassium present in green cane residues can be rapidly transferred to the soil and supplied for the cane crop which means that sugarcane response to potassium fertilisers is reduced.

In fact, significant response to K fertilisation occurred only in 7 of the 15 locations even in soils with low potassium levels at Araçatuba, Guaira2, Planalto, Promissão, S. Rita and S. Joaquim da Barra.

Nitrogen and potassium rates for optimum cane yields were estimated for the 15 locations as N = 148 kg/ha and K2O = 125 kg/ha. Nevertheless, due to the high fertiliser costs, the economical rate of application was 120 kg/ha of N and 70 kg/ha of K2O.

When higher rates were applied, the cane yield gain did not exceed 3 t/ha and therefore did not offset the increased fertiliser costs.

Sugarcane ratoon yield response curves to N and K fertilisation rates (average for 15 field experiments) can be observed in Figures 3 and 4.

![Fig. 3—Sugarcane ratoon yield response to nitrogen fertilisation rates. (Average for 15 field experiments).](image-url)
Conclusions

N fertilisation significantly increased cane yield in green cane systems in 14 of 15 locations whereas K fertilisation increased cane yield at only 7 locations.

Nitrogen and potassium fertilisation rates for optimum cane yields were: N = 148 kg/ha K$_2$O = 125 kg/ha. However, the most profitable rates were: N = 120 kg/ha and K$_2$O = 70 kg/ha.

MOTS CLÉS: Canne en Vert, Nutrition de la Canne à Sucre, Potassium, Azote.

Résumé

DE NOS JOURS, la capacité de production de canne à sucre du Brésil est principalement concentrée dans l’Etat de São Paulo avec environ 60% de la production nationale. L’Etat de São Paulo obéit à des règles environnementales interdisant le brûlage de la canne avant la récolte. Les résidus laissés sur le sol peuvent interférer avec la fertilisation en recyclant des éléments nutritifs et aussi en rendant plus difficile l’incorporation de la fertilisation. Afin de vérifier si les taux de N et K recommandés pour les repousses d’une canne coupée après brûlage sont différents pour la canne coupée en vert, nous présentons dans ce papier la réponse de la canne en repousse à divers niveaux d’engrais azoté et potassique épandus après une coupe en vert. Quinze essais ont été implantés dans diverses régions de l’Etat de São Paulo, Brésil. Tous les essais avaient des résidus de récolte (paillis) à la surface du sol puisque la canne en vierge avait été récoltée mécaniquement sans brûlage. Les engrais avaient été appliqués sur le paillis aux taux de: 0, 60, 120 et 180 kg/ha pour N et 0, 70, 140 et 210 kg/ha pour K\(_2\)O. Chaque essai a été récolté à l’âge de 12 mois. Nos résultats ont montré des réponses significatives à l’application de N dans 14 essais et dans 7 essais pour K. Les taux de N et K\(_2\)O qui ont produit les rendements canne optimaumes ont été: 148 kg/ha pour N et 125 kg/ha pour K\(_2\)O, cependant économiquement la dose rentable est de 120 kg/ha pour N et 70 kg/ha pour K\(_2\)O. Les gains de productivité n’ont pas compensé les coûts quand les taux d’application étaient plus élevés que 120 kg/ha en N et 70 kg/ha en K\(_2\)O. Les résidus de canne à sucre contribuent principalement à la nutrition potassique de la canne à sucre.
FERTILIZACION CON N Y K DE CANA DE AZUCAR EN SOCAS COSECHADAS SIN QUEMAR

PALABRAS CLAVE: Cosecha en Verde, Nutrición de Cana de Azúcar, Potasio, Nitrógeno.

Resumen

La capacidad de producción actual de la caña de azúcar en Brasil tiene base principalmente en el estado de São Paulo, pues representa el 60% de la producción nacional. El estado de São Paulo posee regulaciones ambientales que prohíben la quema de la caña de azúcar antes de cosecharla. La capa de residuos que queda sobre la superficie del suelo puede interferir con la fertilización, a través del reciclaje de algunos nutrientes, pero también dificultando la incorporación de fertilizante. Con el fin de verificar si las dosis de N y K recomendadas para la cosecha de caña quemada difieren de aquellas para cosecha de caña en verde, en el presente trabajo se reporta la respuesta del cultivo de la caña de azúcar en socas, a la aplicación de diferentes dosis de fertilizantes nitrogenados y potásicos en cosecha en verde. Se establecieron 15 experimentos en diversas regiones del estado de São Paulo, Brasil. Todos los experimentos tenían residuos de la cosecha (trash) sobre la superficie del suelo, pues la caña se cosecho mecánicamente, sin quemar. Los fertilizantes se aplicaron sobre el trash, en dosis de 0, 60, 120 y 180 kg/ha de N y 0, 70, 140 y 210 kg/ha de K₂O. Cada experimento se cosecho después a los 12 meses. Los resultados muestran respuestas significativas a la aplicación de N en 14 experimentos, así como respuestas significativas a la aplicación de K en siete experimentos. Las dosis de N y K₂O que produjeron rendimientos óptimos fueron: N = 148 kg/ha y K₂O = 125 kg/ha; sin embargo, las dosis óptimas económicas fueron: N = 120 kg/ha y K₂O = 70 kg/ha. Las ganancias en productividad no compensaron los costos cuando las dosis fueron mayores a 120 kg/ha de N and 70 kg/ha of K₂O. Los residuos contribuyeron, principalmente con los requerimientos de potasio de la caña de azúcar.
THE USE OF A HUMIC ACID-BASED SOIL CONDITIONER IN SUGARCANE CROP

KEYWORDS: Saccharum spp, Fertilisation, Productivity, Humic acid.

Abstract

Efforts have been made to find ways to increase the productivity of sugarcane crops by using less mineral fertilisers, leading to a cost reduction and sustainability. Based on these principles, organic-mineral products have been used to promote physical, chemical and biological alterations in the soil system. The use of a commercial humic acid-based soil conditioner product was evaluated, in order to measure its influence on sugarcane production and to check its interaction with the mineral fertilisation. The experiment was carried out on Santa Candida sugar mill, located in Bocaina, São Paulo state, using the sugarcane varieties RB 867515 (plant cane), and PO88-62 (ratoon). The experiment was laid out in a split-plot design, using 0, 800, 1600 and 2400 kg/ha of the mineral fertiliser 2.5–10–10 (main plot treatments) with 0 and 350 litres/ha of the commercial product (sub-plot treatments) at sugarcane planting, and 0, 800, 1600 and 2400 kg/ha of the mineral fertiliser 10–00–10 (main plots) with 0, 300 and 600 litres/ha of the commercial product (sub-plots), at first ratoon. Results showed that the use of the commercial product causes a significant increase in the crop production, both in plant cane and first ratoon, equivalent to the use of 1200 and 1100 kg/ha (interpolated) of the mineral fertiliser.

Introduction

Organic matter providing enormous benefits to agricultural production is ancient knowledge, but yet little is known about it. Use of organic matter improves soil physical, chemical and biological properties, and has technical advantages.

However, due to high cost and / or large volumes required, the application of organic matter as fertiliser in fields is limited to a small group of growers.

Composition of soil organic matter is still unknown by the great diversity and variability of compounds and origins, but is generally called ‘humus’ due to the large presence of humic acid, which appears to be the ‘active principle’.

Many attempts have been made to increase sugarcane productivity. One of them is to use mineral fertilisers more efficiently, and thus reduce costs and sustain production of the sugar-alcohol sector.

Under this principle, organic minerals with a humic-acid base were selected with the aim to improve the level of soil organic matter, and soil physical, chemical and biological properties.

This work was to determine the effect of an organic soil conditioner, organic mineral humic acid, in plant and ratoon cane. Furthermore, its interaction with mineral fertiliser was also investigated.
Materials and methods

Two trials were conducted at Santa Cândida Mill, City of Bocaina – SP. The first trial was plant cane of variety RB 867515 located in Farm Bateia, with neosoil quartzenic sandy soil found in the production environment D1 (Prado, 2005). After opening the furrows, the application of the organic mineral product was done at the same time as the application of mineral fertiliser. The second trial was ratoon cane of variety PO88-62 located in Farm Santa Inês, with neosoil quartzenic sandy soil found in the production environment D2 (Prado, 2005). The application of organic mineral was performed during the mechanical cultivation of the ratoon.

Experimental design for both trials was randomised blocks in split plots with 4 replications. The main treatment was fertiliser rates. In the plant cane trial, there were two rates of the organic mineral (0 and 350 L/ha) in combination with 0, 800, 1600 and 2400 kg/ha of liquid fertiliser 2.5–10–10. However, in the ratoon cane trial, there were three rates of the organic mineral product (0, 300 and 600 L/ha) in combination with 0, 800, 1600 and 2400 kg/ha of liquid fertiliser 10–0–10. Each plot comprised four rows, 50 metres in length. Samples were taken from the middle 30 metres.

The Agrolmin® organic mineral product used in the experiment was obtained by extraction from a natural peat mine with the following properties: pH = 5.67, total organic matter (humic substances) = 89.72%, total N 5% (patronised from the natural product complemented with mineral N).

At harvesting, cane was cut, weighed and evaluated. Analysis of variance was performed by SAS statistical program, the test medium analysed by the Tukey test at 5% significance.

Results and discussion

There was a significant difference in cane yield related to the rates 1600 and 2400 kg/ha of mineral fertiliser when compared to the control. However, there was no significant difference between the rates of 800, 1600 and 2400 kg/ha. It was also found that the use of 350 L/ha significantly increased the cane yield to 177.78 t/ha, compared to the control, 130.02 t/ha (Table 1).

</table>

Means followed by the same letter are not different by Tukey test at 5% probability.
With regard to mineral fertiliser, there was a significant difference between the rates of fertiliser and control, but no significant difference between the rates of fertiliser at 800, 1600 and 2400 kg/ha. No significant interaction between rates of mineral fertilisers and rates of Agrolmin® were found.

It was also observed during the conduct of experiments that both plant and ratoon cane treated with humic acid showed fewer symptoms of a drought-like root system, thinner stalks and shorter internodes than the plots without this input.

Cane yield was increased by number of tillers and larger diameter of the cane stalks. These symptoms are related to improved plant nutrition by greater absorption of nutrients.

Increased availability of nutrients, particularly nitrogen, was directly related to the increase in the diameter of stem and tillering of culture (Van Dillewijn, 1952; Humbert, 1968; Alexander, 1973; Clements, 1980; Rodrigues et al., 1983; Beauclair, 1984).

This increased availability of nitrogen is related to an increase in content and, consequently, the decomposition and mineralisation of organic matter, as suggested by Beauclair (1984), provided by using humic acid.

Although these results showed that the use of humic acid resulted in a consistent increase in cane yield, it does need a greater number of studies and analysis of the issue to better characterise the causes and effects.

Conclusions

For the cane plant, the use of a commercial product of humic acid of 350 L/ha resulted in a significant increase in cane yield, and the rate equivalent to the use of 800 kg/ha of mineral fertiliser.

In ratoon cane, the rates of 300 and 600 L/ha of humic acid resulted in a significant increase of cane yield equal to 1200 kg/ha of mineral fertiliser.

Use of this soil conditioner may be feasible to increase production combined with a reduction of mineral fertiliser.

Résumé

Des efforts ont été réalisés pour trouver des solutions permettant d’augmenter la productivité des cultures de canne à sucre, diminuer les coûts et augmenter la durabilité. Basé sur ces principes, des engrais organo-minéraux ont été utilisés pour améliorer les propriétés physiques, chimiques et biologiques du sol. Un produit commercial activateur de sol humique acide fut évalué en mesurant son influence sur la production de la canne à sucre et son interaction avec la fertilisation minérale. L’expérimentation fut réalisée sur le complexe de Santa Candida sugar mill, situé en Bocaina, dans l’état de São Paulo, avec les variétés RB 867515 en canne plantée et PO 88-62 en repousse. Le dispositif en split plot comportait les doses d’engrais minéraux en parcelles principales et les doses de produit commercial en sous parcelles. A la plantation, des doses (0, 800, 1600 et 2400 kg/ha) d’engrais minéraux (2.5–10–10) et des doses de 0 et 350 l/ha de produit commercial furent appliquées. En repousse, des doses (0, 800, 1600 et 2400 kg/ha) d’engrais minéraux (10–00–10) et des doses de 0, 300 et 600 l/ha de produit commercial furent appliquées. Les résultats montrèrent que l’application de produit commercial augmente significativement la production à la fois en canne plantée et en repousse, ce qui équivaut par interpolation à une utilisation de 1200 et 1100 kg d’engrais minéral.
Utilización de un acondicionador de suelo a base de ácido húmico en el cultivo de la caña de azúcar

Resumen
Se han realizado esfuerzos para incrementar la productividad del cultivo de la caña de azúcar utilizando menos fertilizantes minerales, con el objeto de reducir costos y lograr sostenibilidad. Con base en estos principios, se han utilizado productos orgánico-minerales para promover alteraciones físicas, químicas y biológicas en el sistema suelo. Se evaluó la utilización de un acondicionador de suelo a base de ácido húmico, con el fin de medir su influencia en la producción de caña de azúcar y su interacción con la fertilización mineral. El experimento se llevó a cabo en el ingenio Santa Candida, ubicado en Bocaina, estado de San Pablo, con las variedades RB86-7515 (plantía) y PO88-62 (soca). Se utilizó un diseño experimental de parcelas divididas, aplicando 0, 800, 1600 y 2400 kg/ha del fertilizante mineral 2.5–10–10 (parcela grande) con 0 y 350 litros/ha del producto comercial (parcela pequeña) en plantía, y 0, 800, 1600 y 2400 kg/ha del fertilizante mineral 10–00–10 (parcela grande) con 300 y 600 litros/ha del producto comercial (parcela pequeña) en soca. Los resultados muestran que el uso del producto comercial provoca un incremento en la producción del cultivo, tanto en plantía como en soca, equivalente al uso de 1200 y 1100 kg/ha (interpolando) del fertilizante mineral.
EFFECTS OF SUBSOILING ON ALFISOL SOIL
PHYSICAL PROPERTIES IN COLOMBIA

By

MARCO ANTONIO GIRON TEJADA

magiron@yahoo.com

KEYWORDS: Subsoiler, Tillage,
Physical Properties, Cane Sugar, Soil.

Abstract
A STUDY was conducted to evaluate the effects of subsoiling on the soil physical properties in the Providencia Sugar Mill S.A. in Colombia. A Steiger tractor of 225 HP and parabolic subsoiler were used with different velocities (3.0 to 4.2 km/h) and spacing between shanks (1.1 to 1.4 m). The soil studied was an Alfisol of the Argelia series with clay texture. The soil properties, namely available water capacity, breaking area, moisture content and lower limit of plasticity, were measured to a depth of 80 cm. Average soil moisture content at the time of the test (13.0%) was below the lower plastic limits (18.10%) in the 0–30 cm layer. When the spacing between shanks was decreased and velocity increased, breaking area increased from 1.4 m² to 1.6 m² and available water content was increased from 16.64% to 20.13%. In conclusion, the subsoiling tillage increased the breaking area and available water content when spacing between shanks was 1.1 m and velocity was 4.2 km/h and decreased soil compaction in an Alfisol soil.

Introduction
Soil compaction is generated by machinery traffic during harvest and agricultural operations. This compaction is related to the moisture content in the soil. Compaction modifies the soil physical properties such as bulk density, penetration resistance, infiltration, available water capacity and can create problems of crop development and decreased production.

To reduce soil compaction, subsoiling is used during soil preparation and also in ratoons. The soil preparation is carried out before planting by two passes to increase the broken area and by one pass between the rows in ratoons.

Factors influencing the soil breaking of the subsoiler are: moisture content, velocity of the tillage, depth and spacing between shanks, design of the implement. This study evaluated the subsoiler use in tillage of sugarcane crops and its effect on soil physical properties such as available water capacity and breaking area.

Material and methods
The trial was carried out in Topacio farm near to Providencia sugar mill in Colombia. The soil is Argelia (Alfisol) with clay texture. A 225 HP tractor was used with parabolic shaped subsoiler. Distances between shanks were: S1=1.1 m, S2=1.3 m and S3=1.4 m, working at a depth of 0.60 m. The working velocity varied between V1=3.20, V2=3.7 and V3=4.15 km/h. The trial plots had an average area of 2 ha.

A hole with dimensions 3x0.80 m and depth 0.80 m was built. A cone penetrometer was used to measure the compaction every 0.20 m and the effect on the soil in the breaking area was determined. The moisture content was measured with pressure plates and rings by the Casagrande method (Gonzales, 1979). The soil samples were evaluated at 0–30 and 30–60 m layers.
The parameters assessed were: penetration resistance, moisture content, available water capacity, plastic limits and the area of breaking by the subsoiler. A 5% probability level was used to test the significance of differences between treatments. The soil samples were evaluated in the soil laboratory of the National University of Colombia.

Results and discussion

Moisture content

Table 1 shows that, in the 0–60 cm layer in the different trials, the moisture content (MC) was lower than the lower plastic limit (LPL). The subsoiling was in the friable range at the 0–60 cm layer, according to the study by Asae (1971), Bukhari (1990), Girón (1992), Gavande (1987) and Chancellor (1971).

Penetration resistance

The values decreased in general with respect to initial values (Table 2). These values were 12.41 kg/cm² in the 0–20 cm layer and decreased to 0.27 kg/cm² in 0–20 cm layer in V1-S1. This shows that subsoiling is beneficial for breaking the soil and agrees with Adeoye (1982), Asae (1971) and Chancellor (1971).

Breaking area

Table 3 shows values of the breaking area in different trials. The breaking area decreased when distance between shanks of 1.56 m² in V3-S1 to 1.17 m² in V3-S3 increased. With increased velocity, the breaking area increased from 1.47 m² in V1-S1 trial to 1.56 m² in V3-S1. The breaking
area increased with a lower spacing between shanks and higher velocity. Similar data were found by Hendrick and Gill (1973), Ide et al. (1987) and Rodriguez (2008).

**Available water capacity**

The initial value was 11.11% in the 0–30 cm layer (Table 4). The available water capacity (AWC) increased when the separation between shanks of the subsoiler decreased and with an increase in the velocity. This value ranged from 16.64% in V1-S1 to 20.13% in V3-S1 trial, in the 0–30 cm layer. Studies by Asae (1971) and Girón found increases in AWC.

**Conclusions**

The subsoiling in soil preparation reduces the compaction of the soils.
High velocity tillage and lower spacing between shanks increases the breaking area and available water capacity.

The moisture content in soil should be lower than the lower plastic limit for good performance of the subsoiler.

Résumé

AFIN D’ÉVALUER les effets du sous-solage sur les propriétés physiques du sol, une étude a été réalisée sur le site de la Providencia Sugar Mill S.A. en Colombia. Un sous-soleur parabolique tracté par un tracteur Steiger de 225 HP a été utilisé à différentes vitesses (3.0 et 4.2 km/h) et espacements (1.1 et 1.4 m) entre étançons. Le sol étudié était un Alfisol à texture argileuse de la série Argélia. Les propriétés du sol, c’est-à-dire la capacité en eau disponible, la surface de cassure, la teneur en eau et la limite inférieure de plasticité ont été mesurées jusqu’à une profondeur de 80 cm. La teneur en eau moyenne au moment du test (13%) était inférieure à la limite inférieure de plasticité (18%) dans la couche 0–30cm. La diminution de l’espacement et l’augmentation de la vitesse ont entraîné des augmentations de la surface de cassure de 1.4 m² à 1.6 m² et de la teneur en eau disponible de 16.4% à 20.13%. En conclusion, le sous-solage en diminuant l’écartement et en augmentant la vitesse, augmente la surface de cassure, la teneur en eau disponible du sol et diminue la compaction d’un Alfisol.
EFECTOS DEL SUBSOLADO SOBRE LAS PROPIEDADES FÍSICAS DE UN SUELO ALFISOL EN COLOMBIA

Resumen

SE REALIZÓ un estudio para evaluar los efectos del subsolado sobre las propiedades físicas del suelo en el ingenio Providencia S.A. en Colombia. Se utilizó un tractor Steiger de 225 HP y un subsolador parabólico, a distintas velocidades (3.0–4.2 km/h) y diversos espacios entre brazos (1.1 a 1.4 m). El suelo bajo estudio fue un Alfisol de la serie Argelia con textura arcillosa. Las propiedades del suelo, tales como capacidad de retención de agua, área de ruptura, contenido de humedad y límite mínimo de plasticidad se midieron a una profundidad de 80 cm. El contenido de humedad promedio en el suelo al momento de la evaluación (13.0%) estaba debajo de los límites mínimos de plasticidad (18.10%) en la capa de 0–30 cm. Cuando se redujo el espacio entre los brazos del subsolador y se aumentó la velocidad, se incrementó el área de ruptura de 1.4 m² a 1.6 m² y el contenido de agua disponible se incrementó de 16.64% a 20.13%. En conclusión, el subsolado incrementó el área de ruptura y el contenido de agua cuando se dejó un espacio entre los brazos del implemento de 1.1 m y se trabajó a una velocidad de 4.2 km/h, y se redujo la compactación de un suelo Alfisol.
A NEW FORMULATED SILICON FERTILISER
FOR BETTER SUGARCANE PRODUCTION

By

KEYWORDS: Silicon Fertiliser, Boiler Ash, Furnace Slag, Humic Substance, Sugarcane Productivity.

Abstract

SILICON (Si) is an important beneficial element for sugarcane and is absorbed by sugarcane, more than any other mineral nutrient. Si is known to promote sugarcane yield, enhance resistance to biotic and abiotic stresses, improve leaf and stalk erectness, and increase P availability. A new Si fertiliser namely SiPlusHS was formulated from sugar mill boiler ash, furnace slag, rock phosphate, zeolite, oxalic acid and humic substance. It formed granules of 3–5 mm in diameter and contained 8–10% soluble Si, 10–12% soluble phosphate and 3–5% humic substance. The effectiveness of this fertiliser was tested under field conditions on irrigated and non-irrigated sugarcane areas, covering areas of 1 and 2 ha, respectively. The fertiliser was applied at the rate of 0, 250 and 500 kg/ha. Results showed that application of 250 kg/ha SiPlusHS could increase cane yield from 2 to 52% and sugar yield by as much as 15–58%. There were no significant differences between applications of 250 kg/ha and 500 kg/ha SiPlusHS. In some areas, SiPlusHS could significantly decrease stem borer attacks. Recently, this new silicon fertiliser has been tested on about 1000 ha in various regions in Indonesia.

Introduction

Sugarcane is an important cash crop in Indonesia and is grown over about 440 000 hectares to produce 2.65 million tonnes of sugar. The average sugar productivity in Indonesia is about 6.17 t/ha, and is the lowest among the sugarcane growing countries of the world. The average of sugar productivity is much lower than its potential yield as, in some areas, sugar productivity could reach 11.0 t/ha (Toharisman, 2009a). Unbalanced and inappropriate fertiliser use seems to be one of the factors responsible for low sugar productivity in Indonesia. Sugarcane fertilisation is still focussed on the use of nitrogen (N), phosphorus (P), and potassium (K).

Sugarcane is capable of rapidly depleting soil nutrients, particularly Si. The aerial parts of an adequately fertilised 12 months old sugarcane crop have been reported to absorb 500–700 kg/ha of Si, compared with 100–300 kg/ha of N, 40–80 kg/ha of P, and 100–300 kg/ha of K (Anderson, 1991). It is thus clear that for the long term and sustainable use of sugarcane lands, the removal of such large quantities of Si has to be balanced by adequate inputs of Si in the form of silicon fertilisers. The removal of Si could be even more important under intensive sugarcane cultivated areas in Indonesia. Mulyadi et al. (2005) reported that the main sugarcane areas in Java are deficient in Si. Matichenkov and Calvert (2002) reported that Si deficiency in sugarcane would not only cause a reduction in sugar yield but would also reduce disease and pest resistance and reduce the tolerance to biotic and abiotic stresses.

Boiler ash and furnace slag can be a source of Si to sugarcane soils in Indonesia but, in view of its low Si availability, a high rate of 1–3 t/ha would be required. In this context, the Indonesian Sugar Research Institute developed a new Si fertiliser namely SiPlusHS, using boiler ash and...
furnace slag supplemented with rock phosphate and humic substances. The object of this study was to evaluate the effects of SiPlusHS on sugarcane yields in different climatic zones in Indonesia.

Materials and methods

Silicate fertiliser formulation

SiPlusHS was prepared by mixing boiler ash (20%), furnace slag (15%), zeolite (10%), rock phosphate (52%), humic substances (2%) and oxalic acid (1%). The addition of oxalic acid enhances the solubility of Si. The mixture was left overnight and was granulated to produce granules of 3–5 mm in diameter. The granulated formulation contained 22–25% of SiO₂, 14–17% of P₂O₅ and 2% of humic substance.

Fertiliser application

Field experiments were conducted to evaluate the effect of SiPlusHS in the rainfed upland areas at Bungamayang Sugar Factory (SF), Lampung, and Tersana Baru SF, West Java as well as in irrigated areas at Tjukir SF, East Java. At Bungamayang SF, SiPlusHS was applied at three rates (1, 250 and 500 kg/ha) in combination with urea, TSP, KCl and dolomite (Table 1). Each treatment was replicated three times in a randomised complete block design. Each plot consisted of 10 cane rows, 50 m long and spaced at 1.3 m.

At Tersana Baru and Tjukir SF, silicate fertiliser was applied at two rates (0 and 250 kg/ha) and each plot size was 2 ha. At planting, all the Si, 30% of urea, and 100% of TSP were applied in the furrows and the remaining 70% of urea and 100% of MOP were applied 2 months after sowing of cane setts. Sugarcane variety PS 864 was planted at Bungamayang SF, whereas varieties PS 851 and PA 190 were planted at Tersana Baru SF and Tjukir SF, respectively. The growth, yield and quality parameters were measured at appropriate stages of growth of sugarcane using standard procedures.

Results and discussions

As shown in Table 2, the application of SiPlusHS fertiliser increased cane and sugar yields at Bungamayang SF. The highest sugar yield (5.60 t/ha) was obtained at 500 kg/ha of SiPlusHS, compared to the control treatment where no SiPlusHS was applied. There was no significant difference in sugar yields between treatments II and III.

The data also suggest that SiPlusHS could reduce phosphate fertiliser (treatment III), from 350 to 250 kg/ha of TSP. Indeed Mulyadi et al. (2005) reported that Si promotes the transformation of slightly soluble phosphates into plant-available phosphates. The increase in sugar yield with the addition of SiPlusHS was associated with a rise of sugar content (rendement) and cane yield. The average sugar yield at Bungamayang SF in 2007/2008 growing season was about 4.8 t/ha.

Field experiments at Tjukir and Tersana Baru SF also showed similar results to the experiment at Bungamayang SF (Table 3). The application of 250 kg/ha of SiPlusHS at Tjukir SF increased sugar yield by 58.1%, whereas at Tersana Baru the increase was about 15.6%. The effect of Si on irrigated land on sugar yield was higher than that in the upland area. Soil moisture seems to play an important role in Si solubility (McKeague and Cline, 1963).

Si fertiliser could also increase resistance of sugarcane to shoot and stem borers, as indicated in Table 4. In the control plots, shoot and stem borers attacked about 1.17% and 0.81% of sugarcane, respectively. The addition of Si could dramatically reduce shoot borer between 10–76% and stem borer between 48–79%. The presence of Si crystals in shoot and stem tissues of plants acts as a defence against feeding by insects having a rather fragile mandible. High levels of Si in tissues of sugarcane plant would confer a higher level of resistance to infections by pests as reported by Elawad et al. (1985). Toharisman et al. (2009b) also reported that the application of SiPlusHS at Jatitujuh, Karangsuwung and Subang SF areas could reduce shoot and stem borers by 75%.

At this time, the new Si fertiliser has been widely used in almost 1000 ha of sugarcane areas in Indonesia, including East Java, Central Java, West Java, Lampung and South Sumatera Provinces.

UNE NOUVELLE FORMULATION D’ENGRAIS A BASE DE SILICIUM POUR UNE MEILLEURE PRODUCTION DE CANNE A SUCRE

Par
ARIS TOHARISMAN, MUHAMAD MULYADI et ABDUL RASJID
Indonesian Sugar Research Institute
atoharis@yahoo.com

MOTS-CLES: Engrais à base de Silicium, Cendre de Chaudière, Scorie de Four, Substance humique, Productivité de la Canne à Sucre.

Résumé
LE SILICIUM (Si), un élément important pour la canne à sucre, est absorbé en quantités plus importantes que pour les autres éléments. Si améliore les rendements de la canne, augmente sa résistance aux stress biotiques et abiotiques, améliore la rigidité de sa tige et de ses feuilles et accroît la disponibilité en phosphore.

SiPlusHS a été formulé à partir de cendres provenant des chaudières de sucrerie, de scories de four, de phosphate de calcium naturel, de zéolite, d’acide oxalique et de substance humique. Cette formulation est constituée de granules de 3 à 5 mm de diamètre et contient 8 à 10% de Si soluble, 10 à 12% de phosphate soluble et 3 à 5% de substance humique. L’efficacité de cet engrais a été testée sur des cultures de canne à sucre en conditions irriguées et pluviales et sur des surfaces respectives de 1 et 2 ha. L’engrais fut épandu aux doses de 0, 250 et 500 kg/ha. Les résultats ont montré qu’une application de 250 kg/ha de SiPlusHS pouvait accroître les rendements canne de 2 à 52% et augmenter le tonnage de sucre /ha de 15 à 58%. Il n’y pas eu de différence significative entre les applications de 250 et 500 kg/ha de SiPlusHS. Dans certaines zones, SiPlusHS a pu diminuer significativement les attaques de borer de la tige. Récemment, cette nouvelle formulation a été testée sur environ 1000 ha dans différentes régions d’Indonésie.
CANE AND SUGAR PRODUCTION OF THE VARIETY ECU-01 WITH N, P, K, S AND MICRONUTRIENT APPLICATION IN PLANT CANE

By

M.E. SALAZAR and M.A. SANCHEZ
msalazar@cincae.org

KEYWORDS: Sugarcane Fertilisation, Micronutrient Applications, ECU-01 Variety.

Abstract

In 2007, the Sugar Cane Research Centre of Ecuador (CINCAE) released their first variety, ECU-01, which has recorded good production throughout locations and ratoons. ECU-01 was grown commercially on 4000 ha in 2009. There is a need to study nutrient management of this variety by determining the effect of N, P, K, S and a mixture of micronutrients (Zn, Cu, Fe, Mn and B) to assess cane and sugar production. The experiment was established in Fluventic Haplustept, Vertic Ustropepts and Typic Haplustert soil types, which represent 59, 45 and 12% of the sugarcane area of Valdez, ECUDOS and San Carlos mills, respectively. Results showed that the highest cane yield (132 TCH) was produced at Valdez Mill, followed by ECUDOS Mill (108 TCH) and San Carlos Mill (84 TCH). The ECU-01 variety exhibited a significant response to 141 kg/ha N with an increase of 15, 40 and 30% tonne of cane/ha (TCH) and 21, 57 and 37% tonne of sugar/ha (TSH) compared to the control treatment (zero fertiliser) in ECUDOS, San Carlos and Valdez mills, respectively. On the other hand, in ECUDOS and Valdez mills, the dosage of 30 kg/ha of P\textsubscript{2}O\textsubscript{5} recorded the greatest production with 120–140 TCH and 15–17 TSH. The rate of 100 kg/ha of K\textsubscript{2}O increased TCH and TSH by 20% in ECUDOS mill and by 8% in San Carlos mill. In Valdez mill, K affected only the sugar concentration. There was no response to S application on TCH and TSH. Only in Valdez Mill, the addition of the micronutrient mixture produced an increase of 2.1 TSH and 11.0 TCH compared with the treatment without micronutrients. Our results have demonstrated that N is the most limiting nutrient in plant cane in all three locations. However, new data will be collected and analysed in first and second ratoon to determine fertilisation strategies for ECU-01 in the ratoon crops.

Introduction

As a result of 10 years of selection, the Sugarcane Research Center of Ecuador (CINCAE) released its first Ecuadorian variety, ECU-01, in July 2007. Sugarcane mills planted at least 600 ha of ECU-01 in 2008 (CINCAE, 2008) and established increase seed plots. In 2009, an increase to approximately 4000 ha was observed. Field trials of ECU-01 documented better response to fertilisation than variety Ragnar in a wide range of soil types and texture (CINCAE, 2004; CINCAE, 2005).

Cane production ranged between 90 to 110 tonnes of cane/ha (TCH), and 7.5 to 10.7 tonnes of sugar/ha (TSH) on plant cane using 80 N, 60 P\textsubscript{2}O\textsubscript{5} and 80 kg/ha of K\textsubscript{2}O. Whereas two ratoons recorded yields of 60 to 140 TCH and 6.0 to 12.5 TSH using 120 N, 100 P\textsubscript{2}O\textsubscript{5}; and 140 kg/ha of K\textsubscript{2}O, under traditional fertilisation rates used by sugarcane mills (CINCAE, 2008).

Studies on fertilisation with N, P and K have shown that nutrient recommendations depend on soil type, sugarcane variety and the number of ratoons (Quintero, 1995). Commercial production of variety Ragnar has been managed with applications of 120 and 150 kg N/ha in plant cane and
first ratoon, respectively (CINCAE, 2004). Preliminary observations with variety ECU-01 in trials at Valdez and San Carlos mills showed acceptable cane yields with low levels of N (40 and 80 kg/ha in plant cane and first ratoon, respectively) (CINCAE, 2007a). However, the sites did not represent soil types commonly used for sugarcane cultivation.

Soil maps drawn by three Ecuadorean sugarcane mills allowed us to choose representative zones to establish an experiment to study the effects of N, P (as P$_2$O$_5$), K (as K$_2$O), S and a micronutrient mixture on cane and sugar production in plant cane of variety ECU-01. This experiment would also allow the calculation of a statistical function which may identify the relationship between soil nutrients and sugar production in Ecuador.

Materials and methods

The experiment was planted at 3 locations: 1) on a Fluventic Haplustept (Valdez mill), 2) Vertic Ustropept (ECUDOS mill) and 3) Typic Haplustert (San Carlos mill) soil, representing 59%, 46% and 12% of the total sugarcane cultivation area. The treatment set up is shown in Table 1.

*This treatment is used to complete the high levels of K$_2$O and S in the analysis of K and S effect; also, to compare the level with the microelement mixture.

Applications of P, K, S and the micronutrient mixture were performed at the base of the row before planting the cane stools. All plots received 35 kg N/ha at sowing to adjust concentrations with the P sources (DAP). The remaining N was applied after 45 and 90 days. Micronutrients were combined in a mixture of 10, 10, 10, and 5 kg/ha of Zn, Mn, B and Cu, respectively. A randomised complete-block design with three replications was used for the experiment at each location; each experimental unit was formed by 6 rows, 10 m long, with 1.5 m between rows. Analysis of variance and linear or quadratic regressions for the rates of the nutrients were calculated with the INFOSTAT program (INFOSTAT, 2009).

Soil samples were taken at 30 cm depth before planting and fertilisation, and immediately after harvest. Soil P concentration, assimilate cations (K$^+$, Ca$^{++}$, Mg$^{++}$) and micronutrients (Zn, Mn,
Fe, Cu) was determined by a modified Olsen extraction. Leaf samples were taken at three and six months after sowing to determine N, P, K, Ca, and Mg concentrations using a mixture of sulfuric acid with selenium. Micronutrients (Zn, Mn, Cu and Fe) were determined by nitric and perchloric acid digestions. A nitric-perchloric acid and chloridric acid method was used for extracting sulfur. Boron was extracted by diluted sulfuric acid (CINCAE, 2007a).

The soil at the three locations was slightly acid (pH: 6.3–6.7), and Mn was between 10 and 20 ppm. Organic matter (OM) was < 1% in ECUDOS mill, while in San Carlos and Valdez mills OM was between 1.64 and 2.23%. The ECU DOS mill location had the lowest Ca (11–18 meq/100 g soil), Mg (4–13 meq/100 g soil) and Cu (4–8 ppm), but had high Zn and Fe content (3.8–6.3 ppm and 57–65 ppm, respectively). The San Carlos location had lower B concentration (1.0–1.3 ppm) than ECUDOS and Valdez mills (2.1–2.7 ppm). Soil P (10–12 ppm), K (0.09–0.18 meq/100) and S (11–16 ppm) concentrations were similar at the three sites.

Results and discussion

Soil response to the application of P2O5, K2O and S fertiliser

A relationship between the fertiliser applied and the soil mineral content was significant in the ECUDOS trial but not at the other locations (Figure 1). However, changes in P availability were found when P2O5 was applied to the soil. A similar trend was observed with applications of K2O and S fertilisers.

![Fig. 1. Relationship between P2O5, K2O and S application and soil contents of P (ppm), K (meq/100 g soil) and S (ppm) evaluated in three locations, 2008.](image-url)
Application of $P_2O_5$ and $S$ increased soil mineral content by 0.085 and 0.041 ppm, respectively in ECUDOS. Therefore, a dosage of 11.8 kg/ha of $P_2O_5$ and 24.4 kg/ha of $S$ increased soil mineral content one ppm each. However, in a previous study in a Vertic Tropaquept soil (sandy loam) from ECUDOS with variety Ragnar a dosage of 30 kg/ha of $P_2O_5$ led to 1 ppm of $P$ increase (Salazar et al., 2008).

Increasing $K$ into the soil solution was small in ECUDOS and San Carlos mills; however, a linear effect was shown for meq of $K/100$ g in the soil with a significant correlation ($R^2=0.70$). Similar effect was observed for $S$ in ECUDOS Mill (Figure 1).

This small response of the soil to applications of these nutrients might have been due to the type of colloidal material present in the soil; probably, there was loss of $K$ because it has less bonding strength to the cation exchange sites than Ca and Mg, or in the case of $P$ maybe there is a fixation of fertiliser phosphate by soil due to precipitation of phosphate compounds such as calcium phosphate (McLaren and Cameron, 1996).

**Cane and sugar production response to the application of nitrogen (N)**

At the three locations, applications of 141 kg/ha of $N$ recorded the highest sugar yields (TSH) (Figure 2). At this rate, in San Carlos and ECUDOS mills, TCH was low (89 and 101 TCH) whereas sugar production was high (11 and 13 TSH, respectively), due to higher sugar concentrations (12.1 and 12.9% pol, in that order). At the Valdez Mill location, yields of 20 TSH were obtained from the highest tonnage of cane (154 TCH) (Figure 2). However, another study (CINCAE, 2007b) showed that ECU-01 can have good yields with only 40 kg/ha of $N$ applied. Nevertheless, that study was conducted in soils with high organic matter (SOM) concentration (2.7%); whereas, in the present study, SOM was only 0.7 to 0.9%. Some studies carried out by Quintero (1995) and Cassman et al. (2002) determined that sugarcane $N$ needs depended on soil type, number of ratoons, and variety; with SOM concentration a key factor affecting the response to $N$ application.
Cane and sugar production response to the application of \( \text{P}_2\text{O}_5 \), \( \text{K}_2\text{O} \) and S

The effect of P, K and S application was different at each location. In ECUDOS and Valdez mills, the application of 30 kg/ha of \( \text{P}_2\text{O}_5 \) increased 7 and 4 TCH and 1.5 and 0.8 TSH compared to 0 application of P (control). A study carried out by CINCAE on Inceptisol and Vertisol soils (sandy loam) showed that 30 or 60 kg/ha of \( \text{P}_2\text{O}_5 \) were enough to achieve maximum sugar yields (Salazar et al., 2008). There was no effect of P in San Carlos mill.

Application of 100 kg/ha of \( \text{K}_2\text{O} \) increased from 100 TCH in the 0 K control treatment to 120 TCH in ECUDOS mill; while, in San Carlos mill, the increase was from 81 to 88 TCH. At this rate, the boost of TSH was higher (20%) in ECUDOS mill than in San Carlos mill (8%). Only, in Valdez mill, the use of \( \text{K}_2\text{O} \) affected sugar concentration from 11.6% pol in the 0 K control treatment to 12.7 and 13.5% pol in the rates of 50 and 100 kg/ha, respectively.

Application of S did not lead to significant differences in cane production at the three locations. This could be due to the high S concentration in the soil (ECUDOS mill, 26–47.3 ppm, San Carlos and Valdez Mills, 11–20 ppm). However, at Valdez Mill, 30 kg/ha of S increased sugar content from 12.3% pol in the 0 S treatment to 13.5% pol. Similar results were observed by Quintero (1995) on Vertisol, Mollisol and Inceptisol soils where no response to S application was found, but a slight increase of sugar content in the juice was observed.

The micronutrient mixture increased yields by 15 TCH and 2 TSH at the Valdez Mill. However, leaf tissue concentrations and plant removal of Zn, Cu, Fe, Mn and B from the soil were not different in the micronutrient mixture treatment compared to zero application of microelement mixture (data not shown), suggesting that there was sufficient micronutrient concentration for sugarcane growth in the soil solution. Therefore, ranges for soil concentration were established at the three locations for Cu (3.0–8.0 ppm), B (1.0–2.8ppm), Fe (14–65 ppm), Mn (4.0–13.0 ppm) and Zn (0.3–0.5).

Conclusions

Cane and sugar production of variety ECU-01 depended on the soil type and crop management in the three locations. The highest cane yields were recorded with the application of 141, 30, 100 and 30 kg/ha of N, \( \text{P}_2\text{O}_5 \), \( \text{K}_2\text{O} \) and S respectively. Nitrogen applications increased both cane and sugar production at the three sites, while responses of tonnage of cane, sugar and % pol to P, K and S were different at each site.

This study has confirmed that N was the most limiting nutrient for plant cane at three mills in Ecuador. Data will be analysed for the first and second ratoon to determine cane yield response to nutrient application in the ratoon crops.

The rate of 100 kg/ha of \( \text{K}_2\text{O} \) increased TCH and TSH by 20% in ECUDOS mill and by 8% in San Carlos mill. In Valdez mill, K affected only the sugar concentration. There was no response to S application on TCH and TSH.

MOTS-CLES: Fertilisation de la Canne à Sucre, Applications d'Oligoéléments, Variété ECU-01.

Résumé

En 2007, Le centre de recherche sur la Canne à Sucre en Equateur (CINCAE) a libéré sa première variété ECU-01, qui s’est révélée très productive dans toutes les zones et repousses. La variété ECU-01 a été cultivée commercialement sur 4000 ha en 2009. La nutrition de cette variété devait être déterminée en étudiant les effets de N, P, K, S et d’un mélange d’oligoéléments (Zn, Cu, Fe, Mn et B) sur la production de ECU-01. L’expérimentation fut réalisée sur les types de sol Fluventic Haplustept, Vertic Ustropepts et Typic Haplustert, qui représentent respectivement 59, 45 et 12% de la surface en canne à sucre des usines de Valdes, Ecuadors et San Carlos. Les résultats montrèrent que les rendements les plus élevés (132 TCH) ont été produits à l’usine de Valdes, suivis par l’usine d’Ecuadors (108 TCH) et San Carlos (84 TCH). La variété ECU-01 a montré une réponse significative à 141 kg/ha d’N avec des accroissements respectifs de 15, 40 et 30% en tonne de canne /ha (TCH) et de 21, 57 et 37% de tonne de sucre /ha (TSH) comparé au témoin (aucun engrais) sur les plantations des usines d’Ecuadors, Calos et Valdes. D’autre part, sur les plantations des usines d’Ecuadors et Valdes, la dose de 30 kg/ha de P₂O₅ a produit le plus avec 120–140 TCH et 1–17 TSH. La dose de 100 kg/ha de K a augmenté TCH et TSH de 20% sur l’usine d’Ecuadors et de 8% à San...
Carlos. A l’usine de Valdes, K a affecté uniquement la teneur en sucre. Il n’y a pas de réponse en TCH et TSH aux applications de S. A l’usine de Valdes, seulement, l’addition d’un mélange d’oligoéléments a produit une augmentation de 2.1 TSH et 11.0 TCH comparé au témoin sans oligoéléments. Ces résultats ont montré que N est l’élément minéral le plus limitant en canne plantée sur tous les sites. Cependant, d’autres données seront collectées et analysées en première et seconde repousse afin de déterminer les stratégies de fertilisation d’ECU-01 en repousses.

PRODUCCIÓN DE CAÑA Y AZÚCAR DE LA VARIEDAD ECU-01 CON LA APLICACIÓN DE N, P, K, S Y UNA MEZCLA DE MICROELEMENTOS EN CAÑA PLANTA

Por

M. E. SALAZAR y M. A. SANCHEZ
msalazar@cincae.org;

PALABRAS CLAVES: Fertilización de Caña de Azúcar, Aplicación de Micronutrientes, Variedad ECU-01.

Resumen

EN EL 2007, el Centro de Investigación de Caña de Azúcar del Ecuador (CINCAE) liberó la primera variedad llamada ECU-01, la cual ha presentado buena producción en diferentes localidades y socas. Desde su lanzamiento el área comercial se han incrementado hasta llegar a 4000 ha\(^{-1}\) en el 2009. Hay una necesidad para estudiar el manejo de nutrientes determinando el efecto de N, P (as P\(_2\)O\(_5\)), K (as K\(_2\)O), S y una mezcla de micronutrientes (Zn, Cu, Fe, Mn y B) en la producción de caña y azúcar. El experimento fue establecido en suelos del tipo Fluventic Haplustept, Vertic Ustrovepts y Typic Haplustert, los cuales representan 59, 45 y 12% del total del área cañera de los ingenios Valdez, ECUDOS y San Carlos, respectivamente. El mayor tonelaje de caña por hectárea (TCH) presentó el ingenio Valdez (132 TCH), seguido por ECUDOS (108 TCH) y San Carlos con 84 TCH. La variedad ECU-01 presentó una respuesta significativa a la aplicación de 141 kg/ha de N con un incremento de 15, 40 y 30% de TCH y 21, 57 y 37 % de TAH comparado con el tratamiento control (cero fertilización) en ECUDOS, San Carlos y Valdez, respectivamente. En los ingenios ECUDOS y Valdez, la dosis de 30 kg/ha de P\(_2\)O\(_5\) tuvo la más alta producción de caña y azúcar (120–140 TCH y 15–17 TAH). La aplicación de 100 kg/ha de K\(_2\)O incremento 20% del tonelaje de cana y azúcar en el ingenio ECUDOS y 8 % en el Ingenio San Carlos. En Valdez el K afectó solamente a la concentración de azúcar. No hubo respuesta a la aplicación de S en el tonelaje de caña y azúcar por hectárea. Únicamente, en el ingenio Valdez, el uso de la mezcla de microelementos produjo un amento de 2.1 TAH y 11 TCH comparado con el tratamiento sin la aplicación de microelementos. Los resultados demostraron que el N es el nutriente más limitante en la producción de caña planta en las tres localidades. Sin embargo, nueva información será colectada y analizada en la primera y segunda soca para determinar estrategias de fertilización en las socas.
AGRONOMIC MANAGEMENT OF INTERCROPPING IN SUGARCANE AND ITS ECONOMIC IMPLICATIONS

By

R.B. KHANDAGAVE

Karnataka Sugar Institute, Belgaum-590 014, Karnataka, India
drrbk123@yahoo.com

KEYWORDS: Number of Millable Canes, Stalk Population, Cane Yield, Intercrops, Economics.

Abstract

GROWTH rate of sugarcane during the initial stages is rather slow with the low canopy coverage, and it is possible to exploit the potential of the cropping system by adjusting crop geometry and utilisation of inter-crops. Therefore, a field experiment was conducted to assess the economic benefits of intercrops with different planting configurations in sugarcane. Dual-row (60–120–60 cm) and single-row (90 cm) methods of planting were deployed as main plots and intercrops comprising sunnhemp, maize, cowpea (green manure), soybean (inter-crop), peanut, potato and french bean were treated as subplots. Planting systems did not alter significantly the number of millable canes (NMC) or cane yield. However, sunnhemp, cowpea grown and soybean recorded higher NMC (92 080, 89 830 and 87 830/ha respectively) than cane alone (85 910/ha), while maize intercropping gave 68 880 NMC and the sugarcane yields were 111.1, 109.1, 106.9 and 70.8 t/ha, respectively for the 4 inter-crops and 107.4 t/ha for cane alone. Higher cane yields are attributed to the optimum shoot population which later on converted higher NMC and cane weight due to in situ incorporation of green manure and its further decomposition in building organic matter content of soil. Detrimental effect on NMC and cane yield was noticed due to intercropping of maize in sugarcane. Compared to the normal single row configuration, dual-row planting with the same cost of cultivation improved B:C ratio from 2.17 to 2:76, due to higher cane yields. As a result of the grain yield of soybean (1.5 t/ha) and lower cost of production in soybean inter-cropping, this strategy recorded the highest net return (Rs68, 336/ha) with B:C ratio of 3.21 compared to other inter-crops. Conversely, although maize and potato yields were higher, these treatments produced lower net income and B: C ratios due to the reduction in cane yield. Post-cane harvest data indicate that inter-cropping has a positive effect on the chemical properties of soil.

Introduction

Sugarcane is one of the more important commercial crops of India and is cultivated with row spacing of 75–90 cm. The growth rate of sugarcane during its initial stages (90–100 days) is rather slow, with the leaf canopy providing sufficient uncovered area for growing of other crops. Inter-cropping in sugarcane with short duration crops is agronomically advantageous and could provide additional revenue (Ayyer, 1963). Further, alterations in planting methods that do not compromise cane yields will provide additional opportunity to exploit the potential of the crop by growing intercrops.

Sugarcane, as a long duration crop, gives income about a year after planting, and there is a dire need to diversify the cropping system to provide shorter-term income by introducing other crops, either as sequential or inter-cropping strategies, especially for farmers having smaller land holdings. Jamuna et al. (2007) indicated that the cane yields were not affected by dual-row planting,
and cane yields were higher with the dual-row system than for wider rows. Devaraj and Shanmugsundaram (1987) observed that cane yield was improved by adopting dual rows of 40–80 cm spacing compared with conventional 80 cm row planting and that the dual-row system allowed growth of intercrops. Therefore, a study was initiated to study the effect of growth and yield attributes, yield of cane and sugar, economics and chemical properties of soil when sugarcane was grown in different row configurations and with or without intercrops.

Material and methods

A field experiment was conducted at the K.J. Somaiya’s Karnataka Institute of Applied Agricultural Research, in India during 1997–98. The vertisol soil had available nitrogen, phosphorus and potassium values of 285, 7.3 and 0.419 kg/ha, mg/kg and cmol/kg respectively and a soil pH of 8.1. The field investigation consisted of two planting methods viz., ridge and furrow planting (90 cm) and dual rows of 60–120–60 cm as main treatments and seven intercrops viz., sunnhemp (green manure), maize, cowpea (green manure), soybean, peanut, potato, french bean and sole sugarcane as subplots in a split plot design replicated four times. An early maturing CoC671 cultivar of sugarcane was used for experimentation. Intercrops viz. sunnhemp, maize, cowpea, soybean, peanut, potato and french bean were sown simultaneously at the time of sugarcane planting. Sunnhemp, cowpea, soybean, peanut, maize and potato were sown in a row proportion of 1:1 in single rows of cane. In the case of dual rows, sunnhemp, cowpea, soybean, peanut and french bean were sown in row proportion of 2:3, while maize and potato were sown in a row proportion of 2:2. Sunnhemp and cowpea were incorporated at 45 days after planting of sugarcane. Yields of different intercrops were recorded at harvest. Sugarcane growth, yield attributes, yield and juice quality parameters were recorded. Soil was analysed as per the standard procedure after harvesting of sugarcane. Gross income, cultivation cost, net return and B:C ratios were calculated for the different systems. Statistical analysis was done by using Duncan Multiple range Test (DMRT) and data were presented in a homogeneous group.

Results and discussion

Experimental results reveal that different planting configurations had no significant impact (p=0.05) on growth and cane yield attributes viz., single cane weight, girth of cane, length of internodes, number of internodes, plant height, NMC, and cane and sugar yields. Of the intercropping systems, sunnhemp, cowpea, soybean, potato, french bean and sugarcane alone treatments gave superior single stalk weight compared to the maize intercropping system (Table 1).

Numbers in each column followed by the same letter are not significantly different at p = 0.05
DAP = Days after planting
However, cane girth, number of internodes and plant height were unaltered in the different inter-cropping systems. However, sunnhemp and cowpea significantly enhanced cane height and number of internodes over other systems.

Similarly the NMC and cane yield were significantly higher (p=0.05) in sunnhemp, cowpea and soybean inter-cropping systems and the cane alone control compared to maize inter-cropping (Table 1). Higher cane yield was obtained due to the optimum shoot population which eventually helped in producing NMC values and in situ incorporation of green manure. Incorporation of green manure and its further decomposition in building organic matter of soil and uptake of nutrients which led to higher cane weight, accomplished with better cane girth and internodal length as observed in the findings of Kathiresan and Ayyamperumal (1996).

Yield of the sugar alone system was similar to that of cane yield in the different intercropping systems, with the exception of the cane-maize system (Table 1). Intercropping of peanut, potato and french bean in sugarcane had no impact on growth parameters and yield of sugarcane, and these results are consistent with the opinion expressed by Srinivas (1996). Sugarcane yield reduction from 107.39 t/ha in the cane alone system to 70.82 t/ha with maize inter-cropping indicates that maize adversely affected the various growth and yield parameters of sugarcane.

**Economics**

The net returns were higher in dual row planting (Rs58,534/ha) compared to single rows (Rs56,628/ha) due to increased yields for the same cost of production (Table 2). Similarly, the B:C ratio in dual rows was higher by 0.29 compared to the single-row method of planting. Among the intercropping systems, sugarcane plus soybean gave highest gross income (Rs99,248/ha), net income (Rs68,336/ha) and B:C ratio (3.21) compared to other all treatments.

The highest net income in sugarcane inter-cropped with soybean was mainly due to higher cane yield (111.09 t/ha) coupled with soybean grain yield of soybean 1.5 t/ha. Similar findings were reported by Biradar *et al.* (1995). Although maize yield were higher compared to other inter-crops, the net income was the least due to drastic reduction in cane yields.

**Chemical properties of soil**

There was no significant difference observed in organic carbon content across planting methods or intercropping systems or their interactions (Table 3). Similar results were observed by Pandit and Sinha (1981) due to incorporation of cowpea. Available nitrogen, phosphorus, potash of the soil after harvest of sugarcane recorded non-significant results with respect to planting methods.
Among the inter-cropping systems, sunnhemp, cowpea, soybean, peanut, potato and french bean showed significantly \((p = 0.05)\) higher residual available nitrogen, phosphorus and potassium compared to maize inter-cropping system. Shankaraiah and Nagaraju (1997) showed improved available nitrogen, phosphorus and potassium due to intercropping and incorporation of legumes.

**Table 3**—Chemical properties of soil as influenced by planting methods and intercropping in sugarcane.

Numbers in each column followed by the same letter are not significantly different at \(p=0.05\)

**Conclusions**

The dual-row system was preferred over single rows due to its higher cane and sugar yield. Additional advantages of obtaining inter-cropping yield can also be exploited. Growing of soybean in sugarcane inter-cropping and incorporation of *in situ* green manures like sunnhemp and cowpea recorded higher yield and also improved the soil chemical properties to help to sustain yield of sugarcane. Maize and potato are not ideal inter-crops in sugarcane.

MOTS-CLES: Nombre de Tiges Usinables, Population de Tiges, Cultures Intercalaires, Economie.

Résumé
LA CROISSANCE de la canne à sucre pendant les premiers stades est plutôt lente avec un faible taux de couverture, et il est alors possible d’exploiter le potentiel du système cultural en adaptant sa géométrie pour des cultures intercalaires. Aussi, un essai en champ a-t-il été conduit pour évaluer les bénéfices économiques de cultures intercalaires avec diverses configurations de plantation en culture de canne à sucre. Des modes de plantation, rang jumelé (60–120–60 cm) et rang simple (90 cm) ont constitué les traitements principaux et des cultures intercalaires comme la crotalaire, le maïs, le niébé (engrais vert), le soja (culture intercalaire), l’arachide, la pomme de terre et le haricot vert, ont constitué les traitements secondaires. Alors que la crotalaire, le niébé et le soja ont produit plus de tiges usinables (NMC) (respectivement 92 080, 89 830 et 87 830/ha) que la canne seule (85 910/ha), la culture intercalaire de maïs a donné 68 880 NMC. Les rendements de canne ont été de 111.1, 109.1, 106.9 et 70.8 t/ha, respectivement pour les 4 cultures intercalaires, et de 107.4 t/ha pour la canne seule. Les rendements les plus élevés en canne sont attribués aux plus forts taux de tallage, donnant plus tard le plus de tiges usinables et les plus forts rendements en raison de l’incorporation de l’engrais vert et à sa décomposition ultérieure en matière organique organique du sol. Comparé au système en simple rang, le rang jumelé, avec le même coût de production a augmenté le ratio B:C (Bénéfice/Coût) de 2.17 à 2.76, en raison des plus forts rendements canne. En raison de la récolte en grain du soja (1.5 t/ha) et du plus bas coût de production de cette culture intercalaire, en comparaison avec les autres cultures intercalaires, cette itinéraire a enregistré le plus fort revenu (Rs68,336/ha) avec un B:C ratio de 3.21. Inversement, quoique le maïs et les pommes de terre aient eu des rendements plus élevés, ces cultures ont produit les revenus nets et ratios B:C les plus faibles en raison de la réduction des rendements canne. Les données après récolte indiquent que les cultures intercalaires ont eu un effet positif sur les propriétés chimiques du sol.
EL MANEJO AGRONOMICO DEL CULTIVO INTERCALADO EN CANA DE AZUCAR Y SUS IMPLICACIONES ECONOMICAS

PALABRAS CLAVE: Numero de Tallos Molederos, Población de Tallos, Rendimiento de Cana, Cultivos Intercalados, Economía.

Resumen

EL INDICE de crecimiento de la caña de azúcar durante los primeros estadios es más bien lento, con poca cobertura del follaje y se puede aprovechar el potencial del sistema intercalado, ajustando la geometría del cultivo y la utilización de cultivos intercalados. De este modo, se condujo un experimento para evaluar los beneficios económicos de los cultivos intercalados con diversas configuraciones de siembra en caña de azúcar. Se establecieron parcelas grandes con método de siembra de surco doble (60–120–60 cm) y de surco simple (0.9 cm), y como parcela pequeña cultivos intercalados como cáñamo, maíz, caupí (abono verde), soya (cultivo intercalado), maní, papa y judías. Los sistemas de siembra no alteraron significativamente el número de tallos molederos (NMC) o el rendimiento de caña. Sin embargo, al cultivar cáñamo, caupí y soya se registró un aumento en NMC (92 080, 89 830 y 87 830/ha respectivamente) que al sembrar caña sola (85 910/ha), mientras el maíz intercalado produjo 68 880 NMC y los rendimientos de caña con los cuatro cultivos intercalados fueron 111.1, 109.1, 106.9 y 70.8 ton/ha, respectivamente y 107.4 t/ha para caña de azúcar sola. Los rendimientos más altos de caña se atribuyen a la población óptima de tallos que consecutivamente se convirtieron en un NMC más alto y mayor peso de caña, esto debido a la incorporación in situ de abono verde y su posterior descomposición en materia orgánica del suelo. Se observó un efecto detrimental en NMC y rendimiento de caña al intercalar maíz con caña de azúcar. Al comparar el surco simple con la siembra en surco doble, este último mejoró la relación B:C de 2.17 a 2.76, por los mayores rendimientos de caña. Como resultado del rendimiento en granos de soya (1.5 ton/ha) y su menor costo de producción, la estrategia de intercalar soya reportó el mayor retorno (Rs68, 336/ha) con una relación B:C de 3.2, comparada con otros cultivos intercalados. Por otro lado, a pesar de que el maíz y la papa produjeron mayores rendimientos, estos tratamientos reportaron menor ingreso neto y menor relación B:C, debido a la reducción en rendimiento de caña. Los datos post cosecha indican que el cultivo intercalado tiene un efecto positivo sobre las propiedades químicas del suelo.
BREEDING RESISTANT SUGARCANE FOR MANAGING THE STEM BORER
DIATRAEA SACCHARALIS: PROGRESS AND PROSPECTS FOR LOUISIANA

KEYWORDS: Insect Resistance, Breeding Strategy.

Abstract

THE STEM borer, \textit{Diatraea saccharalis} (F.), is an important insect pest of sugarcane in Louisiana. Growing resistant varieties is a component of the Integrated Pest Management Program as practised in Louisiana for managing this insect; however, the release of stem borer resistant varieties has been intermittent. In 1986, researchers at the USDA, Agricultural Research Service (ARS) and LSU Agricultural Center – the two breeding programs in Louisiana – initiated an effort to increase stem borer resistance without encumbering the Louisiana sugarcane variety program (LSVP) with an additional selection trait. In this approach, clones with high levels of stem borer resistance are developed at the USDA, ARS in Houma via a recurrent selection program for borer resistance (RSB) and these resistant clones are used as parents in crossing. Advancement data from the Louisiana State University AgCenter’s sugarcane breeding program were evaluated to determine our success in incorporating the new resistant germplasm into the progeny advancing through this program. A statistical test using the cumulative logit model showed non-significant difference (P > 0.05) in advancement rates of clones between the RSB and non-RSB families. However, because of fewer seedlings derived from crosses with at least one RSB parent, very few clones were given permanent variety assignments from the RSB population; only seven in the 1991 to 2002 series. A simulation study was done to determine the effect of increasing selection rates on recovery of RSB clones at the different stages of the breeding program. The cumulative logit model showed that increasing selection rates from Stage I to Stage II will result in a significant increase in the number of RSB clones assigned a variety designation. From this study we propose that the number of resistant crosses be increased and the selection rate of RSB crosses at Stage I be doubled to 13%.

Introduction

Host plant resistance is an important component in the integrated pest management (IPM) of insect pests. Host plant resistance costs the grower little and is compatible with other IPM control tactics (Adkisson and Dyck, 1980). However, unlike diseases that are generally managed with resistant varieties, insect pests of sugarcane are frequently managed by biological control or with insecticides. As a result, sugarcane breeding efforts for insect resistance lag behind efforts devoted to breeding for disease resistance. In fact, susceptibility to diseases has been one of the major incentives for setting up plant breeding programs (Walker, 1987).
Breeding for insect resistance in sugarcane, as with many traits, is likely to be hindered by the complexity of the sugarcane genome and the absence of simply inherited traits (Hogarth, 1987). Several studies have been conducted on the quantitative inheritance of disease resistance in sugarcane (Hogarth et al., 1983 and Hogarth et al., 1993), but few have been conducted for insect resistance. Viator and Henderson (1971) found sugarcane borer resistance to be quantitative in nature, but provided no measures of genetic variation, heritability, or potential gain from selection. White et al. (2001) reported that narrow-sense heritabilities for sugarcane borer damage ratings and for percent damaged internodes were high and comparable in magnitude, $h^2=0.73$ and $h^2=0.76$ respectively, while Milligan et al. (2003) reported broad-sense heritabilities for percent damaged internodes ranging from $H=0.29$ to $H=0.62$. Viator and Henderson (1971), White et al. (2001), and Kimbeng et al. (2006) all presented evidence of a strong additive component to the inheritance of sugarcane borer resistance.

Findings from genetic studies indicate that sugarcane borer resistance could be reliably increased by diligently selecting and crossing among the most resistant parents and then focusing selection on progeny within these crosses. Methods required for the screening and evaluation for resistance have also been established. White (1993) and White et al. (1996) discussed screening and evaluation procedures as well as a breeding strategy for increasing levels of sugarcane borer resistance in sugarcane parental populations.

A final, yet critical aspect of breeding for sugarcane borer resistance is genotypic correlations. When selecting rigorously for a few characters, it is important to understand the correlated responses on other important traits. Milligan et al. (2003) reported low to moderate broad-sense genetic correlations among five stem borer damage measures (bored internodes, pupation success, moth production, and damage rating) and the yield components (sucrose yield, cane yield, sucrose content, stalk number) from an unselected population. All but one of the damage measures were negatively correlated with sugar yields. Fibre was not determined in this study. White et al. (2006) found that varieties with pith were significantly less damaged than those without pith. The authors found that varieties with pith also have higher stalk fibre; a trait that can contribute to lower sugar yields and decreased throughput in raw sugar factories.

The above discussion addresses critical aspects for developing a breeding strategy for sugarcane borer resistance. After initiating a recurrent selection program to identify clones with borer resistance and utilising these as parents, we have become increasingly concerned as to the quality of these clones as parents as no progeny from this material have been released to the grower. Here we summarise 22 years of advancement records from the Louisiana University AgCenter’s Sugarcane Variety Program where at least one parent of the bi-parental cross involved a sugarcane borer resistant parent. Drawing from these records, our object was to propose a strategy for increasing the number of selections derived from sugarcane borer resistance parents. Doing so increases the chances of a selection being made or a clone being recycled as a parent for crossing that possesses insect resistance and desirable agronomic characters.

**Materials and methods**

**Recurrent Selection Borer Resistance Program (RSB)**

A recurrent selection program for developing sugarcane borer resistant parental clones was started at the USDA, Agricultural Research Service (ARS) in 1986. A summary of procedures and results from the first 10 years of recurrent selection can be found in White et al. (1996). These authors report 19 parental clones identified as resistant to the sugarcane borer. By 2008, the number of resistant parental clones had increased to 76; of these, 16 (22%) are currently being used as parents in the Louisiana sugarcane variety program (LSVP). This program is a joint effort between the USDA, ARS, the Louisiana State University AgCenter and the American Sugar Cane League of the U.S.A., Inc.
Incorporation of sugarcane borer resistance from the RSB program

The 1989–1990 crossing campaign was our first opportunity to breed with clones derived from the RSB program. The seedlings derived from these crosses were selected and advanced following the procedures used by the USDA, ARS and the LSU AgCenter’s breeding programs. Bischoff and Gravois (2004) provide a detailed summary of the LSVP. Advancement data from the Louisiana State University AgCenter’s sugarcane breeding program were evaluated to determine our success in incorporating the new resistant germplasm into the progeny advancing through this program.

Statistical methods

Data derived from the advancements of clones for the 1991 to 2002 crossing series were classified into RSB and non-RSB derived crosses. A cross was designated RSB if it had at least one parent (male or female) from the RSB program. The total number of clones advanced from seedlings that survived winter (Stage I) was calculated for the Stage II (first-clonal stage), Stage III (second-clonal stage), Stage IV (variety yield trials/seed-increase stage) and Stage V (assignment of varieties planted in replicated variety trials).

The multinomial cumulative logit model of the logistic procedure of SAS (SAS Institute, 2007) was used to test if the advancement rates were different between the RSB and non-RSB derived populations. The analysis assumed that the stages of selection were ordered with proportional odds (Agresti, 2007). The cumulative logit model is also known as ordered or ordinal logit model (Allison, 2003). The statistical model used was,

\[
\text{Logit } [P(Y \leq j)] = \alpha_j + \beta x, \quad j = 1, 2, \ldots, J-1, \quad \text{Equation 1}
\]

where \(\alpha_j\) is the intercept of the \(j\)th stage and \(\beta\) is the coefficient describing the effect of \(x\) (RSB or non-RSB population) on the advancement rates. The number of seedlings advanced was used to determine the cumulative proportions that were in turn used to compute the odds ratios (Appendix 1). The model in Equation 1 and the SAS code in Appendix 1 were also used for simulating the effect of increasing the selection rate for the RSB population on the chance of increasing genotypes that reached the assignment stage.

Results

The number of seedlings derived from RSB resistant parents was less than 5% of the seedlings derived from non-RSB parents (Table 1). The trends in Table 1 were consistent across all the crossing series from 1991 to 2002 (data not shown). When the number of seedlings advanced was expressed as a percent of seedlings that survived the winter and plotted against stage of the breeding program (Figure 1), the % advancement of clones from RSB and non-RSB parents was similar across stages.

A statistical test using cumulative logit model (Appendix 1) showed non-significant difference (\(P > 0.05\)) in advancement rates between RSB and non-RSB families (Table 2). However, because of fewer seedlings derived from RSB crosses, very few genotypes were advanced to replicated variety trials from the RSB population; only seven from the 1991 to 2002 series. We therefore explored potential strategies for increasing advancements of genotypes from the RSB population.

A simulation study was done using the cumulative logit model (Equation 1) and the SAS code (Appendix 1) to determine the effect of increasing selection rates at the different stages of the breeding program. The sensitivity analysis was performed to determine the stages that would produce the greatest effect on the numbers of genotypes reaching Stage V.

Sensitivity analysis enables the variation in the output of a model to be apportioned to the different sources of the variability that occurs in the input variables (Helton et al., 2006).

The sensitivity analysis was evaluated by increasing the selection rates between the stages and identifying the stage that would result in the greatest and most significant increase in advancement rates. The selection rate from Stage I to Stage II was the most influential resulting in a significant increase in advancement of RSB derived genotypes (Figure 2).

Increasing advancement rates for Stage IV for the overall breeding population, for example, resulted in marginal increases of advancements to Stage V for genotypes from the RSB population alone. Table 2 and Figure 2 show the impact of increasing selection rates from Stage I to Stage II.

There was a marginal increase in the odds of advancing an RSB genotype compared to the odds of advancing non-RSB from Stage II to Stage III, Stage III to Stage IV, and Stage IV to Stage V.

The simulation study showed that increasing selection rates to 8% (Stage I to Stage II) resulted in a 20% (P < 0.01) increase in the odds of advancement to Stage V for genotypes from the RSB population.

A 13% selection rate (double the current selection rate) would almost double the odds of advancement to Stage V and the odds of advancement were tripled at 20% selection rate. The sensitivity analysis also showed that, by adjusting the selection rate at Stage I, the number of genotypes advanced at other stages would significantly (P < 0.05) increase (data not shown).

Discussion

*Diatraea saccharalis* resistance in sugarcane is a highly heritable trait and, by careful selection of resistant parents, the population mean of progeny evaluated in the LSVP can be shifted to higher levels of resistance. For this strategy to be successful, however, a sufficient representation of these crosses must be planted in initial seedling populations and an appropriate selection rate must be practised. The selection stage that is targeted for increasing the selection rates from the crosses derived from parents resistant to the sugarcane borer is important.

Results from the sensitivity analysis showed that increasing selection rates from Stage I to Stage II would result in a significant increase in the number of genotypes assigned. Increasing the selection rates of the intermediate stages (without increasing selection rates at the seedling stage, Stage I) only resulted in marginal and non-significant increases in assignment rates. Furthermore,
increasing the advancement rates from Stage IV alone did not result in significant increases in the number of genotypes advanced to Stage V from RSB families.

The greatest variability in most trait values is in the non-selected seedling population (Stage I). Therefore, increasing selection rates at the seedling stage is expected to capture greater variability and would potentially include those transgressive segregants combining positive agronomic traits with sugarcane borer resistance.

After the seedling stage, further evaluation and selection eliminates those genotypes with poor agronomic performance from a larger pool of sugarcane borer resistant genotypes. Increasing selection rates at later stages did not significantly increase assignment rates because variability is less and many genotypes that combine both high yield potential and borer resistance would have been lost at the seedling selection. Selection in seedlings is inefficient (Cox and Stringer, 1998; Hogarth and Berding, 2006); therefore, higher selection rates from seedlings would provide more genotypes to screen for agronomic traits in later stages.

Consistent strategies are required for increasing the number of borer resistant genotypes that are assigned as well as incorporating borer resistance into the breeding germplasm. Two approaches can be used; selecting more seedlings in Stage I from the RSB parents or increasing the number of crosses made using RSB parents.

The first approach should ensure a greater number of advancements to Stage V, but selecting more seedlings from a smaller population may limit diversity and require the breeder to advance unacceptable clones. Alternatively, increasing the number of crosses made using RSB parentage would result in a larger population to select from and a corresponding increase of RSB genotypes advanced to Stage V at current selection rates. Increasing the number of crosses made with RSB parents would increase the gene pool to select for recombinants that are likely to combine both borer resistance and agronomic traits. The other advantage of increasing RSB parents is that genetic studies can also be carried out to investigate the ability to combine borer resistance and agronomic traits.

Such studies, if positive, would enhance the overall quality of the commercial gene pool, by incorporating an additional desirable trait. Increasing the number of RSB parents does not come without a price. Disadvantages of this approach would be the extra cost (land, labour, equipment, etc.) involved if crosses with these parents add to the number of seedlings evaluated in the program. Alternatively, the number of crosses could remain stable, with a higher percentage of RSB seedlings being planted in the general population. However, this would be done at the expense of traditional commercial breeding crosses.

While the primary objective of commercial breeding is to develop varieties, an additional objective is to improve the gene pool. When selecting from the RSB crosses, in addition to selecting for commercial varieties, we also identify genotypes that may have a small weakness, rendering it not acceptable for commercial production, yet still possessing most of the desired agronomic traits together with borer resistance. Selection of both sets of genotypes will have the positive effect of enhancing the commercial germplasm.

This approach will require evaluating genotype selections targeted to be parental material only, alongside those selected for their commercial potential. The benefits of the RSB program to the commercial program would be enhanced through this approach and thus improve the overall economics of the Louisiana industry.

MOTS CLÉS: Résistance aux Ravageurs, Stratégie d’Amélioration Variétale.

Résumé

Le foreur de la tige, *Diatraea saccharalis* (F.), est un ravageur important de la canne à sucre en Louisiane. L’exploitation des variétés résistantes est un élément du programme de lutte intégrée pratiquée en Louisiane pour la gestion de ce ravageur. Toutefois, l’homologation des variétés résistante a été intermittente. En 1986, les chercheurs de l’USDA, l’Agricultural Research Service (ARS) et le LSU Agricultural Center – les deux programmes d’amélioration variétale en Louisiane – ont initié un effort commun pour augmenter la résistance au foreur de la tige sans encombrer le programme variétal de la Louisiane avec un caractère additionnel en sélection. Selon cette approche, les clones avec des niveaux élevés de résistance au foreur de la tige (PSR) développés par l’USDA, ARS à Houma par l’intermédiaire d’un programme de sélection récurrente ont été utilisés comme parents dans le programme d’hybridation. Des données de sélection du programme d’amélioration de la canne à sucre du Louisiana State University AgCenter’s ont été évaluées pour déterminer les chances de succès en incorporant le nouveau germoplasme résistant aux progénitures sélectionnées à travers ce programme. Un test statistique, utilisant le modèle cumulatif de logit, a démontré une différence non-significative (P > 0.05) dans les taux d’avancement des clones entre les familles PSR et non-PSR. Cependant, en raison d’un nombre réduit de descendants découlant des croisements avec au moins un parent PSR, très peu de clones de la population du PSR ont été alloués des assignations permanentes au statut de variété; seulement sept dans la série de 1991 à 2002. Une étude de simulation a été entreprise pour déterminer l’effet d’augmenter les taux de
sélection sur le recouvrement des clones du PSR à différents stades du programme d’amélioration variétale. Le modèle cumulatif de logit a démontré qu’une augmentation du taux de sélection du Stade I au Stade II pourrait engendrer une augmentation significative des clones du PSR assignés à la désignation de variété. À partir de cette étude, il a été proposé que le nombre de croisements résistants soit augmenté et le taux de sélection des croisements du PSR au Stade I soit doublé à 13%.

MEJORAMIENTO GENÉTICO DE CAÑA DE AZÚCAR PARA EL MANEJO DEL BARREBADOR DEL TALLO DIATRAEA SACCHARALIS: PROGRESOS Y PROYECCIONES PARA LUISIANA

PALABRAS CLAVE: Resistencia A Insectos, Estrategias de Fitomejoramiento.

Resumen

EL BARRENADOR del tallo, Diatraea saccharalis (F.), es un insecto plaga de la caña de azúcar importante en Luisiana. El uso de variedades resistentes es un componente del Programa de Manejo Integrado de Plagas practicado en Luisiana para este insecto; sin embargo, la entrega de variedades resistentes no ha sido constante. En 1986, investigadores del USDA, Servicio de Investigación Agrícola (ARS) y el Centro de Agricultura de LSU – los dos programas de Luisiana – iniciaron esfuerzos para incrementar la resistencia al barrenador del tallo como un carácter adicional, sin modificar el programa de variedades de Luisiana (LSVP). Con esta proyección, clones con niveles altos de resistencia al barrenador del tallo están siendo desarrollados en USDA, ARS en Houma mediante selección recurrente para resistencia al barrenador (RSB) y estos clones resistentes son usados como parentales para los cruzamientos. Datos avanzados del programa de mejoramiento de caña de Louisiana State University AgCenter’s fueron analizados para determinar el éxito de la incorporación del nuevo germoplasma resistente dentro de las progenies avanzadas de todo el programa de selección. El test estadístico usando el modelo logit no mostró diferencias significativas (P > 0.05) entre las evaluaciones de clones avanzados entre familias de las RSB y no-RSB. Sin embargo, debido a que pocas plántulas obtenidas de cruzas con al menos una RSB estuvo presente, muy pocos clones fueron asignados códigos varietales desde las poblaciones de RSB, con únicamente siete de las series 1991 a 2002. Se realizó un estudio de simulación para determinar el efecto del incremento de la tasa de selección para la recuperación de clones de las RSB de diferentes estados del programa de cruas. El modelo logit mostró que incrementando la tasa de selección de Estado I a Estado II incrementará significativamente los clones con códigos varietales provenientes del RSB. Con este estudio proponemos que el número de cruzas resistentes se incrementen y la tasa de selección de las cruzas de RSB en Estado I sea duplicado a 13%.
GGE BIPLOT ANALYSIS USED TO EVALUATE CANE YIELD OF SUGARCANE 
(Saccharum spp.) CULTIVARS ACROSS SITES AND CROP CYCLES

KEYWORDS: GGE Biplot, Genotype-by-Environment (GE) Interaction, Principal Components (PC).

Abstract

MULTI-ENVIRONMENT yield trials (MET) are a series of experiments in which a set of genotypes (G) are evaluated in multiple environments (E). The presence of genotype × environment (GE) interaction observed in MET complicates the selection and/or recommendation of cultivars. Several statistical methodologies have been developed for the analysis of GE interaction. GGE biplot of the SREG model is a recent methodology based on a graph formed with the first two principal components (PC1 and PC2). GGE represents the G main effect plus the GE interaction effects. Thus, GGE biplot provides an adequate graphical tool for visual analysis of MET data. The objectives of this research were to evaluate sugarcane cultivar responses across environments in order to identify high-yielding cultivars with broad or specific adaptation by applying the GGE biplot analysis. Fourteen sugarcane cultivars were evaluated at three sites in the plant, first and second ratoon crops across the middle land zone of the sugarcane growing area of Guatemala, forming nine environments (three sites × three crop cycles). Data on tonnes of cane per hectare (TCH) were recorded. The first two principal components (PC1 and PC2) were highly significant (P<0.01) and explained 73% of the GGE. GGE biplot analysis allowed selection of the sugarcane cultivar PR75-2002 as second on average cane yield and had broad adaptation (stable). Two groups of environments (mega-environments) were defined; the first had seven environments and the second one had two environments. The winning cultivars with the highest cane yield were CG00-120 and CG00-092 for each of those groups (specific adaptation), respectively. The G main effect and GE interaction can be exploited by selection of highest cane yield cultivars for each mega-environment.

Introduction

Multi-environment yield trials (MET) are a series of experiments in which a set of genotypes (G) is evaluated in multiple environments (E), usually considered as being the environments as a combination of sites and years. These trials are important because the presence of genotype × environment interaction (GE) complicates the selection and/or recommendation of cultivars. In order to illustrate this fact, if there is no GE interaction, a single test environment would be sufficient for cultivar testing. Thus, the understanding of the GE interaction observed in MET is very useful in breeding programs in order to identify high-yielding cultivars with broad or specific adaptation (Annicchiarico, 1997; Gauch, 1992; Smith et al., 2001; Yan and Hunt, 2002).

The GE interaction with special interest for breeding programs is that which creates a change in ranking of the cultivars from one environment to another (crossover-interaction). This means that the best cultivar in one particular environment might not be the best in another environment. Several statistical methodologies have been developed for the analysis of GE
interaction (Kang, 2002). Sites (i.e., environment) Regression (SREG) is a linear (additive component) – bilinear (multiplicative component) model which in the bilinear terms absorbs the main effects of G plus the GE interaction (Crossa and Cornelius, 2002; Crossa et al., 2002). Breeders have used the recent methodology GGE biplot from the SREG model to analyse MET data (Burgueño et al., 2009; Yan et al., 2000).

The GGE represents the main effect of genotype plus the genotype by environment interaction (G+GE). GGE biplot of SREG model is based on principal components analysis, and a graph is formed with the scores of the genotypes and the environments of the first principal component (PC1 scores) against their respective scores for the second principal component (PC2 scores). GGE biplot displays the two sources of variation G and GE, and provides an adequate graphical tool for cultivar evaluation (yield and stability), mega-environment analysis (such as ‘which-won-where’ pattern), test-environment evaluation (discriminating among genotypes and representativeness of the mega-environments) and others (Burgueño et al., 2009; Crossa et al., 2002; Ding et al., 2009; Yan et al., 2007).

The present MET study was conducted with 14 sugarcane (Saccharum spp.) cultivars, which were evaluated across nine environments (combinations of three sites and three crop cycles) in Guatemala. The objectives of this research were to evaluate sugarcane cultivar responses across environments in order to identify high-yielding cultivars with broad or specific adaptation by applying the GGE biplot analysis.

Materials and methods

This study was part of a series of multi-environment yield trials of the Sugarcane Breeding and Development Program of CENGICAÑA where 14 sugarcane cultivars were evaluated in nine environments of the sugarcane production area in the middle land zone of Guatemala (Table 2). The nine environments refer to sites × crop cycle (crop-year) combinations. There were three sites: San Bonifacio (280 masl), Margaritas (116 masl) and Tululá (220 masl); and three crop cycles: plant cane (harvest season, 2004–05), first (2005–06) and second ratoon crops (2006–07). Of the 14 cultivars tested, 12 are from CENGICAÑA Guatemala (CG and CGSP) and two testers, one cultivar from Canal Point (CP) and one from Puerto Rico (PR). The field experimental design used for each trial was a Randomised Complete Block with four replications and with experimental units of 75 m². Data on tonnes of cane per hectare (TCH) were recorded.

The GGE biplot from the SREG model was constructed according to the manual and SAS program available at the web page of CIMMYT in Biometrics and Statistic Unit (BSU) or at http://www.cimmyt.org/english/wps/biometrics/. Following Burgueño et al. (2009), Yan et al. (2001) and Yan and Hunt (2002), a brief description and interpretation of the GGE biplot is presented below:

**PC1 (as x-axis) and PC2 (as y-axis)**

The biplot GGE is formed with PC1 scores on the abscissa and PC2 scores on the ordinate for each cultivar and each environment. PC1 represents the average yield of cultivars if the genotype PC1 scores are highly correlated with the genotype main effects; while PC2 is related to the GE interaction.

**Cultivar and environment vectors**

The cultivars and environments can be visualised as vectors from the origin of axis (0, 0) to the end points determined by their scores. The environment scores have the same orientation to the right (same sign). Cultivars that are far from the origin have positive responses with environments that are far from the origin but in the same direction. Ideal cultivars: large PC1 scores (higher mean yield) and PC2 scores near to zero (more stable). Ideal test environments: Large PC1 scores (high capacity to discriminate among cultivars) and PC2 scores near to zero (‘more representative of an average environment’).
External polygon and biplot sectors

External polygon is formed with the cultivars located farthest from the biplot origin (0, 0). These cultivars are part of the corners of the polygon (cultivar markers) and are connected with straight lines. Cultivar markers are the ones with the highest response and they could be the best or the worst in some or all of the environments. Perpendicular segmented lines to each side of the polygon are drawn to divide the biplot in different sectors of cultivars and environments. The cultivar located in the corner of one sector is the winner cultivar with the highest yield in the environment or environments of this sector.

Results and discussion

The combined analysis of variance (Table 1) showed differences statistically significant (P<0.01) among environments, genotypes and GE interaction. Based on the relative contribution of sum of squares, the environmental effect had the highest contribution, followed by genotypes and lastly the GE interaction. The first two principal components (PC1 and PC2) were highly significant (P<0.01) and explained 73% of the GGE (PC1=61% and PC2= 12%). Cultivar PC1 scores and the cultivar yield means (Table 2) were highly correlated (r=0.99), which was expected, since PC1 explained most of the GGE variation (61%). These results are consistent with those of Yan et al. (2001), who indicated that a poor correlation occurs when GGE is explained by PC1 and PC2 in similar contribution (complex GE interaction).

According to the GGE biplot (Figure 1), no cultivar was identified which had high average yield (large PC1 score) and stability in performance (PC2 score near to zero). However the cultivar 13 (PR75-2002) was close to ideal because it had the second highest average cane yield and a PC2 score near to zero (–0.1).

Regarding test environments, S2Y1 (Margartias-plant cane) and S2Y2 (Margartias-first ratoon) environments were identified as near to an ideal environment since they presented large PC1 score and PC2 score near to zero (Table 2 and Figure 1). This indicates that this site (Margartias) would be useful for selecting cultivars which have a high correlation across all environments.

The S3Y1, S3Y2, S3Y3 and S1Y1 environments were near to the biplot origin (0, 0) with short vectors; thus these environments were not useful for cultivar discrimination. The S2Y3 environment had the largest vector with large PC1 and PC2 scores of 5.9 and –3.6 respectively (Table 2).

This environment adequately discriminated the cultivar 5 (CG00-120) with large vector in the same direction. The same interpretation can be given to environments S1Y2 and S1Y3 with the cultivar 8 (CG00-092). These results suggest that the GE interaction in sugarcane increases as the years (crop cycles) also increase.

† Environments are a combination of sites and crop cycles. Sites: S1=San Bonifacio, S2=Margaritas and S3=Tululá. Crop cycles: Y1=Year 1 (Plant Cane), Y2=Year 2 (First Ratoon) and Y3=Year 3 (Second Ratoon).
‡ PCA1 and PCA2 = First and second principal component respectively.

The site 2 (Margaritas) is characterised by adequate soil and weather conditions compared with site 3 (Tululá); therefore, the environments that include the site 2 had high capacity to discriminate among cultivars, as indicated by data in Table 2 and represented graphically in the GGE biplot (Figure 1).
The ‘which-won-where’ patterns were determined by the polygon (Figure 1). The corners of the polygon were formed with five cultivars from which cultivars 5 (CG00-120) and 8 (CG00-092) showed the best response in TCH. The poorest cultivars were 4 (CG00-120), 7 (CG00-092) and 2 (CG00-032) because they are in an opposite direction to the environments. According to the GGE biplot, two sectors (mega-environments) were defined; the first sector made up by seven environments (Margaritas and Tululá with their three crops cycle plus San Bonifacio with its first ratoon); and the second one by two environments (San Bonifacio with its second and third crops). The winning cultivars with the highest yield were 5 (CG00-120) and 8 (CG00-092) for each of the sectors, respectively.

Conclusions

GGE biplot analysis allowed selection of the sugarcane cultivar PR75-2002 as second for average cane yield and with broad adaptation (stable).

Two groups of environments (mega-environments) were defined; the first made up of seven environments and the second one of two environments. The winning cultivars with the highest cane yield were CG00-120 and CG00-092 for each of the groups (specific adaptation) respectively.

The G main effect and GE interaction can be exploited by selection of highest cane yield cultivars for each mega-environment.

MOTS CLÉS: Biplot GGE, Interaction Génotype × Environnement (GE), Composantes Principales (PC).

Résumé

Les essais multi-locaux (MET) constituent une série d’essais variétaux où une group de génotypes (G) sont évalués dans divers environnements (E). La présence de l’interaction génotype x environnement (GE) complique la sélection et/ou les recommandations des cultivars. Plusieurs méthodes statistiques ont été développées pour l’analyse de l’interaction GE. Le biplot GGE découlant du modèle SREG est une méthodologie récente basée sur la courbe formée des deux composantes principales (PC1 et PC2). Le GGE représente l’effet principal G plus les effets de l’interaction GE. Donc, le biplot GGE fourni un outil graphique adéquat pour une analyse visuelle des données MET. Les objectifs de cette recherche étaient d’évaluer le comportement des cultivars à travers les environnements afin d’identifier les cultivars à forts rendements à adaptations larges ou spécifiques en utilisant l’analyse biplot GGE. Quatorze cultivars de canne à sucre ont été évaluées sur trois sites en vierge, première et deuxième repousses dans la zone centrale où la canne est cultivée au Guatemala, totalisant neuf environnements (trois sites x trois récoltes). Le rendement en tonne de canne à l’hectare (TCH) étaient recueilli. Les deux premières composantes principales (PC1 et PC2) étaient hautement significatives (P<0.01) et contribuaient à hauteur de 73% de l’interaction GGE. L’analyse biplot GGE a permis la sélection du cultivar PR75-2002 en deuxième position pour le rendement en canne avec une large aire d’adaptation large (stable). Deux groupes d’environnements (mega-environnements) étaient définis; le premier avec sept environnements et le second avec deux environnements. Les cultivars gagnants avec les rendements les plus élevés étaient CG00-120 et CG00-092 pour chacun de ces deux groupes (adaptation large et spécifique) respectivement. L’effet principal G et l’interaction GE peuvent être exploités en sélectionnant les cultivars avec les plus forts rendements pour chacun de ces mega-environnements.
ANALISIS GGA BIPLOT UTILIZADO PARA EVALUAR EL RENDIMIENTO DE CAÑA EN CULTIVARES DE CAÑA DE AZÚCAR (Saccharum spp.) A TRAVES DE SITIOS Y CICLOS DEL CULTIVO

PALABRAS CLAVE: GGA biplot, Interacción Genotipo × Ambiente (GA), Componentes Principales (CP).

Resumen

ENSAYOS de rendimiento en multi-ambientes (EMA) son una serie de experimentos en los cuales un grupo de genotipos (G) son evaluados en diferentes ambientes (A). La presencia de la interacción genotipo × ambiente (GA) observada en EMA complica la selección y / o recomendación de cultivares. Varias metodologías estadísticas se han desarrollado para el análisis de la interacción GA. GGA biplot del modelo de Regresión de sitios (SREG) es una metodología reciente basada en una gráfica formada con los dos primeros componentes principales (CP1 y CP2). GGA representa el efecto principal de G más los efectos de la interacción GA. Así, GGA biplot proporciona una herramienta gráfica adecuada para el análisis visual de datos provenientes de los EMAs. Los objetivos de esta investigación fueron evaluar las respuestas de cultivares de caña de azúcar a través de ambientes con el fin de identificar cultivares de alto rendimiento con una adaptación amplia y específica mediante la aplicación análisis GGA biplot. Catórice cultivares de caña de azúcar fueron evaluados en tres sitios en plantía, primera y segunda soca a través de la zona media de producción de caña de azúcar de Guatemala, formando nueve ambientes (tres localidades × tres ciclos del cultivo). Se registraron datos de toneladas de caña por hectárea (TCH). Los dos primeros componentes principales (CP1 y CP2) fueron altamente significativos (P <0.01) y explicaron el 73 % del GGA. GGA biplot permitió seleccionar el cultivar PR75-2002 como segundo lugar en el promedio en rendimiento de caña con adaptación amplia (estable). Dos grupos de ambiente (mega-ambientes) fueron definidos, el primero compuesto por siete ambientes y el segundo por dos ambientes. Los cultivares ganadores con mayor rendimiento de caña fueron: CG00-120 y CG00-092 para cada uno de los grupos, respectivamente (adaptación específica). El efecto principal G y los efectos de la interacción GA pueden ser efectivamente explotadas mediante la selección de cultivares de mayor rendimiento para cada mega-ambiente.
TOLERANCE OF SUGARCANE PARENTS TO HERBICIDES AND ITS TRANSMISSION IN PROGENY

By

Mauritius Sugar Industry Research Institute
kramdoyal@msiri.intnet.mu

KEYWORDS: Herbicide Applications, Inheritance of Herbicide Tolerance, Post-Emergence.

Abstract

SUGARCANE varieties with one or both parents in common have been observed to show a similar tolerance level to the tank-mix of diuron and Actril-DS®. This study was initiated to evaluate parent varieties frequently used in the breeding program of the Institute, for transmission of their tolerance to herbicide in crosses. Sixty parents established in pots and later transplanted in replicated field trials were evaluated for their tolerance to the test herbicide tank-mix. Crosses were made with some selected parents with known tolerance and 15 families, comprising 40 seedlings each, were subsequently evaluated for their response to the same tank-mix. Parents differed significantly in their tolerance to herbicide and were classified as: tolerant (T) 10%; slightly susceptible (SS) 34%; moderately susceptible (MS) 25%; susceptible (S) 25%; highly susceptible (HS) 7%. The phenotypic correlation between the degree of tolerance to the herbicide tank-mix evaluated in pots and in the field was moderately high, indicating that assessment of response of genotypes in pots can provide a useful indication of expression of tolerance at field level. The families also differed significantly in their tolerance to herbicide. Generally, crosses between T/SS × MS parents produced about 40% and 46% of progenies in the T/SS and MS classes, respectively. Conversely, S × HS crosses produced a very high proportion (75%) of progenies in the S/HS. The degree of susceptibility to herbicide increases with the degree of susceptibility of the parental combination. A clear-cut segregation towards either T/SS or S/HS groups was not evident that could indicate the action of a major gene. Partitioning of variance indicated a high component of additive genetic variance, high narrow-sense heritability, and the possibility of breeding for the character through a judicious choice of parent varieties.

Introduction

Chemical weed control is a commonly used practice in sustainable sugarcane production. Herbicides are tested individually, in mixed formulation or in tank-mixes to evaluate their efficacy in weed control, the cost of application and the level of phytotoxicity to the crop. More than 100 weed species consisting of broad-leaved weeds, grasses and sedges are common in sugarcane fields in Mauritius; some sixty of the most commonly found ones have been described by Mc Intyre (1991). Tank mixing of two or more herbicides to achieve a broader spectrum of control is a common practice in sugarcane production (Seeruttun, 2007).

Diuron has been widely used as a pre-emergence treatment in sugarcane; it is also tank-mixed with Actril DS® (ioxynil + 2,4-D ester) in post-emergence of weeds. Diuron, a photosynthetic II inhibitor, is a substituted urea herbicide used to control a wide variety of annual and perennial broad-leaved weeds and grasses. Actril DS® is a selective herbicide, a member of the Nitrile and Phenoxy group with ethyl hexyl ester (2,4-D) and ioxynil as active ingredients for the control of broadleaved weeds and vines in sugarcane.
Commercial sugarcane varieties have frequently been tested for their tolerance to post-emergence herbicides in Mauritius (MSIRI 1980, 1990, 1994, 1995) but information on the genetic transmission of herbicide tolerance in sugarcane has not been widely reported. Concurrently, herbicide resistance transformation technology has been widely successful in conferring herbicide tolerance in sugarcane (Autrey et al. 2001/2002; Leibbrandt and Snyman 2001; Enriquez et al., 2001; Butterfield and Ulian, 2006; Snyman et al., 2001). However, herbicide-resistant (HR) transgenic crops can present several risks through escape and proliferation of the transgenic plants as weedy volunteers, hybridisation with and transgene infiltration into related or wild species, and changes in population dynamics of unrelated species and the development of herbicide-resistant biotypes (Warwick et al., 1999; Yong Woong and Do-Soon, 2001; Warwick and Francis, 2005). Breeding for herbicide tolerance constitutes a safe avenue to guard against risks associated with transgenic technology.

Several varieties, released in Mauritius, and having one or both parents in common have been observed to show similar tolerance level to the tank-mix of diuron and Actril-DS®. This study was initiated to evaluate parent varieties, frequently used in the breeding program of the Institute with a view to study the variation for herbicide tolerance and also to obtain information on the transmission of tolerance to herbicide in crosses. It aims to assess the possibility of breeding for herbicide tolerance.

Materials and methods

A total of 60 parent varieties produced locally and imported from diverse sources that are frequently used in the MSIRI breeding program were chosen to evaluate their degree of tolerance/sensitivity to the herbicide tank-mix diuron + Actril DS® at 2.5 + 1.3 kg a.i./a.e./ha using the precision sprayer Micron AutoDos. Five (replicates) of one-eyed cuttings of each variety were planted in plastic pots of size 15 × 15 cm on 20 September 2005 at Réduit Experimental Station (rainfall 1400 mm, elevation 300 m). The five replicates of each variety were grouped together in a single row on concrete flooring in the nurseries and allowed to grow in open sunlight. About 12 weeks after potting, the herbicide tank-mix was sprayed on each plant developed from the pots on 15 December 2005. Sensitivity to the tank-mix of herbicide was visually evaluated on the individual plants two weeks after spraying (WAS) based on a five-point scale as follows: 5-tolerant (T) - no sign of leaf damage, 4-slightly susceptible (SS) – slight chlorosis, 3-moderately susceptible (MS) – moderate chlorosis, 2-susceptible (S) – severe scorching and chlorosis and 1-highly susceptible (HS) – very severe scorching and cane growth stunted.

In April 2006, the pots were transplanted at Union Park Experimental Station (rainfall 3100 mm, elevation 375 m) in 1-m rows with two pots per row spaced at 0.50 m within rows and 1.5 m between rows with two replicates in a completely randomised block design. The plants were allowed to develop freely and they were stubble-shaved seventeen months after transplanting in September 2007. The ratoon plants were sprayed with the same herbicide tank-mix at the same dosage four weeks later in October and the degree of sensitivity to the herbicide was assessed visually four weeks later in November.

A number of crosses were attempted between May and July 2007 between parents varying in herbicide sensitivity based on the evaluation made in pots earlier in 2005 and also on knowledge acquired on the reactivity of the commercial varieties that were included in the trial. Fifteen families, from the 2007 crossing season and past years that have produced enough seedlings were chosen to study the transmission of herbicide tolerance. The trial was laid down with 40 seedlings of each family grown in plastic pots (15 cm × 15 cm) in a randomised complete block design with two replicates of 20 seedlings per family. The same herbicide tank-mix was applied on each seedling at the age of 12 weeks after potting using the precision sprayer Micron AutoDos. Visual assessment of the tolerance level of each seedling progeny was done four WAS as per the rating described above.
Statistical analyses

Means and standard errors (SE) were calculated for each parent variety evaluated in pots and in the field as well as for each family evaluated in pots. Phenotypic correlation coefficient for sensitivity levels of parent varieties recorded in pots and in field was calculated. Frequency distributions for progeny within sensitivity classes were derived for each family. Partitioning of variances was performed between and within families and the estimates of the variance components were derived as per the methodology of Kearsey and Pooni (1996) for bi-parental families.

From expectation of mean squares: \( \sigma^2_W = \frac{1}{2} V_A + V_E \) and \( \sigma^2_B = \frac{1}{2} V_A \), assuming negligible dominance effects; where \( \sigma^2_W \) = expected average variance within full-sib families and \( \sigma^2_B \) = expected variance of true family means, \( V_A \) = additive genetic variance and \( V_E \) = environmental variance. Narrow-sense heritability was calculated as \( h^2 = \frac{V_A}{V_A+V_E} \).

The number of progeny per family, \( r \), was corrected for unequal number of seedlings as a result of differential mortality (Sokal and Rolf, 1981). The standard error of the estimate of narrow-sense heritability was derived from twice the square root of the variance of the intra-class correlation based on the methodology of Fisher (1954) for the estimation of standard error of repeatability.

Results and discussions

Sensitivity levels of parent varieties

The mean sensitivity levels of parent varieties and their assignment to tolerance classes observed in pots and in the field are presented in Table 1. The parent clones differed significantly in their tolerance to the herbicide tank-mix. The frequency distribution of varieties within tolerance classes measured in pots was as follows: tolerant (T) - 10%; slightly susceptible (SS) - 34%; moderately susceptible (MS) - 25%; susceptible (S) - 25%; highly susceptible (HS) - 7%. This distribution indicates a wide variation in the tolerance/sensitivity levels of the parental pool with as high as 32% of the parents with low tolerance level if S and HS classes are grouped together.

There was a fairly good correlation in the reaction of the clones when measured in pots and their relative rating measured in field \((r=0.60**, p=0.01)\) although, for many of the clones, the rating was not strictly the same.

If tolerant and slightly susceptibility clones were grouped together in the tolerant class based on the reaction observed in pots, 18 out of 27 clones (67%) would have been classified in the tolerant class in the field and the rest assigned to the MS class.

From a total of 15 clones classified as MS in pots, an equal percentage of clones 67% (10) would have had the same rating in field. The highest discrepancy between the sensitivity of the clones measured in pots and in the field was observed for the S and HS classes. When these two classes are grouped together as a susceptible group measured in pots, only 33% of clones would have an equivalent rating at field level, 44% would be rated MS and 22% rated as SS such that the MS group is inflated.

It appears that the clones in the field, which were in a ratoon crop with an already well developed rooting system showed a lower sensitivity to herbicide toxicity. None of the clones rated as T/SS in pots would have acquired S/HS rating in the field and few (3) clones with S rating in pots had an SS rating in field. The measurement of herbicide tolerance levels in pots by the precision sprayer can constitute a quick and economic means for assessing the relative sensitivity of varieties to herbicides.

Sensitivity levels of progeny

Most of the crosses used in the progeny evaluation were between parents with determined herbicide tolerance, released for commercial cultivation in Mauritius. The assignment of the sensitivity level for these clones was predominantly based from current experience of their reactivity in commercial fields as well as reactivity shown in the present evaluation.

*T-tolerant, SS-slightly susceptible, MS-moderately susceptible, S-susceptible, HS-highly susceptible
Progeny means for tolerance level, standard error (SE) and mid-parent values for the different categories of crosses measured in pots pooled over replicates are shown in Table 2. In general, irrespective of the tolerance level of the male parent, families with a tolerant or a slightly susceptible female parent had higher mean values for tolerance except cross 265/07 which showed high susceptibility to herbicide. Conversely, families with a MS or S female parent had slightly lower tolerance level (value) except for one cross, 1197/03, which displayed moderate tolerance level.

Table 2—Family mean, standard error and mid-parent value for tolerance level to herbicide mix measured in pots.

*T-tolerant, SS-slightly susceptible, MS-moderately susceptible, S-susceptible, HS-highly susceptible
Generally, crosses involving a tolerant or a slightly susceptible parent yielded a higher frequency of progenies in the T and SS classes. This was particularly prominent in the crosses 1217/03, 1287/03, 1574/06, and 258/07. Only the cross 265/07 with R 575 as the female parent produced progenies that were all susceptible or highly susceptible. Cross 1225/03, which also had R 575 as the female parent, gave progenies which were predominantly grouped in the MS and S classes. It appears that the female parent can exert a more pronounced influence on the tolerance level of its progeny suggesting the involvement of cytoplasmic inheritance. Cross 275/07 gave a wide distribution of progenies in all classes with a relatively high percentage in the tolerant class. The absolute distribution of progenies grouped in three sensitivity classes, T/SS, MS and S/HS, and the percentage of progenies that fits in each of the three classes for crosses grouped in different categories is shown in Table 4.

Table 4—Absolute number of progenies grouped within three classes, T/SS, MS and S/HS, for their reaction to herbicide mix and percentage of progenies within these classes for different categories of crosses grouped together.

* T-tolerant, SS-slightly susceptible, MS-moderately susceptible, S-susceptible, HS-highly susceptible

Crosses between T/SS × MS parents produced about 40% and 46% of progenies in the T/SS and MS classes respectively. Those between T/SS × HS produced about 30% and 22% of progenies in the T/SS and MS classes respectively. Crosses between MS × MS, S and HS parents gave about 19% and 39% of progenies grouped in T/SS and MS classes respectively and nearly 41% in the S/HS class. S × HS crosses produced a very high proportion (75%) of progenies in the S/HS classes. It is clear that the degree of susceptibility to herbicide increases with the degree of susceptibility of the parental combination. Nearly all crosses had an appreciable percentage of progeny in the moderately susceptible class. A clear-cut segregation towards either T/SS or S/HS groups was not evident that could indicate the action of some major genes. It is possible that the two herbicides in the mix might have different genetic control that masked the action of any major gene effect. Transgenic segregation for herbicide resistance (bar) has been demonstrated in sugarcane (Butterfield et al., 2002) and a cultivar transformed with the pat gene, conferring resistance to the herbicide Buster (glufosinate ammonium) was stably expressed during three rounds of vegetative propagation (Leibbrandt and Snyman, 2003).
In addition to the genetic control underlining resistance to herbicide, morphological attributes such as epicuticular wax of leaf surface may influence tolerance level in varieties.

Bi-parental progeny analysis revealed highly significant differences between families for tolerance level to the herbicide mix. Partitioning of variances showed a high proportion of additive genetic variance and high narrow-sense heritability and low standard error estimates. (Table 5).

Table 5—Variance ratios, components of variances and heritability estimates derived from bi-parental progeny analysis of 15 families for their tolerance to herbicide mix.

</table>

However, the heritability value is somewhat inflated from the fact that a number of parents were repeated in a number of crosses. A wider range of unrelated crosses was not available on account of lower fertility levels of some crosses, insufficient pollen-shedding varieties and asynchronous flowering. Nevertheless, the study does indicate that the tolerance/sensitivity level of the progenies to the herbicide mix can be predicted reasonably well on the basis of the reaction levels of their parents and breeding for herbicide tolerance is possible.

Conclusion

This study indicated a wide variation in herbicide tolerance within the parent pool considered with about one-third of the parents rated as susceptible to the herbicide tank-mix diuron + Actril-DS® when evaluation was carried out in pots. There was a moderately high correlation between the tolerance level of varieties measured in pots and in the field, although the phytotoxicity appeared to be less severe at field level. The measurement of herbicide tolerance levels in pots by the precision sprayer can constitute a quick and economic means for assessing the relative sensitivity of varieties to herbicides. Generally, crosses between T/SS × MS parents produced about 40% and 46% of progenies in the T/SS and MS classes respectively. Conversely, progeny derived from susceptible × highly susceptible (S × HS) parents produced nearly 75% of progenies in the susceptible and the highly susceptible classes grouped together. No clear-cut evidence of a major gene to herbicide mix was evident and the transmission of tolerance level to the mixture of herbicide approached an additive model indicating that tolerance/sensitivity level of the progenies to the herbicide tank-mix can be predicted reasonably well on the basis of the reaction levels of their parents.

MOTS CLÉS: Actril DS®, Diuron, Hérédité, Post-Émergence, Tolérance aux Herbicides.

Résumé

Les variétés de canne à sucre ayant un parent en commun ont souvent montré un niveau plus ou moins similaire de tolérance au mélange Diuron et Actril-DS®. Une étude a été entreprise dans le but d’évaluer la tolérance des géniteurs de la canne à sucre, utilisés fréquemment dans le programme d’hybridation du MSIRI, aux herbicides. Un total de soixante géniteurs établis en pots et ensuite transplantés au champ ont été évalués pour leur tolérance à un mélange d’herbicides. Des croisements ont été réalisés avec des parents éprouvés pour leur réaction aux herbicides et 15 familles, comprenant chacune 40 plantules, ont été par la suite évaluées pour leur réaction au mélange d’herbicides. Les parents ont démontré des différences significatives pour leur niveau de tolérance et ils ont été classifiés selon les niveaux suivants: tolérant (T) 10%; légèrement sensible (SS) 34%; modérément sensible (MS) 25%; sensible (S) 25%; hautement sensible (HS) 7%. La corrélation modérément élevée obtenue entre le niveau de tolérance des parents mesurés en pots et au champ démontre qu’une évaluation de la réponse aux herbicides des génotypes en pots peut fournir des indications assez fiables sur leur niveau de tolérance au champ. Les familles ont également démontré des différences significatives pour leur niveau de tolérance. Généralement, les croisements entre les parents T/SS x MS ont produit environ 40% et 46% de leurs descendants dans les classes T/SS et MS respectivement. À l’opposé, les croisements entre parents S x HS ont produit un pourcentage très élevé (75%) de leurs descendants dans les classes S/HS. Le niveau de sensibilité augmente avec le niveau de sensibilité des combinaisons parentales. Une distinction claire des descendants soit en classe T/SS ou S/HS n’était pas évidente ce qui pouvait présager la contribution d’un gène majeur. La décomposition de la variance génétique démontre une contribution importante de la variance additive et une héritabilité au sens strict relativement élevée et indique que la production de nouvelles générations de génotypes tolérantes aux herbicides est possible.
fueron plantados en macetas y luego trasplantados a ensayos replicados en el campo para evaluar su tolerancia a la mezcla de herbicida. Se realizaron cruzamientos con algunos parentales que presentan alguna Resistencia y 15 familias, con un total de 40 plántulas en cada cruza, las que fueron evaluadas también a la misma mezcla del tanque de herbicida. Los parentales fueron significativamente diferentes a la mezcla del herbicida, clasificándose como: tolerante (T) 10%; poco susceptible (SS) 34%; moderadamente susceptible (MS) 25%; susceptible (S) 25%; altamente susceptible (HS) 7%. La correlación fenotípica del grado de tolerancias a la mezcla herbicida evaluada en macetas y en el campo fue moderadamente alta, indicando que las pruebas en macetas podrían proveer información útil sobre la expresión a la tolerancia en el campo. Las familias también disfirieron significativamente en el campo. Generalmente cruzas entre parentales T/SS x MS produjeron alrededor de 40% y 46% de progenies T/SS y MS respectivamente. Contrariamente, los cruzamientos S x HS produjeron una alta proporción (75%) de progenies en el S/HS. El grado de susceptibilidad al herbicida se incrementa con el grado de susceptibilidad de la combinación parental. No se evidenció una clara segregación hacia grupos T/SS o S/HS que indicaría la acción de un gen mayor. Al dividir las variancias se observó un claro efecto aditivo y una alta heredabilidad en sentido estrecho y la posibilidad de realizar mejoramiento para este carácter a través de escoger las variedades para parentales.
GENETIC BASE BROADENING OF SUGARCANE (SACCHARUM SPP.) BY INTROGRESSION OF GENES THROUGH INTERGENERIC HYBRIDISATION

KEYWORDS: Erianthus, Nobilisation, Intergeneric Hybrid.

Abstract

SUGARCANE (Saccharum spp.) is one of the crops for which interspecific hybridisation has provided a major breakthrough for its improvement. However, intergeneric hybridisation has been gaining importance to broaden the genetic base and to obtain commercially useful traits and simultaneously increase the total biomass. The benefits derived from the use of wild species like S. spontaneum have been realised since the early 1900s, and the compatibility of Saccharum officinarum with Erianthus is now being explored to incorporate disease-resistance genes. This genus also has a great potential for vigour, better ratoonability and tolerance to environmental stresses. In E.I.D Parry (India) Ltd, R & D Centre, attempts were made through a conventional breeding program to introduce these traits into commercial sugarcane cultivars. The true nature of these hybrids is confirmed by morphological features like leaf orientation, leaf striping, stalk length, stalk thickness, internode length, stalk colour and bio-chemical features like sucrose, fibre content and analysis through molecular techniques. Selected intergeneric hybrids were used for backcrosses to develop commercial cultivars.

Introduction

Sugarcane breeding has come a long way from the time it was started by the Dutch in Indonesia. The importance of breeding was realised by many industries and thus sugarcane breeding was commenced in earnest with Saccharum officinarum clones collected from Papua New Guinea, Irian Jaya and the Pacific Islands. Badila and Korpi, along with striped Singapore, Malabar Red etc. (Deer, 1921) remained under commercial cultivation until the 1920s when hybrids started to overtake these S. officinarum clones. During the initial period of sugarcane breeding, the improvement of sugarcane relied on the selection of naturally occurring variants of S. officinarum obtained by expeditions to its centre of origin in New Guinea (Ramdoyal and Badaloo, 2002).

In the late 1800s and the early 1900s, interspecific hybridisation with wild species (Saccharum spontaneum L.) provided a major break-through in cane yield and sugar improvement. The Dutch used S. spontaneum clone Kassoer in their breeding program and produced POJ2878, the Java wonder cane. This was followed by the Indians who used a S. spontaneum from Coimbatore and released a nobilised cane, Co205. It was not until after the Second World War that serious effort went into the use of S. spontaneum. A concentrated and systematic effort was made by the CSR Company in Australia and Fiji to nobilise superior S. spontaneum clones with S. officinarum (Roach, 1971; Krishnamurthi, 1987). Some of these F1 populations are available in Fiji and perhaps Macknade Queensland. In Canal Point USA, another program was undertaken to nobilise Thai S. spontaneum (Millr et al., 2005).

It was generally considered that the noble canes would contribute the ability to store sucrose, while the vegetative vigour, good ratooning and disease resistance would come from S. spontaneum. Although the progress was initially good, by the late 1960s it was realised that the...
exceedingly narrow genetic base of the existing clones was beginning to impede further progress (Kennedy, 2001). To break this yield barrier, sugarcane breeders attempted to generate intergeneric hybrids between *S. officinarum* and *Erianthus*. Among the several species of *Erianthus* present in both the old and new world, *E. arundinaceus* and *E. procerus* have a wider distribution in India, China, Myanmar, Thailand, Philippines, Indonesia and New Guinea, while the other species have a restricted distribution (Nair and Praneetha, 2006).

Mukherjee (1958) assigned the origin of the species to the Indo-Myanmar-China region where the species is extensively distributed. The species subsequently spread to the adjoining areas in South and South-East Asia. This is the only cane forming species among *Erianthus* and has enormous potential as a contributor of germplasm to current cultivars for better ratoonability, vigour and tolerance to environmental stresses such as drought and flooding.

Numerous attempts have been made to cross *E. arundinaceus* with sugarcane to introduce these characters into modern cultivars. The need to broaden the genetic base, given the spectra of yield stagnation, and the need to introgress specific characters from wild and associated genera, raised the interest in cane breeding. Intergeneric hybridisation provides the required genetic variability by incorporating useful genes from wild relatives into commercial sugarcane. Further, back crossing with high-sucrose commercial cultivars was essential to develop commercial varieties.

During the 1960s, two clones i.e. one of *Erianthus procerus* and another *E. bengalense* were exported from Coimbatore into Fiji (courtesy T.V. Sreenivasan and M. Naidu) and extensive studies were undertaken with regard to flowering, anthesis, pollen and compatibilities. Crosses were made using *S. officinarum*, Korpi and Badila, with *E. procerus* in Fiji. A series of hybrids i.e. LF 63-51, LF 63-55, LF 63-70, LF 63-71 were selected and used. These hybrids were identified by plant type, internode length and inflorescence shape.

Apart from researches in Fiji, Sreenivasan (pers. comm., 1993) was one of the first to attempt crosses with *Erianthus* and obtained good progenies. He also indicated the chromosome elimination effect in *Erianthus* progenies. One of the major obstacles in the past has been the identification of true hybrids using morphological characters. Sometimes this method of identification appears to be misleading the breeders. To overcome this problem, molecular diagnostic tools have recently been developed for use in sugarcane to identify the putative intergeneric hybrids (D’Hont et al., 1995; Alix et al., 1998, 1999). These tools include sequence-tagged PCR to identify true hybrids at the seedling stage, and genomic *in situ* hybridisation (GISH) to characterise the chromosome complement of hybrids (Piperidis et al., 2000).

A planned intergeneric hybridisation program was started in E.I.D Parry (India) Ltd. to exploit the potential of *Erianthus arundinaceus* to develop commercial cultivars (Krishnamurthi et al., 2004).

**Materials and methods**

**Materials used**

The female parents used were 16 pure *S. officinarum* and 4 commercial cultivars. Four accessions of *Erianthus arundinaceus* were used as males (from Thailand and Indonesia) in 2000–2001 crossing seasons at Bangalore. Clones with less than 5% viable pollen were chosen as females in the crossing program. 63 cross combinations were made and 1625 seedlings were produced. Out of these cross combinations, the three cross combinations viz., Badila x *E. arundinaceus*, Korpi x *E. arundinaceus* and CoC 671 x *E. arundinaceus* produced 111 seedlings subjected to selection based on morphological traits. Twelve putative hybrids were selected for further evaluation.

**Flowering and synchronisation of flowering**

Sugarcane is an intermediate day plant that will flower in response to gradually increasing night length. Most *E. arundinaceus* clones in our germplasm collection flower together with *S.
officinarum cultivars. Based on the need, flowering was synchronised using the techniques developed by Daniels and Krishnamurthi (1967) and Krishnamurthi (1987). The flowering was arrested with night lighting and induction achieved by reducing the day length.

**Crossing techniques**

Crossing with *Erianthus arundinaceus* was not easy as it had to be carried out with precision to overcome many hurdles. The pollen from *Erianthus* was collected at 5.30 am and pollinated before the pollen shedding in the female parent. The pollen collection, pollen viability testing and handling, pollination, fuzz collection, fuzz processing, seedling raising, selection and further crossings were carried out as per Krishnamurthi *et al.* (2006).

**Field evaluation**

The hybrid seedlings were sown in trays and transplanted into pro-trays prior to field planting. The field planting was in rows 1.2 m apart spaced at 60 cm. The selection was carried out based on morphological traits coupled with hand refractometer brix %. The selected hybrids were multiplied in 5.0 m × 1 row plots for seedcane purposes.

The selected intergeneric hybrids were planted in a plot size of 4 rows x 5 m x 4 replications along with female and male parents using RBD design in the 2005–06 season at Pugalur, Tamil Nadu, India. Regular agricultural operations were carried out for this trial. The field characters viz., stalk length (cm), number of internodes, internode length (cm), internode thickness (cm), stalk number per square metre, were collected 10 months after planting. The stalk weight (kg) and cane yield data were collected at the time of harvest (Rajeswari, 2004). The quality parameters viz., brix %, pol %, purity %, fibre % and POCS % were estimated in the laboratory using CSR methods. The analysis was performed on five stalk samples, which were collected at the age of 12 months.

**Molecular analysis**

For the confirmation of the hybrid nature of the F₁ populations, molecular analysis was carried out at the Sugarcane Breeding Institute (SBI), Coimbatore, India. The hybrids were screened along with their male and female parents using sugarcane SSR primer pairs. The amplified products were analysed on PAGE gels with silver staining.

**Results and discussion**

Sugarcane flowering in Bangalore, India is between November and mid-January. The *in vitro* pollen germination test indicated that the pollen germination was ranging between 30% and 90%. The same was found to be true for the *in-vivo* test. It was found that *Erianthus* shed pollen at least three times a day i.e 5.30 am, 9.00 am and 3.00 pm. The pollen produced at 9.00 am and 3.00 pm showed low viability when cultured *in vitro*. The various hybrids produced viable pollen in abundance.

One thousand six hundred twenty five seedlings were produced from 63 cross combinations. Out of these, twelve putative hybrids from the following three cross combinations were used for the field and quality analysis (Table 1). No genuine hybrids were identified from other crosses.

The metric field traits like stalk length (cm), number of internodes, internode length (cm), internode thickness (cm), stalk number per square metre, stalk weight (kg) and cane yield (t/ha) observed from parents and hybrids are presented in Table 2. The selected hybrid progenies exhibit early vigour, recorded higher cane yield and were better in all morphological traits when compared to parents in the research plots.

(** Significance at 1% level)
The quality data (Brix %, Pol % in juice, purity %, fibre % and pure obtainable cane sugar (POCS %)) were collected for all parents (except *Erianthus*) and hybrids. Since there is no extractable juice in the *E. arundinaceus* stalks, only fibre data were recorded.

The mean values of the replicated samples are presented in Table 4. Most of the intergeneric hybrids showed higher fibre % and lower POCS % compared to *S. officinarum* clones.

(** Significance at 1% level)

The molecular work was carried out at the Sugarcane Breeding Institute (SBI), Coimbatore, Tamil Nadu, India. Until now, one hybrid PIH 01-3228 was confirmed by SSR markers specific to *Saccharum* and *Erianthus* (Figure 1).

In Figure 1, hybrids other than those reported in this paper are also shown. The confirmed hybrid has both *Saccharum* and *Erianthus* bands. The molecular characterisation of all hybrids is currently in progress.
In the process of *Erianthus* hybridisation, breeders have to handle issues such as anthesis of male parents which posed a major problem. *Erianthus* is unique in the time for anthesis which takes place at 5.30 am and the viability is more than 50–60%, whereas subsequent anthesis on the same day produces enough quantity of pollen but the viability is less than 10%; hence, pollination is ineffective. Moreover, the pollen has the habit of coagulation. Hence, viability is greatly reduced if not handled carefully. The second major problem encountered was incompatibility with most true *S. officinarum*. The few which give good progeny are *S. officinarum* clones, Korpi, Badila and a few NG clones. The incompatibility might be due to incongruity between the pollen and pistil of the two genera (Lee, 1995). Our experience indicates using commercials like CoC 67-1 and Co 86-032 as females produces a good number of hybrid seedlings.

Molecular techniques paved a new way for introgression of desirable genes from *Erianthus* to *Saccharum*. Other than *E. arundinaceus*, another species, *E. rockii*, has been identified by Chinese sugarcane breeders, and attempts were made to introgress with *S. officinarum*. Cai et al. (2005a) reported that *E. rockii* was distinct from other species of *Erianthus* and *Saccharum* species through SSR and AFLP markers. Verification of intergeneric hybrids of *E. rockii* and *Saccharum* using molecular markers was reported by Aitken et al. (2007) and they observed n+n transmission of chromosomes. Molecular confirmation of hybrids was reported by many scientists in the last few years. Cai et al. (2005b) confirmed the introgression of *E. arundinaceus* into sugarcane by identification of genuine BC₁ progeny from an F₁ intergeneric hybrid x *Saccharum* clone with molecular markers.

Chromosome elimination was also observed in intergeneric hybrids when analysed using genomic *in situ* hybridisation (GISH). Most of these intergeneric hybrids were sterile and unable to use for backcross (Piperidis et al., 2000) whereas the hybrids produced from this project are showing hybrid vigour and produce more than 30 to 40% viable pollen. One hybrid PIH 01-3315 (*Badila* x *Erianthus*) became male sterile and does not produce any viable pollen. Among all the hybrids, PIH 01-3228 (*Korpi* x *Erianthus*) was subjected to molecular analysis and proved to be a putative intergeneric hybrid (Figure1). These hybrids are being used for further backcrosses to develop commercial cultivars.

Résumé

LA CANNE À SUCRE (Saccharum spp.), est une des cultures chez laquelle l’hybridation interspécifique a fourni des avancées majeures pour son amélioration. Cependant, l’hybridation intergénérique a gagné en importance pour élargir la base génétique et obtenir des traits utiles au niveau industriel et, augmenter la biomasse totale conjointement. Les avantages dérivés de l’utilisation des espèces sauvages comme S. spontaneum ont été réalisés depuis le début des années 1900s. Maintenant, la compatibilité du Saccharum officinarum-Erianthus est explorée pour incorporer les gènes de résistance aux maladies. Le genre a également un grand potentiel pour la vigueur, une meilleure repousse et la tolérance aux stresses environnementaux. Au E.I.D Parry (Inde) Limitée, R & D Centre, des tentatives ont été effectuées à travers un programme d’amélioration conventionnel afin d’introduire ces caractères dans des cultivars commerciaux de canne à sucre. L’authenticité de ces hybrides a été vérifiée sur la base des caractères phénotypiques notamment, l’orientation des feuilles, le dépaillage, la longueur de la tige, le diamètre de la tige, la longueur des entrenœuds, la couleur de la tige et les propriétés biochimiques telles que la teneur en saccharose, la teneur en fibre et des analyses par des techniques moléculaires. Des hybrides intergénériques sélectionnés ont été employés dans des programmes de rétro-croisements pour développer des cultivars commerciaux.

Resumen

LA CAÑA DE AZÚCAR (Saccharum spp.) es uno de los cultivos en el que mediante la hibridización interespecífica ha proporcionado un importante avance en el mejoramiento de variedades. Sin embargo, la hibridización intergenérica ha ganado importancia para ampliar la base genética y obtener caracteres comerciales útiles y al mismo tiempo incrementar la biomasa. Los beneficios derivados del uso de especies silvestres como S.spontaneum fueron considerados desde los inicios de 1900, y la compatibilidad de Saccharum officinarum con Erianthus se ha explorado para obtener genes de resistencia a enfermedades. Este género también tiene un gran potencial para vigor, mejorar el rebrote y tolerancia al estrés ambiental. En el Centro de Investigaciones E.I.D Parry (India) Ltd., se han realizado varios programas de cruzas convencionales para introducir estos caracteres en los cultivares comerciales. La verdadera naturaleza de estos híbridos se confirman mediante los caracteres morfológicos como orientación de las hojas, rayado de la hoja, largo de tallo, grosor del tallo, largo del entrenudo, color del tallo, y caracteres bioquímicos como contenido azucarero, contenido de fibra y análisis con técnicas moleculares. Los híbridos intergenéricicos son usados como cruzas recurrentes para el desarrollo de cultivares comerciales.
IDENTIFYING QUANTITATIVE TRAIT ALLELES FOR PHYSIOLOGICAL
TRAITS IN SUGARCANE: AN EXPLORATORY STUDY

KEYWORDS: Quantitative Trait, Stalk Elongation, Leaf Appearance,
Photosynthetic Capacity, Crop Model, Phenotypic Variance.

Abstract

This study attempted to shed light on the feasibility of high throughput phenotyping of
physiological traits and the detection of quantitative trait alleles (QTA) for these traits.
Stalk elongation rate per unit thermal time before and after the 14 leaf stage (SER14 and
SER24), leaf appearance rate per unit thermal time (LAR14 and LAR24), fully expanded
leaf area per leaf (LA) and photochemical light use efficiency (P(ABS)) were measured
for 80 clones of a mapping population in three experiments conducted at Mount
Edgecombe, South Africa. Within-experiment clonal repeatability was highly
significant for all traits. Inter-experiment correlations show that SER24, LA and P(ABS)
were reasonably stable across experiments. Significant single marker-trait associations
were found for all traits and multiple marker-trait associations explained from 39% (six
QTAs to predict LAR24) to 55% (five QTAs to predict SER24) of clonal variance.
However, the low number of markers detected in all three experiments cast doubt on the
reliability of marker-based predictions for LAR14, LAR24 and SER24. Results indicate
that LA and P(ABS) were reasonably stable across environments and can be predicted
reliably from genomic information. P(ABS), as estimated through rapid, non-destructive
chlorophyll a fluorescence measurements, in particular shows great promise because it
has the potential for high throughput phenotyping at an early stage in the plant life
cycle. The promising results obtained here suggest that further research is warranted in
refining experimental protocols and validating marker-trait associations in other
germplasm and environments. This could pave the way to explore the exciting
possibilities that gene-to-phenotype modelling offers for enhancing sugarcane breeding.

Introduction

Crop yield is a complex trait governed by numerous dynamic interactions between plant
processes and environment and management factors. Accelerated improvement in plant
performance is only likely when these interactions and the underlying physiological mechanisms
and genetic basis are better understood. Crop simulation models take some of these interactions into
account by simulating the impact of physiological processes such as plant growth rate, leaf
appearance rate, leaf size and photosynthetic capacity. Models therefore have the potential to
identify trait sets that are most likely to enhance yields in target environments (Hammer et al.,
2006).

In parallel, genetics have determined genetic markers or quantitative trait loci (QTL) for
various traits. This information can be used to better understand processes and interactions that
contribute towards yield, and to enhance breeding (Hammer and Jordan, 2007) For sugarcane,
QTLs have been detected for sucrose content (Ming et al., 2001; Aitken et al., 2006; Aitken et al.,
2008), stalk mass and number (Ming et al., 2002; Hoarau et al., 2002; Aitken et al., 2008) and stalk length and stalk diameter (Hoarau et al., 2002; Aitken et al., 2008). These studies all focused on complex yield component traits rather than simple physiological traits related to yield formation processes of resource capture, resource conversion and biomass partitioning. It is believed that despite the genetic influence on yield and its components, there are strong environmental impacts that will make it difficult to detect stable QTLs.

An alternative approach is to define simple, genetically determined, physiological traits and detect stable QTLs for these. Crop models can then be used to simulate the integrated effect of many of these traits in a given environment and thereby identify desirable ones. Sadok et al. (2007) speak of ‘analysing the behaviour of virtual genotypes in silico for large number of environmental scenarios’. Once the ideotype has been identified, the genomic information could be used for rapid screening of genotypes for crossing or selection. Chenu et al. (2008) gave an excellent example of incorporating a QTL based physiological trait module into the APSIM maize model to accurately predict growth of individual leaves and whole crop response to environmental stresses. The model is based on the work by Sadok et al. (2007) and Reymond et al. (2003). They found that maize leaf elongation rate per unit thermal time, when normalised with respect to vapour pressure deficit (VPD) and soil water potential, were genetically determined and that genotype values could be predicted reliably from QTL information.

In sugarcane, it has been shown that stalk elongation rate per unit thermal time is genetically determined to a large extent (Smit and Singels, 2007). There is also evidence that leaf size and leaf elongation rate show large and consistent genotypic variation (Bonnet, 1998; Robertson et al., 1998). However, little genetic and phenotypic information on these traits are available for the wide range of genotypes in existence.

This study attempted to shed light on the feasibility of high throughput phenotyping of physiological traits and the detection of quantitative trait alleles (QTA) for the following physiological traits namely, leaf appearance rate per unit thermal time (LAR), stalk elongation rate per unit thermal time (SER), fully expanded leaf area per leaf (LA), and photochemical light use efficiency (PIABS). These traits were selected based on (1) their importance in determining resource capture and yield formation, (2) the presence of these or similar traits in crop models (3) ability to derive trait values from experimental measurements, and (3) the expected extent of genetic determination.

The specific objectives were to (1) determine the phenotyping repeatability of these traits, (2) identify genetic markers that can be associated with each trait, and (3) determine the reliability of predicting trait values from genetic marker information.

**Methods**

**Mapping population**

A population of 80 sugarcane clones, derived from the South African Sugarcane Research Institute (SASRI) breeding program, were mapped using linkage disequilibrium methods (Butterfield et al., 2008). The map consists of 2054 AFLP and DArT markers arranged on 492 haplotype fragments.

**Experiments**

Three field experiments (T1, T2, T3) were conducted at Mount Edgecombe (29°42’S, 31°03’E) on a sandy clay loam soil covered with a trash blanket to discourage tillering. Plants were adequately fertilised and irrigated. T1 and T2 have been described by Singels et al. (2009). In T1, five setts of each clone were planted in each of four replicates in May 2006. In T2, setts were germinated in vermiculite in a germination chamber at 30°C and transplanted into the field between 29 May and 7 June 2007, when a seedling height of around 10 cm was reached. The number of plants per replicate and number of replicates were the same as in T1. In T3, the germination
chamber and a heated glasshouse were used to manipulate early development of clones to further improve synchronisation of development stage and planting date. Planting in the field took place from 14 to 30 October 2008 and eight setts of each clone were used as individual replicates. In all experiments, secondary tillers were removed as soon as they were visible and only healthy plants were measured.

On a weekly basis, the emergence date of the youngest fully expanded leaf (top visible dewlap (TVD) leaf) was estimated and numbered (starting from the base), and the leaf length and width recorded together with the TVD collar height from ground level. SER for each plant was taken as the slope of the regression of TVD height vs. thermal time. LAR for each plant was taken as the slope of the regression of number of fully expanded leaves vs. thermal time. A distinction was made between the phase between leaf number 8 and 14 (denoted by LAR$_{14}$ or SER$_{14}$), and the phase between leaf number 15 and 24 (denoted by LAR$_{24}$ or SER$_{24}$). Leaf area per leaf (LA) was taken as the average of the fully expanded area (estimated as leaf length x leaf width x 0.71, Sinclair et al., 2004) of leaf number 15 to 24. Due to limited manpower and changes in measurement protocol, the number of plants and replications that were measured for some traits varied.

Photochemical light use efficiency of TVD leaves was only determined in T2 and T3 by recording fast polyphasic chlorophyll $a$ fluorescence transients (Strasser and Govindjee, 1992) at night with a fluorimeter (Plant Efficiency Analyser, Hansatech Instruments Ltd., UK). Four measurements were taken in the mid-section of each TVD leaf on three plants of each clone in each replication (total of 48 measurements per clone). The recorded chlorophyll $a$ fluorescence data were used to calculate the Performance Index (PI$_{ABS}$), which is a sensitive indicator of photosynthetic electron transport efficiency and photosynthetic capacity (Strasser et al., 2000).

Photosynthetic gas exchange measurements were conducted on three clones that represented groups of clones that displayed consistently high, intermediate and low PI$_{ABS}$ values (i.e. high, intermediate and low photochemical light use efficiency). Measurements were conducted with a portable photosynthesis system (Li-Cor 6400, Lincoln, NE, USA) on attached TVD leaves. Measurement of CO$_2$ assimilation rate (A) were taken at incident photon flux (Q) levels of 0, 50, 75, 100, 125, 200, 400, 800, 1500 and 2000 µmol/m$^2$/s provided by an LED light source (LI-6400-02) at an atmospheric CO$_2$ concentration (c$_a$) of 400 µmol/mol. Leaf temperatures in the leaf chamber were maintained at 25ºC and vapour pressure deficits at 1.3 kPa.

Daily maximum and minimum temperature were recorded throughout all three experiments by a nearby automatic weather station and was used to calculate thermal time using a base temperature of 16ºC.

Data analysis

Clonal repeatability (CR – the ratio of genetic variance to phenotypic variance) was determined from an analysis of variance for each experiment separately. The stability of phenotypic measurements was further assessed by determining the correlation between values of a given trait measured in different experiments.

The average value for each trait for each clone in each experiment was calculated from values for individual plants. Data were pooled over experiments by calculating the average of all values over all plants of a given clone. Correlations between traits were determined by comparing the pooled average trait values.

Association between trait values and marker presence or absence was determined for each experiment separately, using the Pearson’s correlation coefficient. A significance level of P=0.05 was chosen. Stepwise linear regression was then used to select markers ascribing maximum phenotypic variation for each trait. This was done using the pooled average trait value for each clone. Selection for markers was limited to those that had significant marker-trait associations in at least two of the three trials. The prediction error (PE) was taken as the standard error of the regression, expressed as a percentage of the observed range in values of each trait.
Responses of A to Q were fitted with the aid of non-linear regressions. The maximum apparent quantum yield of photosynthesis (\(\phi\)) was determined from the linear response of A to Q that persisted between 50 – 400 \(\mu\text{mol/m}^2/\text{s}\) (Long & Hällgren, 1993). The CO\(_2\) assimilation rate at a Q of 2000 \(\mu\text{mol/m}^2/\text{s}\) was regarded as the light saturated rate of CO\(_2\) assimilation (\(A_{\text{sat}}\)). The calculated values of \(\phi\) and \(A_{\text{sat}}\) were used to establish in the three selected clones to what extent differences in photochemical light use efficiency (deduced from PI\(_{\text{ABS}}\) values) translated into differences in overall CO\(_2\) assimilation capacity.

Results

Clonal repeatability

CR was significant (P = 0.001) for all traits in all experiments and exceeded 0.9 in all cases, except for LAR\(_{14}\) in T1 and T2, LAR\(_{24}\) in T2 (Table 1). The range of values is similar to that obtained by Aitken et al. (2008) and Hoarau et al. (2002) for yield component traits. Correlations between trait values from different experiments (Table 2) show that most traits were reasonably stable across experiments, with the exception of LAR\(_{14}\), LAR\(_{24}\) and possibly SER\(_{14}\). These correlations were also generally in the same range than those reported by Aitken et al. (2008). The results suggest that all traits except LAR and possibly SER\(_{14}\) are likely to be genetically determined and can be phenotyped with reasonable accuracy.

Screening of a large number of genotypes for physiological traits will be more useful for breeding programs when the method of phenotyping is quick and can be conducted at an early development stage of the plant. It would be useful, therefore, to determine the correlation between measurements made before leaf stage 14 and thereafter. When trait values were pooled over experiments, significant correlations were found between traits LAR\(_{14}\) and LAR\(_{24}\) (0.645), SER\(_{14}\) and SER\(_{24}\) (0.467), LA\(_{14}\) and LA\(_{24}\) (0.908). It seems that screening for leaf area before leaf stage 14 could be feasible.

Link between CO\(_2\) assimilation capacity and photochemical light use efficiency (PI\(_{\text{ABS}}\))

The extent by which differences in photochemical light use efficiency translated into differences in overall CO\(_2\) assimilation capacity was determined in clones 2, 60 and 79. These clones had PI\(_{\text{ABS}}\) values that were respectively 49% and 0.5% higher and 43% lower than the average PI\(_{\text{ABS}}\) value for all 80 clones, thus representing high, intermediate and low PI\(_{\text{ABS}}\). This analysis revealed that values
for $A_{sat}$ and $\phi$ corresponded with the relative positions of the three clones according to $PI_{ABS}$. For example, clone 2 (highest $PI_{ABS}$) had $A_{sat}$ and $\phi$ values respectively 39% and 52% higher than in clone 79 (lowest $PI_{ABS}$), while clone 60 (intermediate $PI_{ABS}$) had values respectively 20% and 14% higher than in clone 79.

**Marker-trait associations**

The phenotypic variation accounted for by genetic markers and the reliability of marker-based predictions are given in Table 3. The number of markers detected in all three experiments was considerably lower than the number detected in any two experiments, especially for traits $LAR_{14}$, $LAR_{24}$, $SER_{24}$, suggesting that some of these detections may be false. These results highlight the necessity of multi-experiments for true marker detection and for the need for more precise phenotyping.

The multiple marker-trait associations determined for all traits were promising, with $R^2$ values 0.4 or more, and PE values of 15% or less. The strongest single marker-trait associations explained between 14.3 and 25.3% of the phenotypic variance, which compares well with values reported by Aitken *et al.* (2008) and Aitken *et al.* (2006).

**Table 3**—Number of markers with significant correlations with trait values in all three experiments, in two out of three experiments and the highest number of markers detected in any one experiment; the number of markers selected in the stepwise multiple regression to predict the trait value, the coefficient of determination for the regression, the highest and lowest $R^2$ contribution from individual markers to the regression, and the prediction error (PE) between predicted and observed trait values.

**Discussion**

Results suggest that LA and $PI_{ABS}$ are reasonably stable across environments and can be predicted reliably from genomic information. $PI_{ABS}$, as estimated through rapid, non-destructive chlorophyll $a$ fluorescence measurements, in particular shows great promise because it has the potential for high throughput phenotyping at an early stage in the plant life cycle. At least in the three clones on which detailed measurements of CO$_2$ assimilation capacity were conducted, a strong agreement between photochemical light use efficiency and overall CO$_2$ assimilation capacity (which is most probably an important contributor to high biomass and sucrose yields) was clearly demonstrated.

Observations of stalk elongation and leaf appearance traits were not that repeatable and marker-based predictions were not sufficiently reliable. Possible reasons could be inappropriate sampling techniques or problems with experimental procedures. For example, it was very difficult to synchronise all clones to reach the same developmental stage at the same time. In T2 and T3, germinating setts were initially exposed to artificial environments for different time periods to achieve this. Pests (monkeys, thrips) and disease (pokka boeng) also affected some plants.

Unreliable marker-based predictions could also be due to insufficient separation of genetic and environmental aspects in the trait definition. For example, Robertson *et al.* (1998) found that
temperature affected LA and Smit and Singels (2007) found that genetic control of SER was confounded by site and season effects. Reymond et al. (2003) showed that SER in maize was controlled by soil water potential and atmospheric VPD. In our study, we tried to eliminate soil water status as a source of variation. The impact of VPD on observed SER still needs to be investigated.

The promising results obtained here suggest that further research is warranted in refining experimental protocols and validating marker-trait associations in other germplasm and environments. This could pave the way to explore the exiting possibilities that gene-to-phenotype modelling offers for enhancing sugarcane breeding.

Modèle de Croissance, Variance Phénotypique.

Résumé
CETTE ÉTUDE explore les possibilités du déterminisme phénotypique haut débit des caractères physiologiques et la détection des allèles à effet quantitatif (QTA) pour ces traits. Le taux d’élongation des tiges par unité thermale de temps avant et après le stade 14-feuille (SER14 et SER24), la vitesse d’apparition de la feuille par unité thermale de temps (LAR14 et LAR24), l’expansion totale de la surface foliaire (LA) et l’efficience de l’utilisation photochimique (PIABS) ont été mesurés sur 80 clones caractérisés moléculairement à partir de trois essais à Mount Edgecombe, Afrique du Sud. La répétitivité clonale intra-essai était hautement significative pour tous les traits. Les corrélations inter-expérimentation ont montré que SER24, LA et PIABS étaient raisonnablement stables à travers les expérimentations. Des associations significatives de marqueurs-trait simples étaient observées pour tous les caractères alors que les associations des marqueurs-multiples expliquent entre 39% (six QTAs pour prédire LAR24) à 55% (cinq QTAs pour prédire SER24) de la variance clonale. Cependant, le nombre restreint de marqueurs détectés dans les trois expérimentations émet des doutes quant à la fiabilité des prédictions basées sur les marqueurs associés à LAR14, LAR24 et SER24. Les résultats indiquent que LA et PIABS sont raisonnablement stables à travers les environnements et peuvent être prédites avec fiabilité à partir de l’information génomique. La PIABS, estimée à partir des mesures rapides et non-destructives de fluorescence de chlorophylle a, est prometteuse en particulier car elle démontre un potentiel pour le phénotypage à haut débit à un stade précoce du cycle de la plante. Les résultats prometteurs obtenus suggèrent que davantage de recherche est nécessaire pour raffiner les protocoles expérimentaux et valider les associations marqueurs-trait chez d’autres sources de germoplasme et dans d’autres environnements. Ceci pourrait préparer le terrain pour une exploration des possibilités excitantes qu’offre la modélisation gène-phénotype dans l’amélioration de la canne à sucre.

PALABRAS CLAVE: Caracteres Cuantitativos, Alargamiento del Tallo, Apariencia de Hoja, Capacidad Fotosintética, Variación Fototípica.

Resumen

Este estudio ha intentado clarificar sobre la posibilidad de un sistema eficiente de determinación de caracteres fenotípicos fisiológicos y su detección de alelos de caracteres cuantitativos (QTA). La tasa de alargamiento del tallo por unidad de tiempo termal antes y después de la hoja 14 (SER14 y SER 24), apariencia de la hoja por unidad de tiempo termal (LAR 14 y LAR 24), área de la hoja expandida totalmente por hoja (LA) y eficiencia fotoquímica en el uso de la luz (PIABS) se midieron en 80 clones de las poblaciones en mapeo en tres experimentos realizados en Mount Edgecombe, Sur África. La repetitividad clonal dentro de los experimentos fue altamente significativa para todos los caracteres. Las correlaciones entre experimentos mostraron que SER24, LA y PIABS fueron razonablemente estables a lo largo de los experimentos. La asociación simple entre carácter-marca dor fue significativa para todos los caracteres y la asociación múltiple entre marcador-carácter se explica desde 39% (seis QTAs para predecir LAR24) a 55% de la variación clonal (cinco QTAs para predecir SER24). Sin embargo, el bajo número de marcadores detectados en los tres experimentos dejan dudas en la relatividad de las predicciones basadas en marcadores para LAR14, LAR24 and SER24. Los resultados indican que LA y PIABS fueron razonablemente estables en los experimentos y se puede predecir con confianza desde la información genética. El PIABS, como un estimado rápido, de medida de la clorofila a mediante fluorescencia, en particular, se muestra promisorio para clasificar fenotípicamente en estados tempranos del ciclo de vida de la planta. Estos resultados promisorios obtenidos aquí sugieren que se justifican otros estudios para que garanticen los protocolos experimentales y la validación de la asociación marcador-carácter en otros germoplasmas y ambientes. Esto podría preparar el terreno para explorar la posibilidad de que modelos existentes gen-a-genotipo ayuden a fortalecer los programas de mejora genética.
USE OF HISTORICAL MULTI-LOCATION SUGAR CANE VARIETY TRIALS DATA TO IDENTIFY RELATIONSHIPS AMONG ENVIRONMENTS IN TERMS OF GENOTYPE RESPONSES

By

D. BISSESSUR, C. RAMNAWAZ and K. RAMDOYAL

KEYWORDS: AMMI, Cane Yield (TCH), Genotype × Environment Interaction, Genotype Responses, Multi-Location Trials, PCA.

Abstract

In Mauritius, sugarcane is grown over diverse environments that can be grouped into three main zones: the Superhumid, Humid and Subhumid. In each zone, multi-location variety trials are established with several genotypes to provide reliable information for identifying high yielding varieties. Genotype × Environment (G × E) interaction is the major complicating element in selecting genotypes suitable for commercial production. However, one of the difficult aspects of conducting trials in several environments is the choice of test sites. It is important to plan a rational variety-testing program with confidence. Available historical data were used from four series of final phase trials established in different years to study the main effects environment (E) and genotype (G) as well as G× E interactions. The aim was to identify relationships among test sites in terms of genotype responses and to assess the extent to which environments were similar or different. Cumulative results of a plant crop and three ratoon crops for cane yield (TCH) were analysed. In the superhumid zone, located at high elevation, G× E interaction was not important within the rocky (B) and the deep free (F) soils. In contrast, a significant G× E interaction was observed within B and F soils for locations lying in relatively higher and lower elevations in different sectors. Similarly, among locations in the Humic Latosols (H2) soils and between H2 and L2 soils, interaction was not prominent. Furthermore, the B, F and H soils were found to be the cause of different genetic responses. In the subhumid zone, a highly significant G× E interaction was found between all the Low Humic Latosols (L1, L2) and the Latosolic Reddish Prairie soils (P2 and P3). The study confirmed that trials should be established in B, F, L and P soils mainly but should be replicated within the B and F soils prevailing in the different sectors of the island.

Introduction

In Mauritius, sugarcane is grown over diverse agro-climatic environments that are grouped into three main environments, the Superhumid, Humid and Subhumid zones, and five main soil types. The Superhumid zone, with an annual rainfall of >2400 mm, comprises three main soil types: the Latosolic Brown Forest (B1 and B2) that are rocky intrazonal soils very high in organic matter, have evolved on the late lavas and are strongly to slightly acidic; the Humic Ferruginous Latosols (F1, F2 and F3) are deep free zonal soils high in organic matter, and have developed from the early and intermediate lavas and are strongly to medium acidic; the Humic Latosols (H) soils, which have developed on the intermediate lavas (Parish and Feillafé, 1965).

The Humid zone (1800 mm to 2400 mm) are deep fertile soils that include mostly the Low Humic Latosols (L2) soils, have developed on the intermediate lavas and are medium to slightly acidic.
The Subhumid zone, with mean annual rainfall <1800mm, comprises the Low Humic Latosols (L1, L3 and L4) soils, which are deep soils low in organic matter with good internal drainage developed from the intermediate lavas, and the Latosolic Reddish Prairie (P1, P2 and P3) soils developed from the late lavas below the 2500mm isohyets, which are high in organic matter. Parish and Feillafé (1965) have reported that the whole solum contains varying amounts of cobbles and gravels of unweathered or slightly weathered basalt, and bedrock exposures are common. The P1 and P2 soils are mainly shallow and gravelly whereas most of the P3 soils are very rocky. The soils in the subhumid zone are neutral to slightly acidic.

The percentage area under sugarcane cultivation in the B, F, H, L and P soils in different rainfall ranges across the island are shown in Table 1 below. The B, F and H2 soils of the superhumid zone occupy about 33% of the total area under cultivation, the L2 soil of the humid zone constitutes about 10% of the total area; whereas, for the L1 and P soils in the subhumid zone, the percentage area under cultivation is about 29%.

The breeding and selection program of the Mauritius Sugar Industry Research Institute (MSIRI) currently extends over 11 to 15 years from the time of sowing to the release of a new sugarcane variety. The program includes a preliminary phase of selection comprising a seedling and three clonal stages and a final phase that consists of two stages. At the final phase, about 60 to 80 promising genotypes selected from the third clonal stage of the preliminary phase, are tested in two or more series of trials established in four main soil types B, F, L2 and P1/P2 (Irrigated) throughout the island and harvested at mid-season (mid-August to mid-October).

The second stage (T2) consists of one or more series of trials planted in five complementary soil types to T1, in B, F, H, L1 (irrigated) and P3 or P1/P2 or L1 (non-irrigated), which are harvested early (June to mid-August) and/or late (end October/November) in the season. The number of the sites selected also depends on the availability of land, planting material and human resources. Promising genotypes are evaluated in a wide range of environments and their performance is influenced by the genotype×environment interactions. The magnitude of these interactions determines whether the genotype is adapted to a specific environment, a group of similar environments or to a wide range of environments.

Historical data available in the plant breeding databases was used to study the main effects environment (E) and genotype (G) as well as the G×E interactions in a series of trials established over several years. The aim of this study was to identify relationships among test locations in terms of genotype responses in order to assess the extent of similarities or differences among environments. The results would provide useful information in the choice of testing sites at the final phase of the selection program.
Materials and methods

Availability of reliable data on common genotypes planted in different environments is the main prerequisite of this study. In this respect, the historical data were explored and four series of trials planted at the final phase of testing were considered as per Table 2 below.

Table 2—Multi-location trials harvested at mid-season.

</table>

The first series (Table 2) consisted of trials established in twelve environments in 1979 and harvested at mid-season. The trial design at each site was an RCB with four replications. The same twelve varieties were tested at all sites during 4 years in the plant cane and three ratoon crops. Five of the twelve trials were situated in the superhumid zone, two in the Latosolic Brown Forest soils (B1), two in the Humic Ferruginous Latosol soils (F1) and one in the Humic Latosol soils (H). Six trials were located in the subhumid zone with three trials in the Low Humic Latosol soils (L1 & L2) and three in the Latosolic Reddish Prairie soils (P2 & P3). One trial in the P3 soil was situated in a humid zone.
The second series (Table 2) consisted of ten trials with RCB designs and four replications. The same ten varieties were tested at all sites during 4 years in the plant cane and three ratoon crops. Two trials were planted in each of the B1, H2, L1, L2, and one trial in P2 and P3 soils respectively.

The third series (Table 2) consisted of ten trials with RCB designs and four replications. Ten varieties were tested at all sites during 4 years in the plant cane and three ratoon crops. Two trials were planted in each of the B1, F1, H2, L2 and P3 soils respectively.

The fourth series (Table 2) consisted of eleven trials with lattice designs and three replications. Twenty varieties were used in the trials and five of these were tested at all sites during 4 years in the plant cane and three ratoon crops. In the superhumid zone, three trials were planted in the B1 soils and four in the F1 soils whereas one trial was established in the L1, L2, P1 and P2 soils respectively.

The experimental plots of all the trials consisted of four rows each of 10 m spaced at 1.5 m with pathways 1.0 m wide between blocks of plots.

Statistical analyses

The G×E interaction was partitioned into a number of components of variance by making use of the Additive Main effects and Multiplicative Interaction model (AMMI). The classical analysis of variance constitutes the additive part of the ANOVA model and is used to compute the genotype and environment additive effects. The principal component analysis (PCA) is then used to analyse non-additive interaction effects.

The AMMI models (Gauch, 1987) were fitted to the data of the different series of trials to determine the Genotype×Environment interaction. The model for T genotypes and S environments is given as:

\[
Y_{ij} = \mu + g_i + e_j + \sum_{n=1}^{n'} \lambda_n \alpha_{inj} + \gamma_{jn} + \phi_{ij}
\]

where \(Y_{ij}\) is the mean yield of \(i^{th}\) genotype in the \(j^{th}\) environment; \(\mu\) is the general mean; \(g_i\) is the \(i^{th}\) genotypic effect; \(e_j\) is the \(j^{th}\) environment effect; \(\lambda_n\) is the eigen value of the PCA axis \(n\); \(\alpha_{inj}\) and \(\gamma_{jn}\) are the \(i^{th}\) genotype \(j^{th}\) environment PCA scores for the PCA axis \(n\); \(\phi_{ij}\) is the residual; \(n'\) is the number of PCA axes retained in the model.

One requirement of the AMMI model is that the matrix of means should be larger than \(3 \times 3\), requiring more than 3 genotypes to be tested in 3 or more environments (Gauch and Zobel, 1989). Hence, in cases when the number of trials was less than three, the classical analysis of variance with the following model was used:

\[
Y_{ij} = \mu + g_i + e_j + g_i e_j + \epsilon
\]

where \(\mu\) is the general mean; \(g_i\) is the \(i^{th}\) genotypic effect; \(e_j\) is the \(j^{th}\) environment effect; \(g_i e_j\) is the interaction effect and \(\epsilon\)’s denote the random errors.

The two middle experimental rows of each plot were harvested and the plot weight for each variety recorded to determine the cane yield per hectare (TCH) for the first, second and third ratoon crops.

Statistical analysis was performed on the cumulative data of the 1st, 2nd and 3rd ratoon crops using Genstat for windows (Release 11.1) for each environment within series of trials and the residual errors were used for tests of significance after pooling.
Results and discussion

The results are summarised in Tables 3 and 4 for the superhumid zone and Tables 5 and 6 for the subhumid zone.

The superhumid zone

Table 3—F values with significance levels from AMMI/Classical ANOVA models for Environment, Genotype and G×E interactions for cane yield in the B, F and H soils of the superhumid zone.

</table>

In the superhumid zone, a significant G×E interaction was observed between the B & F soils as well as between the B & H and F & H soils for the character cane yield (Table 3), indicating that the performance of the genotypes was different in these environments. Highly significant differences were detected among genotypes and environments. The genotypes SS (11.9%–61.0%)
contributed more to the total SS than the environments SS (1.23%–57.4%) for the character evaluated (Table 4). The ratio G×E interaction SS to the main effect for environment represented a relatively higher percentage than that of the main effect for genotype.

Within the B soils, results from the two series of trials (1984 and 1993), showed that the G×E interaction was significant whereas results from the other two series (1979 and 1982) did not show any significant G×E interaction (Table 3). This can be due to the fact that in 1984 and 1993 the trials were established in different parts of the island under quite different climatic conditions in terms of altitude and annual rainfall (Table 2) whereas, in 1979 and 1982, the trials were established at higher elevation with higher rainfall compared to the other two year series. It appears that within the B soils, the presence of different agroclimatic conditions may lead to inconsistent performance of the genotypes, which indicates that more than one trial should be established in this type of soil, in the South and in the Centre/Eastern part of the island.

Within the H soils, the trials established at different locations and under quite similar agroclimatic conditions in the east and south of the island (Table 2) did not show any significant G×E interaction (Table 3). Only one trial can be planted either in the east or in the south of the island in the H soils.

Within the F soils (Table 3), no significant G×E interaction was found for the trials planted in 1979 in the south of the island with high rainfall. However, the results from trials planted in 1984 (Table 2) at high altitude in the south and centre of the island with relatively different mean annual rainfall showed a significant G×E interaction. The trials established in 1993 in the east, south and centre of the island at different altitude and rainfall also indicated a significant G×E interaction. The results imply that the genotypes need to be tested in more than one location in the F soils in the South and the Centre/East.

In some cases, classical ANOVA did not detect any significant interaction whereas the AMMI analysis revealed a significant interaction confirming the accuracy of the AMMI model as also reported by Gauch Jr. et al. (1988), Srivastava et al. (1999) and Bissessur et al. (2001).

The subhumid zone

In the subhumid zone, a significant G×E interaction was observed within L1, P2 and P3 soils, and between L1 & L2, L2 & P3, P2 & P3, L1 & P2, L1 & P3, L2 & P2 soils (Table 5). However, no significant interaction was observed within the L2 soils as well as between L2 and H2 soils. The results indicated that it was necessary to establish trials in each of the L and P soils of the subhumid zone but there is no need to replicate trials in L2 and H2 soils. The genotypes SS contributed about 5.1% to 58.2% to the total SS whereas the environments SS contributed about 0.03% to 67.4% and the interaction SS contributed about 0.03 to 17.3% for the character evaluated (Table 6).

In the P2 and P3 soils the genotype SS (34.9% and 30.2%) contributed relatively more to the total SS than the environment SS (0.03% and 27.2%). The ratio G×E interaction SS to the main effect for genotype represented a slightly higher percentage than that of the main effect for environment. The results highlighted the importance of G×E interaction and justified the necessity of establishing more trials in the subhumid zone, particularly in the L1 and P soils whereas replication of trials in L2 and H2 soils was not necessary.

These results confirm the current practice of establishing trials in each soil type, and trials in H2 soils can be considered as complementary to trials in L2 soils. They also confirm the inconsistent performance of some commercial varieties in B and F soils that prevail in different sectors of the island. The current practice of implementing a second series of trials in soil groups in different sectors of the island is fully justified.

Conclusions

The results indicated that:

- in the superhumid zone, the performance of the genotypes among the B, F and H2 soils was significantly different and justified the establishment of trials in each soil type.
• there was no significant interaction within H2 soils indicating consistent performance of the genotypes among the locations and replication of trials within H2 soils is not necessary.

• presence of a significant interaction within the B and the F soils implied the need to replicate trials in these soils in the different areas where these soils prevail.

• G×E interaction was very important in the subhumid zone and justified the establishment of more than one trial in each of the L and P soils.

• no significant G×E interaction between the L2 and H2 soils indicated that there is no need to replicate trials between these soils.

PALABRAS CLAVE: Análisis de AMMI, Producción de Caña (TCH), Genotipo× Interaccione Ambientales, Respuesta Genotípica, Ensayos de Localidades Múltiples, PCA.

Abstract
EN LA ISLA DE MAURICIO, la caña de azúcar se cultiva en varios ambientes que pueden ser agrupados en tres zonas: Súper-húmedo, Húmedo y Sub-húmedo. En cada zona, se establecen ensayos con varios genotipos cubriendo varias localidades para obtener información confiable e identificar variedades de alta producción. La interacción genotipo× ambiente (G× E) es el elemento más complicado para seleccionar genotipos aceptables para producción comercial. Sin embargo, uno de los aspectos difíciles para conducir experimentos en diferentes localidades, es escoger el sitio para el estudio, por ello es necesario planificar un programa racional de evaluaciones para obtener datos confiables. Datos históricos disponibles de cuatro series en ensayos de fase final establecidos en años diferentes fueron usados para el estudio de los efectos ambientales (E) y genotipo (G) así como las interacciones (G× E). El objetivo fue identificar las relaciones entre sitios en términos de la respuesta del genotipo y evaluar en qué magnitud los ambientes fue similar o diferente. Los resultados acumulativos de caña planta y tres socas para producción de caña (TCH) fueron analizados. En la zona súper-húmeda, localizada en mayor altitud, la interacción G× E no fue importante dentro de suelo rocoso (B) y los profundos y libres (F). En cambio una interacción significativa G× E se observó dentro de los suelos B y F en localidades ubicadas en altitudes medias y bajas de diferentes sectores. En forma similar, entre las localidades con suelos Humic Latosols (H2) y entre suelos H2 y L2, la interacción no fue prominente. Pero, los suelos del tipo B, F y H, podrían ser la causa de la diferente respuesta genética. En el suelo sub-húmedo, se observó alta significación de la interacción G× E entre todos los Latosoles Húmedos Bajos (L1, L2) y los Latosoles Rojizos de Pradera (P2 y P3). El estudio confirmó que los ensayos podrían establecerse principalmente en los suelos B, F, L y P, pero deberían ser replicados en los suelos B y F más comunes en los diferentes sectores de la isla.
SCREENING AGRONOMICALLY ACCEPTABLE CLONES FROM FAMILIES ASSESSED UNDER NON-MOISTURE LIMITING CONDITIONS IN A MANAGED MOISTURE-LIMITED ENVIRONMENT FOR ENHANCED PRODUCTIVITY AND DETERMINATION OF POSSIBLE SELECTION TRAITS

Keywords: Moisture-Stress Tolerance, Managed Moisture Stress Screening, Cane Productivity, Post-Stress Rejuvenation.

Abstract

MOISTURE stress is the primary abiotic stress occurring in almost all cane growing areas of India, causing drastic reduction in cane and sugar productivity. Under this situation, development of productive, moisture-stress tolerant cultivars assumes greater importance to sustain cane and sugar production. Hence, the study was undertaken to identify families and traits of importance for genetic enhancement of sugarcane productivity under moisture-stress environment. A hybrid seedling population of 45 diverse inter-varietal crosses was studied for variability parameters and percent superior segregates for cane and sugar productivity in seedling and clonal generations under non-moisture stress and moisture-stress environments, respectively. Further, path analysis and mean performance were studied to identify important contributing traits for productivity under moisture stress involving 50 productive selections in clonal stage III with three standards. The polycrosses involving Co 8013, CoV 92101, C 81615, CoC 771, Co 8371, general crosses involving Co 88025 and CoC 671 as female parents, and a cross Co 740 × CoA 7602 exhibited a better range of variability for sugar and cane productivity and produced better percent superior/transgressive segregants. The genotypic path analysis involving six biophysical traits revealed that the light use efficiency (LUE) under moisture stress and photosynthesis rate after alleviation of stress through enhanced transpiration largely contribute to cane productivity. Similarly, the path analysis of 20 other traits under moisture stress emphasised the major role of early internode formation, root length and biomass, leaf area and leaf sheath moisture at the end of the formative stage for higher cane yield. The other traits like tiller number at the mid-formative stage and single cane weight (SCW i.e stalk weight) at harvest can also be considered as selection criteria for improvement of cane productivity. Hence, for genetic enhancement of sugarcane productivity under moisture-limited environments, the families/crosses identified could be considered as ‘proven’ for isolating productive moisture-stress tolerant progenies. The traits identified are effective and useful for identification of productive moisture-stress tolerant clones. Clones identified could be promoted to advanced yield trials.

Introduction

Moisture stress is one of the major constraints to improving sugarcane productivity in India. The extreme decline in the cane area and production due to drought is a strong reminder of the dependence of the sugarcane production on rainfall. The majority of the sugarcane area in the country experiences drought during the formative phase (60–150 DAP) which is the most sensitive growth stage (Naidu, 1976; Gascho and Shih 1983; and Venkataramana, 2003). In this context, for
sustained cane and sugar production, development of productive sugarcane cultivars which can tolerate moisture stress assumes greater importance.

In breeding for stress tolerance, cane yield and tolerance to the stress factors are to be considered, as the cane yield under stress is a function of genotype response to stress and the yield potential (Moore, 1987). Selection for stress tolerance in a suboptimal environment (moisture stress) may advance seedlings with poor yield potential. Hence, with this basic philosophy in view, initial seedling selection based on productivity features is conducted under non–moisture limiting conditions. Further, the fairly large selected population consisting of productive progenies is advanced to clonal stage-I and evaluated under moisture-limiting conditions to identify tolerant genotypes, families, and contributing traits.

The estimates of genetic variability parameters for cane and sugar yield component traits in seedling generation under non-moisture stress and in clonal stage I and its ratoon under moisture stress is reported in our earlier paper (Patil et al., 2008). The study identified the traits viz., tiller number, number of millable cane (NMC), single cane weight (SCW), and hand refractometer (HR) Brix (°) as most reliable and repeatable across seedling and clonal generations under non-moisture stress and moisture-stress environments, respectively.

In the present paper, the results obtained are discussed to identify families and traits contributing towards improved productivity under a moisture-stress regime. Further, the performance of top 10 productive clones is also discussed in the context of contributing traits.

Material and methods

The potted seedling population, comprising 3124 sturdy hybrid progenies derived from 45 diverse inter-varietal crosses, was transplanted to an augmented randomised block design –II, with 22 blocks and four commercial check cultivars viz., CoC 671, Co 86032, CoM 88121 and Co 740 at the Agricultural Research Station, Sankeshwar (University of Agricultural Sciences, Dharwad, Karnataka, India, 15°29’N, 74°59’E) under non-moisture stress conditions. The trial had an inter-row spacing of 0.9 m and an intra-row spacing of 0.6 m. Any gaps from failed seedlings were filled with corresponding hybrid seedlings after 15 days. Recommended cultural operations were carried out during the crop season with regular irrigation schedule based on 75% moisture depletion. The seedling population was evaluated for various cane yield traits viz., tillers per seedling (at 90 days after transplanting), cane girth (cm), millable cane height (cm), number of internodes, internode length, number of millable canes (NMC), single cane weight (SCW), cane yield per clump and HR Brix (°) (270 days after transplanting).

A total of 828 seedlings were selected based on superior or on par cane yield and/or HR Brix (°) compared to the best commercial check. The selected clones were planted in 3-m row length in an augmented RBD-II with nine blocks (CT-I) in a moisture-stress environment. Each block comprised 92 clones and four check cultivars planted randomly. The seed rate of 12 eye buds/m was followed with recommended practices under moisture stress. The stress was created by withholding irrigation from 50 to 160 days after planting (DAP), i.e., formative phase which generally coincides with summer months during which the crop generally suffers from moisture stress and the clones were scored for important cane yield traits and HR Brix (°) (330 DAP).

Fifty moisture-stress tolerant selections from clonal stage I and three commercial check cultivars were evaluated in RBD with two replications. The trial was planted in paired rows of 6 m length with spacing of 1.8 m and 0.9 m between and within pairs respectively. The seed rate (10 eye buds/m) and all standard management practices, excluding drought management practices, were followed for raising the crop. In this experiment, irrigations were skipped from 50–160 DAP and observations on various traits viz., physiological, biophysical, root parameters, cane and sugar components were recorded. The physiological traits viz., leaf area index (LAI) and mean tilt angle (MTA) of leaves at 150 DAP were measured by using portable LICOR canopy analyser system. The characters like 8th leaf area (as per Romero, 1987), leaf sheath and lamina moisture percent and
relative water content were also measured using standard procedures followed in sugarcane and other field crops. The portable photosynthesis system (LI-6400 LICOR, Nebraska, Lincoln., USA) was used to measure biophysical traits like rate of photosynthesis (µ mol CO₂/m²/s), transpiration (m mol of H₂O/m²/s), conductance (µ mol CO₂/m²/s), leaf temperature (°C), water use efficiency (µ mol CO₂/m mol of H₂O) and light use efficiency (µ mol CO₂/µ mol PAR). These observations were made on the top fully opened leaf, from 10 am to 12 noon, on both sampling stages i.e., at moisture stress (mid-formative phase) and after alleviation of stress (i.e., after irrigation at the end of formative phase). The root parameters like number and dry weight (g) per clump and root length were also recorded in cm.

The data collected on various traits were subjected to correlation and path analyses. The data were subjected to Anova and Anacova by the methods proposed by Cochran and Cox (1957). The genotypic correlation coefficients (r_G) among all the traits were determined from the variance and covariance components. The correlation coefficients were further partitioned into direct and indirect effects with the help of path coefficient analysis. The 10 most productive clones, relative to the commercial checks, were considered in detail to determine what traits may be important in determining productivity under moisture-limited conditions.

Results and discussion

Among 20 biparental crosses involving commercial cultivars, the cross Co 740 × CoA 7602 produced progenies with a better range for cane yield and HR Brix (°) with better percent superior progenies in normal irrigated environment (Table 1). Though one transgressive segregant was recovered from the cross in clonal stage III, the cross scored a lower percentage of superior progenies in the moisture-stress regime in clonal stage I.

Out of 17 poly crosses, five involving female parents Co 8013, Co 8371, CoC 771, CoV 92101, and C 81615 produced better percentage of superior progenies with a wide range of variability for cane yield and HR Brix (°) both in seedling and clonal generation under non-stress and stress environments. Transgressive segregates (productive) under moisture stress were recovered from all these five polycrosses. The CoV 92101 PC produced a maximum of three productive segregants.

Eight general crosses produced a better number of progenies wherein only two viz., Co 88025 GC and CoC 671 GC exhibited a better range of variability for both cane yield and HR Brix (%). Both the general crosses produced transgressive segregates under moisture stress.

Character association analysis in selected sugarcane progenies evaluated under moisture stress environment

In sugarcane, cane yield is a complex character influenced by a number of inter-related component traits. This often influences the direct relationship with cane yield and, as a result, the information based on correlation coefficients is not dependable. Since path coefficient analysis gives a more realistic relationship of characters, an attempt has been made in the present study to identify the effective components of cane yield having either positive or negative significant association with cane yield.

Path coefficient analysis was used in working out the direct (diagonal values) and indirect (off diagonal values) effects of 20 characters on cane yield per plot under moisture stress (data not presented). The genotypic path coefficient analysis accounted for a major part of the total variation in cane yield as indicated by relatively lower residual effects.

The results of the present investigation indicated some interesting facts. The characters like average number of internodes, tillers at 80 DAP, average root length and root number had a relatively high positive correlation with cane yield, but had negative direct effects. A similar observation was made by Patel et al. (1993). However, Khan et al. (2001) reported a positive association of number of internodes, number of millable canes and millable cane height with cane yield and positive direct effect.

From a breeder’s viewpoint, characters could be useful as selection criteria if they not only have a high positive correlation, but also exert high direct effects. In this context, number of internode formed shoots (at 120 DAP), single cane weight, average long root length, 8th leaf area, and leaf sheath moisture had a significant and positive association (correlation) with cane yield per plot and exerted high direct effect. Similar results were obtained by Bodhinayake et al. (1998), Kamat and Singh (2002) and Wagih et al. (2003). However, Srivastava et al. (1997) expressed a contrasting view to these findings.

Single cane weight, which is an important cane yield component, was highly significantly correlated with cane yield and with a better direct effect indicating its importance in enhancing cane yield. However, Bissessur et al. (2001) expressed that, in any environment, selection of a combination of traits is more important than any single trait.

The characters like cane height, number of internode formed shoots at 160 DAP, and root dry matter had a relatively high positive association with cane yield, but their direct effects were relatively lower indicating direct selection for these traits may not be effective under a moisture-stress environment. Bodhinayake et al. (1998) expressed similar views with respect to number of roots in the surface horizon.

The juice extraction percent, relative water content, and mean tilt angle (leaf angle) of leaves had a low non-significant negative association with cane yield but had higher direct negative effects suggesting higher cane yield genotypes can be identified with acute leaf angle.

Hence, from the genotypic path analysis study, for improvement of cane yield under moisture-limiting conditions, emphasis must be placed on the number of internode formed shoots at 120 DAP, single cane weight (at harvest), average long root length, 8th leaf area, and the leaf sheath moisture at the end of the formative stage.

The other traits like number of internode formed shoots at 160 DAP, cane height and girth at harvest also can be considered as additional selection criteria for improvement of cane yield, under moisture-limiting conditions.

Path coefficient analysis of bio physical traits for cane yield

Path coefficient analysis was used to determine the direct (diagonal values) and indirect (off diagonal values) effects of six biophysical traits under moisture stress and non stress (after alleviation) conditions on cane yield per plot (data not presented). The genotypic path coefficient
analysis accounted for only about 50 percent of the total variation in cane yield as indicated by considerable residual effects.

All the bio-physical traits under stress condition in the mid-formative stage had no significant association with cane yield. Similarly, little variation for photosynthetic traits among sugarcane clones was observed by Singh et al. (1994). Even after alleviation from stress, all the photosynthesis related traits except photosynthesis rate had non-significant association with cane yield, whereas photosynthesis rate only had significant positive association with cane yield indicating the clones differed significantly with respect to this parameter after alleviation from moisture stress. The cultivars also differed for their ability to recover from stress after irrigation. Ali et al. (2003) reported that drought tolerant clones had a remarkable ability to recover after re-watering if the stress period was not prolonged or too severe.

Photosynthetic rate after alleviation from stress (0.716) had the highest direct positive effect on cane yield, followed by Light Use Efficiency (LUE) under moisture stress (5.322). The highest negative direct effect on cane yield was from transpiration rate after alleviation of stress (–0.644) followed by photosynthetic rate under moisture stress (–6.001) (Table 2). This suggests that the varietal adjustment/adaptive ability under moisture stress through better light use efficiency and regaining higher photosynthesis rate after relief from stress are important parameters which had positive direct effects on cane yield, and high rate of photosynthesis after stress alleviation is equally important for rejuvenation of cultivars which was achieved through high transpiration. The better LUE under stress and high photosynthesis rate after alleviation of stress are important for mitigating stress and regaining normal (or enhanced) growth. Genotypes with such important features could be ideal under moisture stress, as results clearly indicated the role of these traits towards higher productivity. This finding is in accordance Adarsha (2004), who reported cotton genotypes responded for rejuvenation ability through higher stomatal conductance. Both the maintenance of photosynthetic ability in stress and better rejuvenation capacity after stress alleviation are important for imparting moisture stress tolerance in sugarcane progenies studied. Srivastava et al. (1996) reported the role of rejuvenation capacity for drought-tolerant cultivars Co 1148, Co 5769, and Co 5823 through high stomatal conductance and transpiration. The higher positive indirect contribution of photosynthesis rate to cane yield per plot was through LUE under stress.

Hence, from the genotypic path analysis study, LUE under stress and high photosynthesis rate after stress alleviation through high transpiration largely contribute to cane yield. Hence, for improvement of cane yield under moisture stress environments, emphasis must be placed on LUE under stress and high photosynthesis rate after stress alleviation as evidenced in productive progenies in the moisture-stress environment.

Contribution of important traits towards productivity under moisture stress

The analysis of variance of the replicated clonal data revealed highly significant differences among the genotypes for all characters except leaf temperature, WUE percent under stress, and 8th leaf area. The mean values for important contributory traits in the top ten superior cane yielding progenies over best check are given in Table 2.

The important cane yield components, single cane weight, NMC, and millable cane height played a major role among various other components, contributing towards excellence of nine progenies:- SNK 632, SNK819, SNK 822, SNK 827, SNK 024, SNK 813, SNK 707, SNK 782, and SNK 806 over the best check Co 86032.

The internodes formed shoots, root dry weight, average long root length, LAI, and 8th leaf area had a significant role among various physiological parameters studied in cane yield formation. The superior top 10 cane yielding progenies recorded a higher number of internode formed shoots even under moisture-stress condition indicating their tolerance to moisture stress or the potential to maintain growth rate under moisture-stress condition. The tolerance capacity could be due to higher...
root dry matter and deeper (long) root growth, features observed in top productive progenies compared to the best check Co 86032. In addition, these progenies also had higher leaf sheath moisture percent, lower leaf lamina moisture percent, and higher LAI and 8th leaf area.

The maintenance of a productive shoot population under moisture stress is an important character for better productivity. This was studied through mortality percent of tillers at 90 and 120 DAP, i.e., mid-formative stage under moisture stress. The top productive progenies exhibited lower mortality percent at the initial (90 DAP) stress period, whereas higher mortality was observed at later (severe) stages of moisture stress, thereby reducing total shoots per unit area. The progenies produced a higher number of productive shoots (internode formed shoots) compared to the check variety Co 86032. In the case of the moisture-stress sensitive variety Co 86032, though total shoot population maintained was high with reduced mortality, the productive shoots (internode formed shoots) were lower, thereby reducing single cane weight and lower NMC at harvest.

The top productive progenies did not differ much from the best check Co 86032 for all the photosynthesis related traits under the moisture-stress condition, indicating minimum role of these traits for imparting moisture stress tolerance. Instead, the high productive progenies SNK 632, SNK 819 and SNK 024 had inferior water use efficiency because of higher transpiration compared to checks. The higher productivity in spite of lower water use efficiency could be due to their inherent capacity to utilise moisture available at lower soil layers through a deep root system compared to the check cultivars which were more sensitive to moisture stress. Thereby these progenies maintain growth under stress at comparatively high expense of water, i.e., low water use efficiency.

The rejuvenation capacity after alleviation from moisture stress is also an important parameter for higher cane productivity under a moisture-stress environment. In the case of top productive progenies, SNK 632 and SNK 819, photosynthesis rate was significantly higher compared to the best check (Co 86032) after relief from stress (Table 2), indicating their higher rejuvenating potential to utilise available moisture, and this could also be due to a better root system.

The pedigree of these top productive progenies indicate that the crosses Co 8013 PC, CoV 92101 PC, C 81515 PC, Co 88025 GC, Co 740 × Co A7602, CoC 771 PC, Co 8371 PC, CoC 671 GC, and CoC 771 PC were promising for obtaining superior progenies to improve productivity under a moisture-stress environment. This indicates the role of parents, Co 740, CoA 7602, and Co 8013 in attributing drought tolerance to their progenies. These findings suggest the importance of family selection and also the role of parental selection with required features to obtain heterotic progenies combining better moisture-stress tolerance and higher productivity.

**Conclusion**

The bi-parental cross Co 740 × CoA 7602, the poly crosses involving female parents Co 8013, Co 8371, CoC 771, CoV 92101 and C 81615 and general crosses involving female parents Co 88025 and CoC 671 found proven on the basis of variability obtained for cane yield and HR Brix (°) and recovery of transgressive segregates. For improvement of cane productivity under a moisture-stress regime, emphasis must be placed on traits like early cane internode formation, stalk weight at harvest, root length and leaf sheath moisture at end of formative phase. Among biophysical traits, the light use efficiency at stress and photosynthesis rate after alleviation of stress are important for identification of productive genotypes. The performance of the top 10 productive hybrid progenies clearly demonstrated the contribution of the above traits towards improved productivity under moisture stress. The productive progenies could be promoted to advanced yield trials and also be utilised in current breeding programs as donors for moisture-stress tolerance.

Résumé

Le stress hydrique est le principal facteur abiotique prévalent dans presque toutes les régions cannières de l’Inde, occasionnant une baisse sévère de la productivité en sucre. Sous ces conditions, le développement des cultivars productifs, tolérants au stress hydrique revêt une grande importance pour maintenir la production sucrière. Par conséquent, cette étude a été entreprise afin d’identifier les familles et les caractères appropriés pour sélectionner des génotypes améliorés capables de rehausser la productivité sous un régime de stress hydrique. Une population de plantules issues de 45 combinaisons génétiques ont été étudiées sur les générations clonales issues de plantules et de boutures pour leur paramètres de variabilité génétique à l’aptitude à produire des clones supérieurs pour le rendement en canne et en sucre en absence et en présence de stress hydrique respectivement. De plus, l’analyse des pistes et la performance moyenne ont été étudiées pour identifier les caractères importants contribuant au rendement sous les conditions de stress hydriques chez 50 génotypes sélectionnées au stade clonal III avec trois témoins. Les polycroisements impliquant Co 8013, CoV 92101, C 81615, CoC 771, Co 8371, des croisements généraux comprenant Co 88025 et CoC 671 comme parent femelle et un croisement Co 740 × CoA 7602 ont démontré une large gamme de variabilité pour le rendement en canne et en sucre et produit un pourcentage plus élevé d’individus transgressifs et supérieurs. L’analyse des pistes génotypiques comprenant six caractères biophysiques ont démontré que l’efficience de l’utilisation de la lumière (LUE) sous conditions de stress hydrique et le taux de photosynthèse après allègement du stress par la transpiration accentuée ont contribué largemen t au rendement canne. De même, l’analyse des pistes de 20 autres caractères sous des conditions de stress hydrique a souligné le rôle majeur de la formation précoce des entrenœuds, la longueur des racines et la biomasse, la surface foliaire et l’humidité de la gaine en fin de stade de développement pour des rendements plus élevés. Les autres caractères comme le tallage à mi-chemin du stade de formation, et le poids de la tige (SCW) à la récolte peuvent aussi être considérés comme critères de sélection pour améliorer le rendement. Par conséquent, pour le rehaussement génétique de la productivité de la canne dans les environnements de stress hydrique, les familles/croisements identifiés pourraient être considérés comme « éprouvés » pour l’identification de descendance tolérante et plus productive sous les conditions de stress hydrique. Les caractères identifiés sont efficaces et utiles pour la sélection des clones performants et tolérants au stress hydrique. Ces clones pourraient être promus au stade essais variétaux.
PRUEBAS DE CLONES AGRONÓMICAMENTE ACEPTABLES DE FAMILIAS EVALUADAS BAJO CONDICIONES LIMITADAS DE POCA HUMEDAD USANDO UN AMBIENTE CONTROLADO CON LIMITACIONES DE HUMEDAD PARA INCREMENTAR LA PRODUCTIVIDAD Y DETERMINACIÓN DE POSIBLES CARACTERES DE SELECCIÓN

PALABRAS CLAVE: Tolerancias a Estrés por Humedad, Evaluaciones de Estrés Bajo Condiciones Controladas, Producción de Caña, Rejuvenecimiento Pos-Estrés.

Resumen

EL ESTRÉS por humedad es el principal estrés que ocurre en casi todas las aéreas cañeras de la India, causando reducciones drásticas en la producción de caña y azúcar. Bajo estas circunstancias, el desarrollo de cultivares productivos y tolerantes al estrés por humedad es de gran importancia, para sostener la producción de caña y azúcar. Por ello, el estudio se llevó a cabo para identificar familias y caracteres de importancia para mejorar genéticamente la productividad bajo condiciones ambientales de estrés. Una población híbrida de 45 cruzas intervarietales fue estudiada para identificar la variabilidad de parámetros y el porcentaje de segregantes superiores para producción de caña y azúcar en plántulas de semilla sexual y trozos de generaciones clonales bajo condiciones ambientales de no-estrés y estrés, respectivamente. También, se realizó el análisis de sendero y el comportamiento promedio para identificar los caracteres importantes que contribuyen a la productividad bajo condiciones ambientales de estrés de 50 materiales seleccionados de Estado III con tres testigos. Los policruzamientos que incluyen Co 8013, CoV 92101, C 81615, CoC 771, Co 8371, y las cruzas generales con Co 88025 and CoC 671 como padres femeninos, y una cruz de Co 740 × CoA 7602 mostraron un mejor rango de variabilidad en producción de azúcar y caña, así como un mejor porcentaje de segregantes trangresivos superiores. El análisis de sendero del genotipo que incluyó seis caracteres biofísicos mostró que la eficiencia del uso de la luz (LUE) bajo estrés de humedad y la tasa de fotosíntesis luego de disminuir el estrés a través de la transpiración, contribuyó enormemente para la producción de caña. En forma similar el análisis de sendero para otros 20 caracteres bajo estrés de humedad mostró un rol principal en la formación temprana de los entrenudos, largo de raíz y biomasa, área de hoja y humedad de de la superficie de la hoja al final del estado formativo para alta producción de caña. Los otros caracteres como número de tallos en la mitad del estado formativo y el peso de tallos individuales (SCW) a la cosecha pudieron usarse como criterios de selección para mejorar la producción de caña. Para el mejoramiento de la producción de caña bajo condiciones limitadas de humedad, las familias/cruzas identificadas pudrían ser consideradas como ‘pruebas’ para separar progenies tolerantes y productivas bajo condiciones de estrés por humedad. Los caracteres identificados son útiles y efectivos para la identificación de clones tolerantes y promover su uso para otros ensayos de rendimiento.
EFFECT OF ALTITUDE ON SUGARCANE FLOWERING SYNCHRONISATION IN CUBA

KEYWORDS: Sugarcane, Flowering, Synchronisation.

Abstract

SUGARCANE breeders have found some difficulties in making crosses associated with flowering induction and synchronisation. The objectives of this investigation were to evaluate the relative importance of the factors involved in the altitude for sugarcane flowering induction and to establish the basis of a controlled breeding program. This study is related to flowering of 100 sugarcane cultivars from 1990–2007 at three altitudes (100, 400 and 800 m above sea level) in Cuba. Sugarcane flowering is primarily in response to photoperiod, and it is conditioned by additional factors that can reduce, inhibit or delay it. In September, the average maximum (28–30°C) and minimum (21–22°C) temperatures were optimum for flowering. The extent of flowering was much greater at 400 m, with a marked reduction at 100 m, and intermediate at 800 m. In Cuba, late-flowering sugarcane cultivars start to tassel in the first week of December. At lower altitude, the same cultivars have earlier flowering by an average of 2–4 weeks. A negative linear correlation between percentage of pollen fertility and altitude was observed. In the study, a rise in altitude was accompanied by a large drop in maximum temperature and very little change in the minimum range. Growing cultivars in nurseries at different altitudes proved a useful tool to increase the clonal range and extent of flowering in Cuba.

Introduction

Sugarcane flowering is a complex physiological process consisting of multiple stages of development, each stage having specific environmental and physiological requirements (Julien, 1972).

Natural flowering is variable because it is affected by environmental factors such as daylength, temperature, moisture and nutrition.

Flowering of parental clones is restricted to specific periods, but there are clones that flower at different dates and therefore cannot be used easily in crossing (Nuss and Berding, 1999).

The Cuban sugarcane breeding program began at Cienfuegos in 1905 and it continues until the present time. At this time, Cuban National Center for Sugarcane Hybridisation is located in Sancti Spíritus (Caraballosol et al., 1999/2000).

Sugarcane flowers naturally in Sancti Spíritus, but the number of clones, intensity and flowering date, as well as the fertility of pollen, is different among sites located in different altitudes and years (Aguilar and Debernardi, 2004).

The objectives of this investigation were to evaluate the relative importance of the factors involved in the altitude for sugarcane flowering induction and to establish the basis of a controlled breeding program.
Materials and methods

Experimental locations

The trial was carried out at three locations in the Cuban National Center for Sugarcane Hybridisation (NCH), located in different altitudes within Guamuhaya’s mountains (Table 1).

masl = metres above sea level

Photoperiod at Cuban National Center for Sugarcane Hybridisation

The three experimental sites have similar latitude (22°). The sunrise and sunset data used were obtained through the Spanish Armada’s web site:
http://www.armada.mde.es/ArmadaPortal/page/Portal/ArmadaEspannola/ciencia_observatorio/03_Efemerides--01_Sol--02_Salidas_es

The duration of the day was calculated, and the inductive period was determined, considering that it is produced between times while the day lasts for 12.5 and 12.0 hours. With these data, the time of daily decrease was also calculated using the formula

\[
\text{Daily decrease} = \frac{30}{IP},
\]

where IP = Inductive period (days) and 30 are the minutes for daylength of the IP.

Climate of experimental locations

Data were provided by the Cuban National Meteorology’s Institute for the three altitudes over an 18 year period. Variables taken monthly were:

- Maximum average temperature (Tx)
- Minimum average temperature (Tn)
- Maximum average relative humidity (RHx)
- Minimum average relative humidity (RHN)
- Total rainfall (TR)
- Day with rainfall (DR)

Each variable was divided in three ranges (high, middle and low) as it is indicated in Table 2. This information was used to calculate the range of temperatures and its relationship with flower induction.

**Cultivars**

One hundred random cultivars from the Cuban Sugarcane Germplasm Bank, with a wide genetic variability, were used in the study. For each cultivar, number of stalks, flowered stalks and percentage of flowered stalks (PFS) were analysed. Date of flower emergence (DFE) and percentage of pollen fertility (PFP) also were recorded.

Results and discussion

**Flowering by test locations**

Buenos Aires, located at 400 m altitude, was the site with highest and earliest flowering, and intermediate values for pollen fertility (Figures 1–3). Mayari, located at 800 m altitude, was the site with latest flowering and had lower pollen fertility than Guayos, located at 100 m altitude. Those results enable the design of a strategy for sugarcane flowering synchronisation and sex management in cultivars flowering at the three test locations.

![Fig. 1—Flowering intensity by location.](image)

![Fig. 2—Date of first flower emergence by location.](image)

![Fig. 3—Pollen fertility by location.](image)

Comparisons among locations of different altitudes have been carried out in some countries. Van-Breemen et al. (1963) report greater flowering in Km 14 area, located at 450 m altitude in the Dominican Republic, while Clements and Awada (1964) found a tendency for greater flowering above 390 m in Hawaii. On the other hand Yeu (1980), in China, reported better flowering 335 m in the town of Chungshen. In Australia Pollock (1981) found good flowering in Walkamin at 580 m. Nayamuth et al. (2003) in Mauritius reported a tendency to better flowering with altitude. Aguilar and Debernardi (2004) studying the variety CP72-2086 at different altitudes of Mexico reported better flowering at 292 to 477 m. In Guatemala, Polo (2005) reported good flowering at two heights (300 and 760 m).

**Inductive period in NCH**

The inductive period in the NCH (22° north latitude) is from days 247 to 272. That is to say, from 4–29 September, totalling 26 days with a decrease of 1.15 minutes/day (Figure 4).

![Fig. 4—Photoperiod at 22° north latitude (1: flower induction; 2: daylength; 3: sunrise with morning twilight; and 4: sunset with morning and evening twilight).](image)
Value of decreasing of 1 minute per day has been used in some countries to produce flowers in artificial conditions (Brett and Harding, 1974; Miller and Li, 1995; Nuss and Berding, 1999; Silva et al., 2005; Berding et al., 2007). This analysis suggests that the photoperiod is not a problem for flowering under our study conditions.

**Flowering and climate relation**

The temperature (maximum and minimum) was the climate variable with the greatest influence on flowering (Table 3). The other variables didn't have such a marked influence. These would be associated with no difference between locations for rainfall. In contrast, the temperature, mainly maximum, decreases with altitude.

The mean values for temperature are the best indicators for flowering potential (Figures 5 and 6). The best results were obtained at the experimental site located at 400 m (Buenos Aires). Optimum values of temperature reported by Nuss (1980) ranged 23–28°C, while Berding (2005) considered critical temperature for flowering to be 21–32°C.

Table 4 shows a sudden decrease in the maximum temperature with altitude but not in the minimum temperature. As a result, there is a narrower range between the temperatures. Clements and Awada (1967) reported an appropriate flowering in ranges of temperatures between 6–10°C.

Flowering is sensitive to decreases in low temperature (Coleman, 1962). Panicle emergence is delayed at temperatures below 21°C (Clements and Awada, 1967, Nuss and Brett, 1977). Lower temperature increases the time for emergence of the panicle, but also the final duration (Edwards and Paxton, 1979). When night temperatures rise, flowering could be increased by 11 days in the tropics (Berding, 1981).

The development of the pollen is especially sensitive to cold temperatures (Brett, 1950; Levi et al., 1978; Chilton et al., 1967; Berding, 1981). Dunckelman (1967) was able to increase or to induce pollen fertility of sugarcane parents through the control of the climate (introducing the plants at night inside a glasshouse) and selection of male progenitors. The pollen fertility decreases when temperature is lower than 18°C or higher than 27°C (Nuss and Berding, 1999; Moore, 1987). According to optimum flowering temperature values (Table 5), the best location to exploit flowering, in Cuba, was Buenos Aires.

Conclusions

- Buenos Aires is the location for highest flowering in Cuba, of the locations studied. It is located at 400 m altitude, with the best ranges of maximum (28–30°C) and minimum (21–22°C) temperature, in the month of September when the inductive period takes place, with similar values at other sites of good flowering in the northern hemisphere.
- There were differences in cultivars flowering date and pollen fertility among the locations studied. They enable the design of a breeding program with greater use of the parents flowering in these three locations through their synchronisation.

MOTS-CLÉS: Canne à Sucre, Floraison, Synchronisation.

Résumé

Les généticiens-sélecteurs ont des difficultés pour réaliser des croisements en raison des problèmes liés à l’induction et à la synchronisation de la floraison. Les objectifs de ce travail visent à étudier l’importance relative de l’altitude sur la floraison et d’établir les bases pour l’hybridation contrôlée. L’étude concerne l’influence de l’altitude (100, 400, et 800 m au-dessus du niveau de la mer) sur la floraison de 100 cultivars de canne à sucre à Cuba entre 1990-2007. La floraison de la canne à sucre est fonction de la photopériode, mais elle est aussi tributaire d’autres facteurs qui peuvent réduire le taux de floraison, l’entraver ou la retarder. En septembre, les températures moyennes maximales (28–30°C) et minimales (21–22°C) conviennent à la floraison. Le taux de floraison était plus important à 140 m, intermédiaire à 800 m avec une réduction marquée à 100 m. À Cuba, les cultivars à floraison tardive fleurissent dans la première semaine de décembre. La floraison de ces cultivars est avancée de 2-4 semaines en moyenne à une élévation inférieure. Une corrélation négative linéaire a été observée entre la fertilité pollinique et l’altitude. Une élévation croissante engendre une baisse significative des températures maximales mais avait peu d’effet sur les minimales. La plantation des pépinières de cultivars à différentes altitudes augmente les possibilités de floraison pour le programme d’hybridation à Cuba.
EFECTO DE LA ALTITUD SOBRE LA sincronización DE LA floración DE LA CAÑA DE ÁZUCAR EN CUBA

PALABRAS CLAVES: Caña de Azúcar, Floración, Sincronización.

Resumen

Los mejoradores de caña han encontrado dificultades para realizar cruzas en relación al florecimiento y su sincronización en caña de azúcar. Los objetivos de este estudio fueron estudiar la importancia relativa de los factores que se involucran con la altitud para el florecimiento de la caña de azúcar y establecer las bases para un sistema controlado de cruzamientos. El estudio relaciona al florecimiento de 100 cultivares entre 1990–2007 en tres altitudes (100, 400 and 800 m sobre el nivel del mar) en Cuba. La floración de la caña de azúcar está dada principalmente por el fotoperíodo y está condicionada por varios factores que pueden reducir, inhibir o demorar el proceso. En Septiembre, el promedio de temperatura máxima (28–30°C) y mínimo (21–22°C) fueron óptimos para la floración. La floración se extendió mejor a los 400 m de altitud, con una reducción marcada a los 100 m, e intermedia a los 800 m. En Cuba, las variedades que florecen tardíamente inician con un promedio de 2–4 semanas más temprano. Un correlación lineal negativa entre el porcentaje de la fertilidad del polen y la altitud fue claramente observada. El estudio mostró que un incremento en la altitud estuvo acompañada por una baja de la temperatura máxima y un pequeño cambio dentro del rango mínimo. El estudio demostró que al sembrar cultivares en parcelas a diferentes altitudes es una herramienta útil para incrementar el rango de clones a usarse y extender la floración en Cuba.
DEVELOPMENT OF SUGARCANE VARIETIES IN COLOMBIA
FOR SITE-SPECIFIC AGRICULTURE

KEYWORDS: Sugarcane, Varieties, Agroecological Zones, Site-Specific Agriculture.

Abstract
SUGARCANE variety CC 85-92 is currently planted on more than 69% of the area in sugarcane in Colombia, a situation that is of concern in light of possible disease problems that could affect the productivity of the industry. Thus, CENICAÑA has focused on selecting varieties within the framework of site-specific agriculture. After the regional trials, from three to five varieties per series that are equal to or better than the check used in these trials are made available to the sugar mills. The most promising varieties then undergo a process of multiplication and monitoring to determine response to different agroecological zones and to make available to the growers more varieties with site-specific adaptation. To date, varieties CC 92-2804, CC 93-3895 and CC 93-4418 stand out. In the semidry zone, these three varieties yielded equal to or better than CC 85-92, thereby constituting promise for the industry.

Introduction
The Colombian Sugarcane Research Center (CENICAÑA) considers the selection and development of a sugarcane variety as the result of integrating the knowledge of its researchers, agronomists from the sugar mills, and sugarcane growers who seek to increase the productivity and profitability of a given agroecological zone. The approach used in CENICAÑA’s field research is site-specific agriculture (SSA), which provides the framework for the Variety Program in its varietal selection and development processes. The fourth version of the agroecological zoning of the Cauca River Valley, based on a detailed study of soils and the regional water balance, established the existence of 149 agroecological zones in the 216 764 ha studied (Carbonell et al., 2009).

The progress made in selecting and developing varieties within the framework of SSA, the identification of the agroecological zones where certain varieties have greater productivity, and the definition of different alternatives for planting varieties in the different agroecological zones of the Colombian sugar sector are presented here.

Materials and methods
Agroecological zoning
The fourth approximation of the agroecological zones for the sugarcane crop in the Cauca River Valley was based on a detailed study of soils (scale 1:10 000) that the sector carried out in the total area planted with sugarcane (216 764 ha) as of 2002 and on more complete information on daily rainfall coming from 216 pluviometric stations for more than 15 years. The new agroecological zones were formed in accordance with the following factors: (a) regional water balance, which includes rainfall and evapotranspiration; (b) a detailed study of soils in the area planted with cane in the Cauca River Valley; (c) homogeneous soil groups, defined on the basis of soil texture, moisture regime and effective depth of the soil or the distance that the roots of plants can penetrate without chemical or physical barriers; and (d) water regime groups formed in accordance with the water balance and the permeability of the soil and adjusted for signs of poor drainage, depth and the slope of the terrain. The agroecological zoning was generated with the
Geographic Information System, while statistical methods and geostatistics were used to analyse the data. A total of 149 zones were identified (Carbonell et al., 2009).

**Selection sites**

To facilitate the selection of varieties within the SSA approach, the 149 agroecological zones were regrouped on the basis of two criteria: water regime and soil texture, forming three zones: Semidry, Wet and Piedmont. Selection sites were established in each zone, where parallel processes of plant breeding are being carried out, facilitating the selection and development of varieties for the different agroecological zones of the sugar sector.

Selection for the Semidry Zone is centralised at CENICAÑA’s San Antonio de los Caballeros Experiment Station (SAES). Selection for the Wet Zone is carried out at the Cachimbalito Sugar Estate (Incauca S.A.) and occasionally at the La Cabaña or La Victoria sugar estates (La Cabaña Sugar Mill). Selection for the Piedmont Zone is done primarily on the Piedechinche Sugar Estate (Providencia Sugar Mill) and occasionally on Los Ranchos Sugar Estate (Central Castilla Sugar Mill).

**Germplasm evaluation**

At each of the varietal selection sites, CENICAÑA’s germplasm bank (1305 entries) was evaluated, identifying the varieties that were adapted best to each zone and then forming elite parental groups. The selection of the parents to be used in the crosses was done using the System of Information of Varieties – SIVAR, where there is a specific module for programming crosses. This module uses an algorithm that takes into account varietal traits such as sucrose (% cane), stalk diameter, leaf shedding, flowering, tillering, lodging, population and height, which are scored by means of descriptors that are expressed in relation to the check, as well as resistance to smut, rust and mosaic diseases, which are scored in accordance with the international scales proposed by the International Society of Sugar Cane Technologists (ISSCT) (Viveros et al., 2009).

**Selection of clones**

For each of the varietal improvement sites, specific crosses are designed and made each year, both at the SAES and at the Sugarcane Research Station in Tapachula, Mexico, due to high naturally flowering induction. True seed is planted in each varietal improvement site to establish seedling populations where selection is carried out at the different stages. In Stage I, the selection is done by family, identifying the best crosses for sucrose in the plant crop, and then in the first ratoon selecting the best individuals phenotypically that pass on to Stage II. Then, the best clones are selected for continuing on to Stage III and are planted in two agroecological zones for two crops, at the end of which varieties are selected for the regional trials, which are planted in the principal agroecological zones of the Cauca River Valley. The regional trials are established at the sugar mills with the largest area in the agroecological zones of greatest interest in order to obtain the best coverage possible. The regional trials are set up in experiments with a lattice design: 6-furrow strips along the plot with 3 replications over 3 crops. This experimental design gives varietal production results very similar to their performance on a commercial scale (CENICAÑA, 2008).

**Monitoring and multiplication**

At the end of the process, approximately 9–9.5 years after several cycles of selection, certain varieties stand out for their productivity in terms of TCH, sucrose (% cane) and TSH. Although the information that is available about these varieties comes from small areas, the results characterise the best varieties with respect to the check and orient the multiplication for conducting the final evaluations on harvest, lifting, transportation and delivery of the cane, as well as factory processes. CENICAÑA, together with the sugar mills and growers, carries out the planting and multiplication of the new varieties, identifying the sites or agroecological zones where those new varieties have a level of productivity higher than the most cultivated variety in the zone. Similarly, agroecological zones are identified where those varieties are equal to or have slightly less productivity than the
most cultivated variety in the same zone. In this way, the sites, agroecological zones or niches are identified where the new varieties warrant planting or where they should be because of low productivity.

Results and discussion

Selection sites

The 149 agroecological zones identified by Carbonell et al. (2009) were regrouped according to the water regime groups and the textural classes of the soil, thereby forming (a) the **Semidry Zones** (H0, H1 and H2 as described by Carbonell et al. (2009)), comprising 41 of the 149 agroecological zones, except for those located in the Piedmont of the Eastern and Western Andean mountain ranges, for a total of 135,975 ha; (b) the **Wet Zones** (H3, H4 and H5), which comprise 47 of the 149 agroecological zones, excluding those located in the Piedmont of the Eastern and Western Andean mountain ranges, for a total of 55,345 ha; and (c) the **Piedmont Zones**, which comprise 61 of the 149 agroecological zones in accordance with the groups of soils located in the Piedmont of the Eastern and Western Andean mountain ranges, but without taking into account the water regime conditions. This zone is comprised of 25,444 ha.

Evaluation of the germplasm bank

In each of the varietal improvement sites, CENICAÑA’s germplasm bank (approximately 1305 entries) were evaluated and characterised in two crops. The best varieties are identified based on production of cane, sucrose (% cane) and health, establishing elite groups of varieties that are used in crosses specific for each improvement site.

The design of the crosses is done using a tool that simultaneously takes into account all the traits with their respective restrictions, seeking complementarity and beginning by comparing the first variety of the group with the second and so on with the others. Then, the second variety is compared with those that follow and so on until finishing the comparisons between all the varieties in the group.

The basic principle of the algorithm consists of adding the values of the two varieties being considered for a given trait; if the sum is equal to or less than a given critical value, this process continues on to the second trait and so on until completing all the comparisons. If at any time the sum of a trait goes over the critical level, that cross will not be made.

Selection of clones

Every year, the selection process is begun with 120,000 seedlings that are distributed among the three selection sites. The best genotypes (clones and varieties) are selected in each of three stages and selection sites in accordance with the criteria or traits that the selected genotypes should have, referred to as *fundamental* (i.e. high content of total reducing sugars, high production of cane per ha, low flowering, and resistance to smut, rust and mosaic) and *desirable* (e.g. erect, high leaf fall, hairless leaf sheaths, resistance to yellow leaf virus, ratoon stunting disease, leaf scald and the yellow sugarcane aphid).

When the varieties have all the fundamental traits and some of the desirable ones, they continue the selection process through the three stages in each of the selection sites, until reaching the end of the process when 10–15 varieties are considered apt for establishing the regional trials located in the Semidry, Wet and Piedmont Zones, depending on their respective selection site.

Given that the conditions of these selection sites represent agroecological zones with different levels of productivity, specific objectives have been established as follows: (1) for the **Semidry zone**, varieties are selected that increase the minimum sucrose content by 5% and maintain the TCH in comparison with the check in the zone; (2) for the **Humid zone**, varieties are selected that increase the minimum sucrose content by 5% and increase the TCH by 15%; (3) for the **Piedmont zone**, varieties are selected that maintain the sucrose content and increase the TCH by 15%.
At the end of the process, approximately 9–9.5 years after having planted all the progeny of a given cross, some clones stand out for their productivity in TCH, sucrose (% cane) and TSH. Although the information that is available on these varieties comes from small plots, the results characterise the best varieties with respect to the check and orient the multiplication of the same for conducting final evaluations on the harvest, lifting, transportation and delivery of the cane, as well as factory processes.

**Multiplication and monitoring of the new varieties**

CENICAÑA’s agronomists, together with agronomists from the sugar mills and the growers, carry out the planting and multiplication of the new varieties, identifying the sites or agroecological zones where those new varieties have a higher level of productivity than the most cultivated variety in a given zone. Similarly, agroecological zones are identified where those varieties are equal to or have a lower level of productivity than the most cultivated variety in the same zone. In this way, the sites, agroecological zones or niches where the new varieties merit being planted and where not are determined. As a result of the selection, development, monitoring and multiplication of the varieties that are being carried out, there is a renovation of the varieties that the Colombian sugar sector has been planting for several years (see Table 1).

When comparing this information with that obtained in previous years, it can be seen that varieties V 71-51, PR 61-632, MZC 74-275, RD 75-11 and Co 421 have been decreasing their area planted, being replaced by new higher yielding varieties in the respective agroecological zone. The sugar sector’s dependency on CC 85-92 can also be observed in more than 69% of the zone, which is a risk from a sanitary standpoint given that it is not exempt from the influx of a new pest or disease that can cause losses in production as has occurred in other countries (Magarey et al., 2001).

As a result of the multiplication and monitoring of the new varieties, data are given on the monitoring and multiplication of varieties CC 93-3895, CC 92-2804 and CC 93-4418, as an example of the three varieties with greatest growth in the industry during the past two years.
Variety CC 93-3895 has been harvested on 3857 ha in 51 agroecological zones, and has been equal to or higher in productivity (TCH, real factory yield and TSH) in 35 of them. Figure 1 shows the zones (10H2, 5H2, 7H0, 23H2, 29H1, 8H5, 6H2, 11H4, 6H4, 10H4 and 11H5) that cover 23 242 ha (11%) of the total area planted in cane, where CC 93-3895 is significantly higher in productivity (green colour) than the checks CC 85-92 and CC 84-75. Agroecological zones (15H0, 23H1, 11H1, 11H0, 15H1, 6H1, 5H4, 5H5, 30H2, 30H0, 5H3, 18H1, 31H0, 6H0, 22H0, 13H2, 18H3, 7H2, 10H5, 1H1, 8H3, 21H2, 6H3 and 8H2) where CC 93-3895 is equal in productivity (blue colour) to the checks cover 132 615 ha (65%) of the total area planted in cane. Those agroecological zones (30H1, 14H2, 11H3, 18H5, 14H1, 13H3, 18H2, 11H2, 24H2, 15H2, 8H4, 30H3, 23H4, 31H2, 17H5 and 18H0) where CC 93-3895 is lower in productivity (red colour) than the checks cover 33 446 ha (16%) of the total area planted in cane. The zone where the variety has been planted most is 6H1, where 954 ha have been harvested; the commercial results over the various crops are given in Table 2. Productivity has been stable over the four crops despite the decrease in the age of the cane at harvest.

Fig. 1—Agroecological zones where CC 93-3895 had a productivity (TSHM) higher (green), equal to (blue) or less (red) than the commercial varieties (CC 84-75 and CC 85-92) most planted historically at the same site.

Variety CC 92-2804 has been harvested on 1103 ha located in 24 agroecological zones, resulting in productivity equal to or higher than the checks CC 85-92 and CC 84-75 in 19 of them. Figure 2 shows the agroecological zones (32H2, 13H2, 15H2, 11H1, 15H1, 18H1, 1H1, 11H3, 6H3, 31H0, 22H1 and 27H1) which cover 56 278 ha (28%) of the land in cane, where CC 92-2804 has been significantly higher in productivity (green colour) than the checks. The agroecological zones (11H0, 6H1, 30H0, 11H2, 6H2, 7H0 and 10H4) where CC 92-2804 is equal in productivity (blue colour) to the checks, which represent 78 672 ha (39%) of the total area planted in cane. The agroecological zones (18H0, 23H2, 22H0, 15H0 and 26H1) where CC 92-2804 is lower in productivity (red colour) than the checks cover 8161 ha (4%) of the area planted in cane. The agroecological zone where the variety has been planted most is 6H1, where 388 ha have been harvested; the commercial results are shown in Table 3. Productivity has been quite stable over the seven crops, despite decreases in the age at harvest.

Variety CC 93-4418 has been harvested on 721 ha located in 17 agroecological zones, resulting equal to or higher in productivity than the checks CC 85-92 and CC 84-75 in 12 of the zones. Figure 3 shows the zones (30H2, 11H3, 6H1, 23H1, 11H2, 6H2 and 10H3) where CC 93-
CC 93-4418 was significantly higher in productivity (blue colour) than the checks, representing 72 286 ha (36%) of the total area planted in cane.

The zones (30H1, 11H0, 18H0, 11H1 and 22H0) where CC 93-4418 was equal in productivity (blue colour) to the checks represent 52 623 ha (26%) of the total area planted in cane. The zones (30H0, 18H1, 18H2, 26H1 and 6H0) where CC 93-4418 was lower in productivity (red colour) than the checks, cover 12 627 ha (6%) of the area planted in cane. The agroecological zone where the variety has been planted most is 11H0, where 216 ha have been harvested. The commercial results are given in Table 4. Productivity has been quite stable over all crops.

More precise and specific information by agroecological zone and other varieties in terms of productivity can be consulted on CENICAÑA’s Web page http://www.cenicana.org, Site-Specific Agriculture and Map Server, where one enters the property of the grower according to the sugar mill, lot and agroecological zone. With that information, you can construct the graphic representation of TCH, % sugar yield and TSH in so called isoproductivity curves for the agroecological zone of interest, using the same Map Server.

**Conclusions**

- Of the 16 varieties most cultivated by the Colombian sugar sector, 11 were developed by CENICAÑA and occupy 87% of the 211 932 ha planted.
• CC 85-92 continues to be the most widely planted although its percentage of participation in the sector last year did not increase, perhaps reaching its maximum % adoption in 2009.
• Varieties CC 93-3895, CC 93-4418 and CC 92-2804 have increased their area of planting the most in the last two years.
• By multiplying and monitoring CC 93-3895, CC 93-4418 and CC 92-2804 in the different planting sites, it was possible to prove the stability of their productivity over plant cane and several ratoons in the main agroecological zones where each of them is planted.

Résumé
LA VARIÉTÉ de canne à sucre CC 85-92 est actuellement cultivée sur plus de 69% de la surface cannière en Colombie. C’est une situation inquiétante, du point de vue maladies, qui peuvent affecter la productivité de l’industrie. Ainsi, CENICAÑA a mis l’emphase sur une sélection qui cible des zones spécifiques de la production cannière. Après les essais régionaux, trois à cinq variétés émanant de chaque série, et dont leurs performances sont égales ou supérieures aux témoins, sont mises à la disposition des sucreries. Les variétés les plus en vue ont été soumises à un processus de multiplication et de contrôle afin de déterminer leur comportement dans diverses zones agro-climatiques dans le but de mettre à la disposition des planteurs celles qui sont adaptées à leurs conditions spécifiques. À ce jour, les variétés CC 92-2804, CC 93-3895 et CC 93-4418 se sont avérées les plus prometteuses. Dans la zone semi-aride, ces variétés ont une performance égale ou supérieure à celle de CC 85-92, ce qui est prometteuse pour l’industrie.

PALABRAS CLAVE: Variedades, Caña de Azúcar, Zonas Agroecológicas.

Resumen

El sector azucarero de Colombia tiene actualmente sembrada la CC 85-92 en más del 69% el área en caña de azúcar, situación que preocupa por la posibilidad de aparición de enfermedades que puedan afectar esa variedad y la industria. Por esa razón CENICAÑA adelanta de manera continua la obtención y selección de variedades con el enfoque de agricultura específica por sitio. Una vez finalizadas las pruebas regionales del proceso de selección, se entregan a los ingenios azucareros entre tres a cinco variedades por serie, las cuales igualan o superan al testigo empleado en dichas pruebas. Esas variedades consideradas promisorias deben seguir un proceso de multiplicación y seguimiento que determina su respuesta en las diferentes zonas agroecológicas. Cada día el número de variedades disponibles para los cultivadores es mayor con adaptación específica por sitio, buscando así aumentar la productividad del sector azucarero colombiano. En el proceso de multiplicación y seguimiento se destacan las variedades CC 92-2804, CC 93-3895 y CC 93-4418 entre otras, sembradas en campos comerciales de los diferentes ingenios azucareros. Los resultados indican que bajo las condiciones de la zona semiseca estas variedades se comportaron iguales o superiores a CC 85-92 en las zonas agroecológicas en donde se evaluaron y para la industria se constituyen en alternativas de siembra.
FAMILY SELECTION IMPROVES THE EFFICIENCY AND EFFECTIVENESS OF SELECTING ORIGINAL SEEDLINGS AND PARENTS

Abstract

FAMILY selection has been used in several sugarcane breeding programs for many years, and has been shown to be superior to individual selection (also known as mass selection), in terms of gains from selection, resource efficiency, and cost of operation. Other breeding programs have expressed interest in family selection, but the technique has not been widely adopted for logistical reasons. Suggestions for overcoming the constraints to family selection are made. Family selection has also been shown to provide a superior method for estimating the breeding value of parent clones. Objective data on the performance of families provides invaluable information on the breeding performance of parent clones. Best Linear Unbiased Predictors (BLUPs) can be estimated for a range of traits from the results of family selection trials, and these are estimates of breeding value. In Australia, current research is aimed at improving the BLUP estimates by combining data across all selection programs, including family × environment interactions, and partitioning the genetic effects of each parent into additive and non-additive genetic effects.

Introduction

Family selection is used in the Australian and West Indian sugarcane breeding programs (Cox and Hogarth, 1993; Kennedy and Bellamy, 1997) and a modified version of family selection is used in Brazil (Bressiani et al., 2005), Colombia (Victoria, pers. comm.) and Argentina (Issa Joya, pers. comm.). The potential of family selection to be more efficient than individual selection at the original seedling stage of selection was first identified by Hogarth (1971). However, at that time, family plots had to be cut and weighed manually, and the cost was prohibitive.

When mobile weighing equipment was developed in Australia (Hogarth and Mullins, 1989), there was an opportunity to assess the benefits of family selection, and several research projects were conducted. There has also been interest in family selection in other countries such as Indonesia (Sukarso, 1986), Cuba (Ortiz and Cabellero, 1989), South Africa (Bond, 1989), Hawaii (Wu and Tew, 1989), Florida (Tai and Miller, 1989) and Louisiana (Chang and Milligan, 1992a, b). However, family selection has not been widely adopted and this may be because suitable harvesting and weighing equipment is not available. In this paper, we suggest methods that could be used to implement family selection without such equipment.

Cox and Hogarth (1993) showed that the most efficient method of family selection was likely to be based on the performance of families in replicated plant crop trials, followed by within-family selection in the first ratoon crop. McRae et al. (1993) and Cox et al. (1996) presented further
evidence that a combination of family and individual selection was likely to be more effective than family selection alone. Jackson et al. (1995) reviewed family selection in sugarcane and described its implementation in Australian regional selection programs. Family selection in Australia has proved to make better use of available resources and is less costly than individual selection in original seedlings.

Family selection is not just an effective method for selecting original seedlings; results from family selection trials can also be used to estimate the breeding value of the parent clones that produced the families. Stringer et al. (1996) and Barbosa et al. (2004, 2005) studied Best Linear Unbiased Predictors (BLUPs) of parental performance estimated from family selection trials. BLUPs are estimates of breeding value, which is the additive genetic component of the genotype. Stringer et al. (1996) showed that BLUPs were more effective than the empirical algorithm previously used by BSES (Hogarth and Skinner, 1986, 1987). Superior combinations were identified with less information so that a reduction in the generation interval is possible. Hence, since the early 1990s, BLUPs have been used to select parents for cross pollination in Australia. Until recently, data from each selection program were analysed separately and genotype×environment interaction for the families and parents was not considered. Current research by Atkin et al. (2009) and Atkin et al. (personal communication) is aimed at improving the breeding value estimates by combining data across all selection programs, including family×environment interactions and partitioning the genetic effects of each parent into additive and non-additive genetic effects.

In this paper, we will examine the theoretical basis for using family selection, examine the results of some family selection trials, suggest how family selection could be implemented without mobile weighing equipment, and discuss recent advances in the selection of parent clones and the adoption of a new genetic evaluation system.

**The theoretical basis for family selection**

At the original seedling stage of selection, each genotype is represented by only one plant. The phenotype of that plant depends on its genotypic value and the effect of the micro-environment in which the plant is grown. The environmental effect includes the effect of competition between plants, and Skinner (1961) showed that competition can have a highly significant effect on selection efficiency. The relative importance of the genotypic and environmental effects can be determined by conducting quantitative inheritance studies.

Skinner et al. (1987) showed that the degree of genetic determination (or heritability in the broad sense) for yield of cane at the original seedling stage was 0.17 or less (often much less) on an individual basis, but increased up to 0.75 on a family basis. This means that, on an individual basis, most of the variability among phenotypes is due to environmental effects. Consequently, selection for yield of cane on an individual basis will be largely ineffective in original seedlings. On the other hand, when families are weighed, most of the variability among families is due to genetic effects, so that the better families can be selected effectively.

When selected clones from the best families are planted into larger plots, the environmental effect is reduced relative to the genetic effect, and selection of individuals becomes more reliable.

It is important to recognise that most sugarcane traits are not inherited perfectly additively, especially cane yield, which is controlled about equally by additive and non-additive inheritance (see, for example, Hogarth (1987)). The implications of this are that parent clones can be selected for high sugar content or disease resistances based on the phenotypes of the parent clones but selection of parents for cane yield is much less reliable. As cane yield is a very important character, a strategy needs to be developed to maximise the chance of identifying families with high cane yield potential. The strategy developed in Australia is to plant as many experimental families as possible but relatively few seedlings are planted from each family (usually about 80 seedlings).
When the families are weighed in the plant crop, high yielding families are identified and, assuming their performance is satisfactory for other characters, these families are repeated in subsequent years in greater numbers. This maximises the chances of identifying high yielding families without wasting precious resources on planting a large number of seedlings from families that do not perform well.

**Results from family selection research trials**

McRae *et al.* (1993) found that both individual and family selection were effective in an experiment conducted in the Burdekin region of Australia. In this experiment, the trial was planted later than commercial planting and the plant crop was poorly grown. They found that selection of families from the well-grown ratoon crop was more effective than family selection in the poorly-grown plant crop.

Nevertheless, both individual and family selection from the plant crop were effective, and the best method was combined family and within-family selection. That is, individual genotypes are only selected in the best families identified by family performance in the plant crop. In view of the experimental results, families are now planted in the Burdekin at the same time as commercial planting so that ‘normal’ crops are grown.

Cox and Hogarth (1993) and Cox *et al.* (1996) studied combinations of family and within-family selection in two experiments at the Bundaberg Experiment Station in Australia. They obtained gains of 3.4% and 5.3% from individual selection and gains of 9.7% and 12.9% respectively from a combination of family and within-family selection. Thus, combined family and within-family selection was about 2.5 times better than individual selection alone.

**Family selection procedure**

Approximately 300 full-sib families are planted in each of the four regional selection programs in Australia. We aim to plant 80 seedlings per family in four replications of 20 seedlings. For each replicate, the seedlings are spaced at 50 cm in a single row of 11.4 m. If there are insufficient seedlings, there may be only two replicates from some families.

Typically, selection in family trials is a combination of family and within-family selection. Family selection is undertaken in the plant crop by assessing the performance of each family for cane yield, sugar and fibre content, and then concentrating selection efforts on the best performing families.

Only families in the top 40% undergo further selection in the ratoon crop, while poorer families are discarded as whole units. In addition, the numbers of individuals selected from within these top families depend on their performance in the plant crop. For example, 32 out of 80 individuals may be selected from the best 10% (i.e. 40% of individuals per family), 24 from the next 10%, 16 from the next 10%, and 8 from the next 10%. This means that the best families are selected at the highest rate.

**Family selection without harvesters or mobile weighing equipment**

A number of breeding programs worldwide have expressed interest in family selection, but have been unable to implement it due to problems with harvesting and weighing the plots. There are two possible methods to overcome this problem, depending on the resources available.

**Method when cane is cut manually**

If cane is cut manually and the cutters can be relied on to identify plots, it is suggested that families be planted in two replicates of 45 seedlings. However, three-row plots should be used rather than single-row plots. At harvest, the cane cutters can load the cane from the three–row plot of cane into one bundle for easy weighing. Weighing can be done either mechanically using a grab with scales or manually with a boom and grab. Before the advent of mechanical harvesting and weighing, replicated trials in Australia were cut manually and weighed by using a boom and grab.
Method when cane is cut mechanically

If cane is cut mechanically or the cane cutters can not be relied on to identify the ends of plots reliably, it is suggested that four replicates of single-row plots could be used as in Australia. To weigh the plots, the sampling method developed by Hogarth and Skinner (1967) could be used. Using this method, all the stalks in the plot are counted, and 40 stalks are cut from each plot. This 40-stalk sample would be weighed, and the plot weight estimated from the total number of stalks and the weight per stalk. By cutting 40 stalks from each plot, a path is cut through the trial allowing easy access of weighing equipment through the trial. A similar method was used in Australia for replicated trials when mechanical harvesters replaced manual cane cutters but before the development of mechanical weighing systems.

Estimation of breeding value of parents

Hogarth and Skinner (1986, 1987) developed an empirical method for evaluating the breeding potential of a parental clone based on agronomic performance called Net Merit Grade (NMG), disease resistance status, and selection rates from crosses involving that parent. This method was an improvement on the previous intuitive method, but the correlation between predicted performance and actual performance of crosses was only about 0.40–0.50. A major problem with the method was that the most important data about the performance of parent clones were the selection rates from families involving the parents. The most useful selection rate data were the rates from advanced stages of selection, so that it took many years (often at least 10 years) to obtain good data on new parent clones.

When Stringer et al. (1996) developed their method for estimating breeding values based on BLUPs, the correlation between predicted and actual performance improved. Furthermore, useful data were obtained as soon as the plant crop of family selection trials was harvested, so that useful parent clone performance data were available many years sooner. Cox and Stringer (1998) reported on BLUP estimates, based on NMG, for parents of families harvested from 1993 to 1996, which were correlated with actual family performance in 1995, 1996 and 1997. For 81-172 families with BLUP estimates for both parents, the correlations were 0.62–0.65 compared with 0.45–0.50 for the previous system for estimating breeding value. It should be emphasised that the BLUP estimates were often based on results of a single family selection trial whereas the previous breeding values were estimated from many years of selection data.

The NMG system for assessing clonal performance was described by Skinner (1967) and is based on tonnes cane per hectare (TCH), CCS (sugar content), fibre percent and visual appearance grade. Clones (or families) are compared with standard clones (or families), and a bonus is given if the CCS is higher than the standard CCS and a penalty is applied if fibre content is higher than the standards’ fibre. When BLUPs were first used to estimate breeding value of parent clones, the NMG of a family was calculated by comparing family performance with the mean of several standard (proven) families.

Problems with the NMG system

The problems with the NMG system and how to overcome them were detailed by Stringer et al. (2009). The issues will be described briefly in this paper.

The traditional genetic evaluation system relied on NMG and independent evaluation of clones for disease resistance and sugar quality. The system was inefficient because:

- Weightings of the different traits of importance in a cultivar did not reflect their true economic value. For example, NMG was highly correlated with TCH, so there was greater emphasis on selection for high TCH relative to high CCS. This was effective in maximising sugar yields, but high TCH clones have higher production and harvesting costs and produce a lower economic return for the whole industry than is possible with clones using optimal economic weightings for all traits.
• NMG did not incorporate disease resistances which were assessed independently for selection purposes. This is not as effective as index selection.

• NMG did not use inherent genetic correlations between traits and environments, even though many clones were tested at multiple sites and regions. An analysis that combines all trial results will produce a superior assessment of the true genetic value of a clone.

• NMG did not take account of variable data quality across trials and traits. BLUPs can overcome this problem.

• Breeding values predicted using BLUPs on data collected from family selection trials did not use pedigree information to calculate a NMG score.

The improved Genetic Evaluation System (GES)

The improved system is based on the theory of selection index (Hazel, 1943; Smith, 1936). A selection index considers all traits of economic importance and weights those traits with an appropriate economic weight. Economic weights were derived from a model developed by Wei et al. (2006) who obtained information from a consultative group consisting of a range of industry experts. Income and cost structures for the entire production, processing and marketing chain were used in the model by linking the incomes and costs with sugarcane traits. By changing one unit of a trait while holding other traits constant, the change in cost of producing one tonne of sugar became the economic weight of the trait. The economic importance of a disease was determined by its risk factor or potential damage. Cane yield loss was assumed to be the only damage caused by a disease with no effect on CCS.

It is also necessary to predict breeding values (BVs) of parent clones, which is achieved by using the statistical software ASReml (Gilmour et al., 2006). Until recently, the approach involved analysing each trial separately to identify outliers and site specific spatial variation as defined by Gilmour et al. (1997). Ten years of data were then combined with pedigree information on each parent within a region. A mixed model approach with a biparental genetic model (Henderson, 1984; Mrode, 2005) was used to obtain BLUPs for each parent. This approach was limited by not considering genotype×environment interaction for the families and parents. In a recent approach developed by Atkin et al. (2009) to use family data more efficiently, data from all four selection programs are now combined to exploit genetic variances and covariances between trials and regions (Atkin et al., personal communication). Additionally, the genetic effects of each parent are partitioned into additive and non-additive genetic effects (Costa e Silva et al., 2004). By using all available information from family trials and genetic correlations across regions, more reliable estimates of BV of parents are obtained.

To determine the best families, seven years’ data from each region are combined, excluding pedigree information. Data are analysed using a mixed model to partition individual family effects, and regions are assumed to be independent. BLUPs for each family within each region are estimated.

The Economic Breeding Value (EBV) of a parent clone is estimated from a selection index that incorporates the genetic effects and the economic weightings. The index is optimised to give estimates that have the most relevance for commercial production of sugarcane.

Conclusions

Family selection has been used in the Australian sugarcane breeding program for almost 20 years. There is a strong body of evidence to show that a combination of family and within-family selection is more effective (greater genetic gains) and more efficient than individual selection alone. In recent years, there have been major improvements to the way family selection is used in the BSES-CSIRO Joint Venture variety improvement program. We have replaced NMG with a new
selection index for estimating both the genetic value of families and the breeding value of parents, which uses economic weights of the various traits in a sugar production system and the best genetic estimates. This is part of an improved genetic evaluation system. We have also greatly improved methods of analysis by accounting for spatial variation, combining all data (over years and locations) and, for parents, partitioning the genetic effects into additive and non-additive genetic effects.

Résumé

LA SÉLECTION familiale a été utilisée dans plusieurs programmes d’amélioration variétale depuis de nombreuses années, et s’est avérée supérieure à la sélection individuelle (également connue comme la sélection massale) en termes de gains en sélection, utilisation des ressources et coûts de l’opération. D’autres programmes d’amélioration variétale ont exprimé un intérêt pour la sélection familiale, mais la technique n’a pas été largement adoptée pour des raisons de logistiques. Des suggestions pour surmonter les contraintes de la sélection familiale sont faites. La sélection familiale a également démontré qu’elle peut fournir une méthode supérieure pour estimer la valeur génétique des parents. Les données objectives sur la performance des familles peuvent fournir des informations inestimables sur la performance des géniteurs. ‘Best Linear Unbiased Predictors’ (BLUP) peuvent être estimés pour une gamme de caractères à partir des résultats des essais de sélection familiale, et représentant des estimations de la valeur des parents. En Australie, la recherche actuelle a pour but d’améliorer les estimations du BLUP en combinant des données provenant de tous les programmes de sélection, y compris les interactions famille x environnement, et en décomposant des effets génétiques de chaque parent en effets génétiques additifs et non-additifs.
LA SELECCIÓN FAMILIAR MEJORA LA EFICIENCIA Y EFICACIA DE SELECCIÓN INICIAL DE LAS PROGENIES Y PROGENITORES

PALABRAS CLAVES: Selección Familiar, Progenies Iniciales, Selección Parental.

Resumen

LA SELECCIÓN familiar ha sido usada en varios programas de mejoramiento de caña de azúcar por varios años, mostrando ser mejor que la selección individual (conocida también como selección masal), en términos de ganancia por selección, eficiencia de uso de recursos y costos de operación. Aunque otros programas de mejoramiento han expresado interés por el uso de la selección familiar, esta técnica no ha sido usada mayormente por razones logísticas. Algunas sugerencias para superar los obstáculos del uso son sugeridas. La selección familiar también ha mostrado ser superior para estimar el valor genético de los parentales como una información objetiva sobre el comportamiento de las familias y la capacidad de cruzas de los clones parentales. Las mejores predicciones lineales no sesgadas (BLUPs) pueden ser estimadas para un rango de caracteres desde los resultados de los ensayos de selección familiar, que a su vez son los estimados del valor genético. En Australia, actualmente los experimentos están encaminados a mejorar los estimados de BLUP, combinado datos de todos los programas de selección, incluyendo las interacciones familia×ambiente, separando los efectos genéticos de cada progenitor entre los efectos aditivos y no-aditivos.

KEYWORDS: Sugarcane Smut, Incursion, Disease Screening, Breeding Strategies.

Abstract

ALTHOUGH sugarcane smut was first detected in the Ord River Irrigation Area of West Australia in 1998, the major sugarcane areas along the east coast of Queensland and northern New South Wales were not affected by the disease until it was found near Childers in June 2006. Since then there has been a rapid disease escalation and smut has now been found in most sugarcane regions of Queensland, but not in New South Wales. It is estimated that smut will be found on every farm in the Bundaberg-Childers, Mackay and Herbert regions in 2009 and economic losses will be recorded in some crops of susceptible varieties. This paper documents the development of the smut epidemic in Queensland, the strategy now in place to replace smut-susceptible varieties and the breeding approaches adopted pre- and post-incursion. A key feature was the screening of varieties, advanced clones and parents in Indonesia from 1998 onwards. Breeding strategies aim to minimise industry economic losses and maintain the rate of genetic gain. This should result in a high proportion of resistant and intermediate varieties being harvested by 2012 and the on-going release of new, highly productive, smut-resistant varieties to the Australian sugarcane industry.

Introduction

The Australian sugar industry is spread along a narrow 2500 km coastal strip of eastern Australia from Grafton in northern New South Wales (latitude 29.7°S) to Mossman in Queensland (latitude 16.5°S). The major cane growing regions are separated by cattle pasture or natural vegetation and these provide natural barriers to pest and disease spread. The Australian sugar industry has a well established internal quarantine system, supported by State Government legislation, and the alignment of quarantine boundaries with these natural barriers has limited the spread of serious pests and diseases such Fiji leaf gall, mosaic and cane weevil borers.

Sugarcane smut (Ustilago scitaminea Sydow syn. Sporisorium scitaminea) was found for the first time in Australia in July 1998 in the Ord River Irrigation Area (ORIA) of Western Australia (Riley et al., 1999), more than 2000 km from the main production areas on the east coast. Western Australian and the east coast sugarcane production areas are separated by tropical savannah with very sparse population. The Western Australian sugar industry had one small sugar mill with 4000 ha of commercial cane, and strict quarantine restrictions governed movement of machinery and cane from Western Australia to the eastern states to prevent human-assisted smut spread. The industry in Western Australia ceased production in 2007.

The smut resistance of Australian varieties was largely unknown in 1998 when smut was found in Western Australia. Limited information was available from overseas countries, but this was mainly for older varieties and there was disparity between ratings obtained from different countries. BSES established a testing program in Indonesia within months of the incursion in...
Western Australia (Croft et al. 2000) and information on the resistance of some Australian varieties became available from Western Australia (Engelke et al. 2001) with time.

Smut was found on the east coast of Australia in the variety Q205 in the Childers district in June 2006 (Croft et al., 2008b). This paper describes the spread of smut throughout Queensland, the response of the industry to the incursion, the impact of the disease on the industry and pre- and post-incursion strategies used in the BSES-CSIRO Variety Improvement program.

Smut spread within Queensland

Smut was found near Childers in June 2006 and intensive surveys showed the disease was already widespread in the Bundaberg-Childers region (Figure 1). Only a small number of farms were heavily infested and these were mainly in the Redridge area. The initial finding triggered a search for smut in other major cane growing regions. In November 2006, the disease was found in the Mackay region approximately 600 km north of Childers and, in December 2006, in the Ingham region a further 600 km north (Figure 2). In both the Mackay and Ingham regions, the disease was also well established and appeared to have been present for a number of years. It is possible that the three regions became infested at the same time, possibly from the same weather event that carried spores from the original source (Western Australia or overseas). The Mackay and Ingham findings meant there was no chance of containing smut within the southern region.

Fig. 1—Location of smut infested farms in the Bundaberg-Childers region of Queensland in October 2006. Infested farms are marked in red and the cane growing properties are highlighted in grey.
After the Ingham finding, nearly 12 months elapsed before the next two regional smut detections; these were in Maryborough, only a short distance south of Childers, and in Proserpine, a short distance north of Mackay (Figure 2). By the end of 2008, smut was found in all the remaining major cane growing regions. Smut detections in 2007 and 2008 probably represented spread from the three initially-infested regions. Only the most southerly sugar mills in the Australian industry remain free of smut (southern Queensland and New South Wales). However, it is highly probable that the disease is already present in some of these areas. Initial detections have been quickly followed by rapid local disease spread.

Spore trapping provided early warning of smut spread into new regions (Magarey et al., 2009a). Traps consistently detected smut spores 12–18 months before symptoms were detected in the field.

![Fig. 2—Smut findings in Queensland.](image)

**Spread within infested districts**

When smut was found in the Bundaberg-Childers region in 2006, susceptible varieties accounted for 78% of the crop with the two most widely grown varieties, Q188\(^A\) and Q205\(^A\), being rated susceptible.

An intensive surveillance program was conducted in the Bundaberg-Childers region between June-November 2006 (Croft et al., 2008b). A total of 8649 blocks on 1052 properties were inspected and 2.2% of the blocks and 7.4% of the properties inspected were smut-infested. The highest incidence was in the variety Q205\(^A\), with 8.3% of blocks infested. No disease was found in resistant crops, but some was found in crops of intermediate varieties. Trace back on one of the most heavily infested farms in the region suggested the disease had been present at least since the 2003/04 crop.
Monitoring of a series of farms within the district in 2007 and 2008 (Magarey et al. 2009b) provided information on disease spread; from this it was estimated that by mid-2009 all farms would become infested (Figure 3).

The planting of smut susceptible varieties was banned in the Bundaberg-Childers region in September 2006. Over 3750 t of seed cane of resistant varieties was transported 600–1200 km into the area to assist growers to transition to resistant varieties. The proportion of smut-susceptible varieties had fallen below 50% by 2009 and it is predicted that none will remain by 2011 or 2012.

Fig. 3—Estimated spread of smut in the Bundaberg-Childers region from 2004 to 2009 and the total area planted and the area of susceptible varieties. A field was considered to be infested if it had one smut whip.

Smut spread and variety replacement has progressed at similar rates in the Ingham and Mackay regions (Figure 4) where the most susceptible varieties are Q157, Q158, Q174\(^{A}\) and Q207\(^{B}\). Disease spread has been faster in the Ingham region relative to Bundaberg-Childers (Magarey et al., 2009b). Higher temperatures are likely to be favouring pathogen activity and varietal susceptibility.

Industry impact

Direct yield losses from smut have been minimal because the disease was detected before it had spread widely, smut response plans were quickly implemented in each region, smut resistant varieties were available from pre-emptive screening in Indonesia/Western Australia and growers have rapidly transitioned to resistant varieties.

Smut detection in a region was accompanied by virtually no further planting of susceptible varieties; this led to only isolated cases of primary infection (infection from infected seed cane) in susceptible crops–thus lowering direct yield losses.

Growers also have removed many smut-infested crops before disease levels have escalated, again reducing direct losses and slowing disease spread / buildup by minimising inoculum production.
Fig. 4—Estimated smut spread in the Mackay and Ingham regions (Inf) from 2004 to 2009 and the area of susceptible (S) varieties. A field was considered to be infested if it had one smut whip.

However, smut has had a significant financial impact via increased costs from premature ploughout of infested fields and shortened crop cycles. In most cases, growers have been able to plant resistant varieties with equal or better yield potential compared with the susceptible varieties they replaced. However, on occasions, a limited choice of resistant varieties has meant that some indirect losses have resulted.

The variety Q208$^b$ is high yielding, intermediate-resistant to smut and is likely to be the major variety in coming years. It has excellent yield and sugar content over a wide range of environments. A number of new high yielding smut resistant or intermediate varieties have been released since the smut incursion and these have good yield potential, including KQ228$^b$, Q232$^b$, Q238$^b$ and Q240$^b$.

**Smut strategies used in the BSES-CSIRO Variety Improvement program**

*Pre-incursion screening*

In preparation for a smut incursion, BSES negotiated a contract in 1997 with the Indonesian Sugar Research Institute to screen Australian varieties for resistance to the disease (Croft *et al.*, 2000). In 1998, another program was established by CSIRO, WA Agriculture and BSES to screen varieties for resistance in Western Australia (Engelke *et al.*, 2001). Initial studies showed that a high percentage of Australian varieties were susceptible to the disease.

Eleven smut trials were conducted in Indonesia from 1998–2008 (Croft *et al.*, 2008a). Varieties were shipped to Indonesia and planted in an open quarantine plot on Puteran Island, a site isolated from commercial sugarcane fields. After one year in quarantine, the varieties were planted in smut resistance trials on Madura Island to the east of Java. The standard smut dip inoculation method was used (Ferreira *et al.*, 1980). A set of 10–12 standard varieties was included in all trials. All trials consisted of four replicates with 10 two-eye-setts per replication, except for trials 1 and 2 which had three replicates of six two-eye-setts per replicate. The resistance ratings were based on the ISSCT scale of 1 to 9 (Hutchinson, 1970), where 1 = highly resistant and 9 = highly susceptible.
Eight smut resistance trials were conducted in the ORIA of Western Australia using the same techniques used in Indonesia, except that the trials consisted of only three replicates and four standard varieties.

Indonesian smut trials included a total of 2035 varieties with many varieties being tested in two or more trials. The distribution of resistance classes is shown in Figure 1. The predominantly Australian varieties screened in Indonesia have a strong bias towards susceptibility, with 66% of varieties in the susceptible range (rating 7–9). In contrast, in the ORIA only 43% of varieties were rated susceptible (Figure 5). Only varieties imported from overseas (with reputed smut resistance) and varieties from the Australian breeding programs that were already identified as intermediate to resistant in Indonesia were included in smut trials in the ORIA (except for the first two trials).

The proportion of the 2006 crop (tonnes harvested) produced by resistant, intermediate and susceptible varieties in each east-coast region is shown in Figure 6.

Susceptible varieties (rating 7–9) contributed more than 65% of the crop in all regions except the Burdekin and New South Wales, while in the Herbert the figure was more than 80%.

The Indonesian and ORIA screening trials provided information on varietal resistance allowing the east-coast industry to minimise losses from the smut incursion.

Smut-resistant varieties were rapidly propagated in all regions and planting of susceptible varieties was banned. Resistant or intermediate-resistant varieties such as Q177A, Q200A, Q208A, KQ228A and Q232A were propagated using traditional methods, spaced one-eye setts or tissue culture for rapid distribution to growers.

**Pre-incursion breeding strategy**

In 2001, when information became available from the Indonesian and ORIA resistance trials, a strategy was adopted that 50% of the crosses made in the BSES-CSIRO Variety Improvement Program would have an average smut rating for the parents (mid-parent rating) < 6.5.
When information was available for only one parent, further information was sourced for grandparents, providing a better estimate of the resistance of a cross. The initial data showed that, in 2000, only 20% of crosses had an intermediate smut mid-parent rating ($\geq 3.5$ and $< 6.5$) and there were virtually no resistant crosses ($< 3.5$) (Figure 7).

Fig. 6—Proportion of the 2006 crop (tonnes harvested) planted to smut-resistant, intermediate and susceptible varieties in the 6 production regions on the east coast of Australia.

Fig. 7—Mid-parent smut rating of crosses made in the BSES-CSIRO Variety Improvement Program 2000–2008 (Resistant = average of parent smut ratings $< 3.5$, intermediate $\geq 3.5$ and $< 6.5$ and susceptible $\geq 6.5$).
From 2000 to 2004 the proportion of crosses with intermediate mid-parent rating steadily increased as a result of this strategy but the proportion with resistant mid-parent rating remained at or below 10%. To improve the situation, one of the BSES photoperiod facilities was dedicated specifically to making smut-resistant crosses, supplementing the crosses made from field grown flowers. In 2004, the smut breeding strategy was again reviewed and modified to embrace a target of 25% crosses with mid-parent ratings in the resistant range and at least 25% in the intermediate range.

These goals were almost achieved in 2005 and were exceeded in 2006. After the 2006 smut incursion, only a small number of susceptible crosses with high breeding value were made, and in 2007 and 2008 approximately 10% of crosses were rated susceptible.

**Post-incursion screening**

BSES commenced screening trials in Bundaberg in August 2006. At this time, the quantity of available smut spores was limited so varieties were inoculated by painting a spore paste (0.1 g spores (approximately $1 \times 10^8$ spores)/mL in distilled water with 0.05% Tween 20) onto each bud. Whole stalks were used and the inoculated stalks were incubated overnight at 31°C and 100% relative humidity before planting into the field. The trials consisted of two replicates, and three stalks were planted per replication. Results were obtained for 1007 varieties and 10 standard varieties.

In 2007 and 2008, 1591 and 2257 varieties (respectively) were screened with the standard dip inoculation method. A similar number are planned for 2009. Four hundred tentative selections from stage 2 from each of the 4 regional selection programs, advanced selections from the final selection stage and parent clones were included in these trials. After dip inoculation, the inoculated one-eye setts were planted in trays of vermiculite and incubated in a chamber at 31°C for 7–10 days. These were transferred to a screen house for a further 7–10 days, potted out into peat pots and placed on outside benches for 3–6 weeks before being transplanted to the field.

Eight one-eye-setts from each variety were planted per replicate. Trials consisted of two or three replicates, depending on the selection stage of the test clones. Advanced parents or foreign clones were planted in three replicates, and clones from the early stages of the breeding programs (tentative selections from stage 2) were planted in two replicates. The plants were rated for percent smut infection and disease severity 3–4 months after transplanting, then ratoonied and rated again when the ratoon crop was 5–6 months old.

The 2007 and 2008 Bundaberg smut screening trials had high levels of smut infection; 54% of clones had greater than 30% smut infected plants in 2007 and 63% in 2008 (Figure 8). Further effort is required to reduce the proportion of smut susceptible clones in the Australian breeding program.

Following the smut incursion in 2006, a strategy was developed to minimise the impact of smut in the breeding program. The effective size of the program was dramatically reduced by the high frequency of smut susceptibility in breeding and selection populations; this inevitably impacted on the rate of genetic gain. In addition, many of the high breeding value parent varieties were susceptible to smut. To overcome this, a dual approach was adopted.

The smut strategy for the **Core** Variety Improvement Program is to only plant seedlings from crosses with a mid-parent rating <5. Similar strategies have been successfully followed for many years for other major diseases in Australia including Fiji leaf gall, leaf scald and pachymetra root rot.

The core program has been described elsewhere, but briefly it incorporates three selection stages, with family and individual selection in stage 1 (true seedlings) with stages 2 and 3 involving clonal selection. There are four regional programs.

However, a strategy needed to be developed to exploit high breeding value but smut-susceptible parents. This has been called the **SmutBuster** program and is basically designed to
select and exploit the low frequency of smut resistance in susceptible crosses (e.g. S*S, S*I). Each year approximately 40,000 seedlings from these crosses are planted at Bundaberg. This population is screened for smut resistance in a two-phase program, first as seedlings and then as clones.

Fig. 8—Frequency distribution of classes of percent smut infected plants for clones screened for smut resistance in Bundaberg in 2007 (1591 clones) and 2008 (2257 clones).

Post-incursion breeding strategy

There is no generally acceptable method for screening original seedlings. In 2006, original seedlings were planted directly to the field in November-December and a paste of smut spores was painted onto the buds of two decapitated standing stalks of each seedling in April 2007. This inoculation failed, with no smut infection developing. In 2007, seedlings at the 3–6 leaf stage, six weeks after transplanting, were trimmed to approximately 20–30 mm above the growing point and then sprayed with a suspension of approximately 1 x 10^6 viable smut spores per mL onto seedlings. The inoculated seedlings were placed in an incubation chamber at 31°C overnight and then planted to the field.

An experiment was established to examine three methods for inoculating original seedlings:

1. Dip inoculation of four week old seedlings. The seedlings were teased from the germination medium, washed in water and dipped in a spore suspension of 1 x 10^6 viable smut spores per mL for 10 min. The seedlings were then planted into potting mix in 90 mm peat pots and placed in an incubation chamber at 31°C overnight. The pots were planted to the field 4–6 weeks later.
2. Trimming and spray inoculation of seedlings at the 3–6 leaf stage, six weeks after transplanting from the germination trays. Plants were trimmed to approximately 20–30 mm above the growing point and then sprayed with a suspension of approximately 1 x 10^6 viable smut spores per mL onto seedlings before planting to the field.
3. Natural spread by planting the seedlings between smut-infected spreader rows.

In this experiment, 50 seedlings from 12 families with varying smut resistance were included in each treatment. An un-inoculated batch of seedlings was planted in a low smut risk area.
The un-inoculated seedlings were grown to maturity and then screened for smut resistance using the standard dip-inoculation method to estimate the resistance in each of the families.

The results indicate that dip inoculation when transplanting seedlings into peat pots is an effective method for screening true seedlings (Figure 9) and this practice was adopted in 2008. Natural spread was also effective but this method requires considerably more area to allow for spreader rows. The dip inoculation method allowed 23% of seedlings that develop smut whips to be discarded; however, the data from the control (34%) indicated 11% of susceptible clones may escape using this method. A second screening using normal clonal inoculation methods is required to adequately screen this population. About 10 000 seedlings with no smut and good visual appearance are selected and a 3-eye sett of each is cut. These are inoculated in family groups, incubated overnight at 31°C and planted to the field as spaced plants. Again, plants with no smut and good visual appearance are selected and about 2500 of these clones are propagated for stage 2 trials in each region.

![Fig. 9—Smut expression over time on sugarcane true seedlings inoculated using various methods. Clones (control) were planted separately and assessed once on plant crop. Error bars indicate standard error of means.](image)

The core program will provide 2500 clones with a high frequency of resistant and intermediate types that will be combined with the 2500 smut-resistant clones selected from more susceptible crosses, effectively doubling the size of the stage 2 clonal assessment trials (CAT).

This expanded program is critical to maintaining breeding progress for improved productivity, while ensuring that all new varieties have sufficient smut resistance. The program is summarised in Figure 10.

**Conclusions**

Sugarcane smut has spread rapidly throughout the Queensland sugarcane industry since it was first detected in 2006. The preparations for a smut incursion prior to its arrival allowed the Queensland and New South Wales industries to minimise losses and to quickly start the replacement of smut-susceptible varieties with resistant or intermediate-resistant varieties.

The BSES-CSIRO Variety Improvement Program commenced breeding for smut resistance in 2000 and the benefits of this pre-emptive breeding program, ultimately, will provide more highly-productive smut-resistant varieties and improved profitability of the Australian sugarcane industry.
Core program

- Based on smut-resistant parents (R*R/I)
- Stage 1–family and within family selection (4 regions)
- Stage 2–clonal assessment trials (2500 x 4 regions*)
  * Different clones

SmutBuster program

- Based on high breeding-value smut-susceptible parents (S*S/I)
- Stage 1–seedling and clonal screens for smut (40 000 x 1)
- Stage 2–clonal assessment trials (2500 x 4 regions**)
  ** Common clones

- 400 tentative selections (x4) screened for smut
- Stage 3 final assessment trials (150 x 4 regions)

Acknowledgements

The authors would like to acknowledge the contributions of many sugarcane industry groups and the Queensland Government Biosecurity section in the emergency response to sugarcane smut. Smut resistance trials in Indonesia were conducted by staff of the Indonesian Sugar Research Institute particularly Irawan and Ari Kristini. Smut trials in the ORIA involved staff of BSES, CSIRO and Western Australian Department of Agriculture particularly Tim Triglone, Phillip Jackson and Bill Webb. Smut trials in Bundaberg involved many BSES staff particularly Vicki Bardon, Dennis Taylor, Simon Manson, Rebecca James and George Bade. Smut resistance trials and studies on smut spread were partly funded by the Sugar Research and Development Corporation. The contribution of Primary Industries and Fisheries is also acknowledged.

PALABRAS CLAVE: Carbón de la Caña de Azúcar, Incursión, Evaluación de la Enfermedad, Estrategias de Fitomejoramiento.

Abstract
AUNQUE el carbón de la caña de azúcar fue detectado por primera vez en el área del Río Ord del Oeste de Australia en 1998, las principales aéreas de caña de azúcar a lo largo de la costa este de Queensland y Norte de New South Wales no fueron afectadas por la enfermedad hasta que fue encontrada cerca de Childers en Junio de 2006. Desde entonces, ha habido una rápida escalada de la enfermedad y el carbón se encuentra ahora en la mayoría de regiones cañeras de Queensland, pero no en New South Wales. Se estima que el carbón se encontrará en todas las unidades de producción en las regiones de Bundaberg-Childers, Mackay y Herbert en 2009, esto provocará pérdidas económicas en algunos campos con variedades susceptible. Este artículo documenta el desarrollo epidémico de la enfermedad en Queensland, la estrategia que hoy se dispone para reemplazar variedades susceptibles a carbón y los programas de fitomejoramiento adoptados en pre- y pos-entrada de la enfermedad. La clave del proceso fue el inicio de ensayos desde 1998 en adelante, para evaluación de variedades, clones avanzado y parentales en Indonesia. Las estrategias de mejoramiento buscan minimizar las pérdidas económicas de la industria y mantener la tasa de ganancias genéticas. Esto daría como resultado una alta proporción de variedades resistentes e intermedias cosechadas para el 2012 así como las nuevas variedades que están siendo entregadas que son altamente productivas y resistentes al carbón para la industria azucarera Australiana.

KEYWORDS: Erianthus, Saccharum spontaneum, Introgression Breeding, DNA Markers.

Abstract

In 2002 a collaborative program of breeding and research was commenced, aiming to utilise wild germplasm from China for sugarcane improvement in both China and Australia. Some results and recommendations arising from this program to date are reported here. The program aimed to: 1. Characterise genetic diversity in Chinese S. spontaneum and Erianthus arundinaceus; 2. Conduct crossing between Chinese S. spontaneum and Erianthus spp. and sugarcane, and initial evaluation of the resulting progeny; 3. Assess if and how DNA markers can be used to identify genome regions of positive or negative value from wild clones, and to assist in programs aiming to introduce new genes from wild canes into commercial cultivars; 4. To quantify genotype × environment interactions between Australia and China. Results from the genetic diversity studies indicated a high level of genetic diversity in both S. spontaneum and Erianthus arundinaceus in China, and provide a basis for targeted sampling and use of this material in future breeding efforts or for core collections. Two hundred and two crosses from a range of S. spontaneum and Erianthus clones generated viable seeds, and 100 of these crosses have been verified (to date) using DNA markers as producing true hybrids. These results were significant in relation to Erianthus spp. in providing (to our knowledge) the first report of verified fertile Saccharum × Erianthus hybrids in the world, despite many past efforts. Several case study populations derived from S. spontaneum and Erianthus clones were used for Quantitative Trait loci (QTL) mapping. Several apparently important QTL for cane yield were identified from S. spontaneum. An approach to apply DNA markers in future introgression breeding in sugarcane is recommended, based on the results and experience obtained. Another significant result was the first (to our knowledge) documentation of genotype × country interactions. Somewhat surprisingly, moderate to high (>0.6) genetic correlations in performance of families and clones between trials in China and Australia were observed, despite some contrasting environmental and management conditions. This result supports ongoing collaboration between China and Australia via exchange of selection trial results and selected germplasm.

Introduction

Genetic improvement in most crop species has been characterised by incremental gains over time, with occasional larger ‘jumps’ in progress when some favourable new germplasm or genes are
found and used. In sugarcane, a major ‘jump’ arose with interspecific hybridisation in the early part of the 20th century when noble cane cultivars (Saccharum officinarum) were crossed with the wild species S. spontaneum and with hybrids derived from this wild species, by Indonesian and Indian breeders (Roach, 1989). Genotypes arising from these early programs (such as POJ2878, Co205) quickly became utilised not just as cultivars but also as parental material in sugarcane breeding programs world-wide. Following the success of these early interspecific hybridisations, sugarcane breeding programs have since largely concentrated on utilising clones derived from these early programs in further cycles of crossing and selection. However, this has contributed to a situation where most parent clones within sugarcane breeding programs around the world trace back to a relatively small number of key ancestors (Arceneaux, 1967; Roach, 1971). This small sampling of clones for breeding, combined with a perception among some sugarcane breeders of desirable traits in wild canes such as adaptation to environmental stresses, has led to ongoing interest from breeders in the introgression of new sources of germplasm (Roach, 1989).

Some serious attempts since the initial interspecific hybridisations to introgress new sources of germplasm have been made in several countries and are still ongoing. The focus in most has been on use of S. spontaneum but effort on other species including S. robustum in Hawaii (Heinz, 1967) and Miscanthus spp. in Taiwan (Lo et al., 1986) has also occurred. More recently, activity targeting Erianthus arundinaceus in several countries (eg. Miller and Tai, 1992; Legendre, 1989; Piperidis et al., 2000) has occurred, motivated by apparently desirable characters in this species such as vigour, drought tolerance, water logging tolerance, and disease resistance (personal communication with various breeders).

Generally, the procedure used in introgression breeding involves initial crossing between S. officinarum or commercial type parents and the wild species followed by several cycles of backcrossing to commercial sugarcane parents. However, the process of introgression breeding is generally very long, with each cycle of crossing and subsequent selection of progeny usually taking between six and eight years. Given that two or more backcrossing cycles are usually necessary to regain high levels of sucrose, it is clear that introgression breeding represents a long-term commitment. Further, commercial success has not always been achieved, with some major efforts (mostly not reported in the literature) not yet leading to released cultivars. The time and risk factors have acted to reduce the level of resources devoted in most sugarcane breeding programs to introgression breeding despite universal awareness of its potential value. Roach (1984, 1989), based partly on direct experience with the CSR program in Australia, listed several reasons for the failure of some efforts to provide more productive varieties. These reasons were largely related to inferior traits in the wild donor clones, and difficulties in selecting and combining the desirable portions of both the wild type and the recurrent parents during subsequent selection cycles. Another problem noted was the lack of cytological or genetic backup to confirm the hybrid nature of initial clones derived from interspecific hybridisation and selected for further crossing.

The surge in development and application of DNA markers in plant improvement programs starting in the 1980s potentially opens new horizons in crop improvement, and particularly introgression breeding. Two broad applications of DNA markers in relation to better utilisation of exotic germplasm can be readily identified. First, DNA markers may help determine genetic relationships among materials in collections, helping identify core sets of clones sampling major genetic diversity for breeding. Second, markers may be used to map quantitative trait loci (QTL) and facilitate identification and introgression of favourable genetic components from exotic germplasm.

Tanksley and Nelson (1996) and Tanksley and McCouch (1997) argue that, for most quantitative traits of commercial value, the phenotype of exotic genotypes will nearly always be dominated by the presence of unfavourable alleles, making identification of sources of potentially valuable genes using phenotype impossible for most quantitative traits. They suggested that the old
paradigm of utilising exotic germplasm involving ‘looking for the phenotype’ is being replaced by a new one involving ‘looking for the genes’ because of availability of QTL mapping.

In China, large scale collection of sugarcane related germplasm from the wild occurred during the 1980s and 90s. Many clones arising from these collections are maintained in the National sugarcane germplasm collection in Yunnan province (maintained by Yunnan Sugar Research Institute, YSRI) and in another collection in Hainan province (maintained by Guangzhou Sugar Industry Research Institute, GSIRI). Sugarcane breeders expect many of these clones to contain individual traits and genes of commercial value if they could be identified and recombined in other agronomically suitable genetic backgrounds. In 2002, breeders and scientists from China and Australia began a collaborative program designed to study and utilise wild germplasm from China, targeting eventual development of cultivars in both countries as the end goal. Of particular interest was to explore the role of DNA markers in assisting in introgression breeding in sugarcane.

This project had four main objectives as follows:

I. To characterise the genetic diversity available in the Chinese collections.

II. To generate progeny derived from Chinese *S. spontaneum* and *Erianthus* spp, and to commence field evaluation of these in China and Australia.

III. To determine if and how DNA markers could be used to help introgression breeding.

IV. To assess if selection in China could be used for Australia, and vice versa, through GE studies.

The aims of this paper are to summarise some progress with this collaborative program, some results to date, and possible future directions.

**Genetic diversity studies**

*S. spontaneum*

A diversity study was carried out on a collection of 443 clones of *S. spontaneum* sampled from across its geographic range and maintained in germplasm collections at BSES Ltd (Australia), Copersucar (Brazil), United States Department of Agriculture (USA) and the collections in China. 676 polymorphic AFLP markers were scored across all clones and the data subjected to principal component analysis (PCA). Two main clusters were identified with PCA which corresponded to clones collected from the tropics (mostly from southern India and SE Asia) and the sub-tropical (mostly northern India and China) regions. As seen in other *S. spontaneum* diversity studies, within each of these two clusters there was a tendency for clustering to be based on local geographic origin. Overall, an extremely high level of polymorphism was detected, with a large number of markers appearing in fewer than 10% of the clones, supporting the view that, of all the *Saccharum* species, *S. spontaneum* is the most diverse. While new sources of diversity were identified within the Chinese *S. spontaneum* collections, there was no obvious grouping of this material overall from other *S. spontaneum* clones collected in other parts of Asia.

*Erianthus*

A diversity study was also carried out with 220 clones of *Erianthus arundinaceus*, of which 123 clones were sourced from the National Nursery of Sugarcane Germplasm Resources (NNSGR) at YSRI in China, 74 clones from the BSES Ltd. Collection in Australia, and 23 clones taken from the collection of Copersucar in Brazil. Similar methods as used for the *S. spontaneum* study were applied. We found that *E. arundinaceus* from China was quite dissimilar and much more diverse than that collected from Indonesia (the latter comprised the other source of most clones studied). Within China, there was a major differentiation among material collected from eastern versus western China (ie. in contrast to differentiation on latitude). The results highlighted the uniqueness and importance of the genetic diversity within China for this species.
We also conducted research to help resolve the position of the species *Erianthus rockii*, a species unique to China and which is of interest in developing drought resistance, and which was used to produce hybrids with sugarcane during the collaborative program. The results suggested this species was distinct from other *Erianthus* and *Saccharum* species and was more similar to *Miscanthus* species. Details of this study were reported by Cai et al. (2005).

**Generation of progeny from *S. spontaneum* and *Erianthus***

Within the collaborative breeding program, 202 crosses were made by YSRI and GSIRI. Microsatellite markers that were highly polymorphic in sugarcane were used to check samples of progeny from crosses, following methods described by Cai et al. (2005). Samples of progeny from one hundred and forty-six crosses have been checked to date with DNA markers (example shown in Figure 1) with 100 showing at least some true hybrid progeny (Table 1). As expected, highest proportions of crosses delivering viable seed but ‘non-true progeny’ (arising from selfing of the female or pollen contamination) were those involving *Erianthus*, with crosses between sugarcane (*S. officinarum* or commercial cultivars) and *S. spontaneum* delivering true hybrids. Of particular significance and importance in this project was the verification of fertile hybrids derived from (*Saccharum × Erianthus*) × *Saccharum*. This result was the first validated backcross material from *Erianthus* in our experience, despite considerable efforts by other breeding programs in the past. This important result means that it should be possible to utilise the *Erianthus* genome in future sugarcane improvement.

![Fig. 1—Examples of checking progeny from crosses involving *Erianthus* using DNA markers. These are results from a single micro-satellite primer (one of three used routinely for checking), showing two groups of parents and progeny. The group on the left shows grandparent Guangzhe 14 (*S. officinarum*) which was crossed with YN95-34 (*Erianthus arundinaceus*) to produce YN2000-499, which in turn was crossed with YN2000-341 to produce putative BC1 progeny, a random sample of which is shown to the right. There is no evidence of bands characteristic of the *Erianthus* grandparent in YN2000-499, which appears to arise from selfing of Gangzhe 14, and therefore no evidence of BC1 progeny being derived from *Erianthus*. By contrast, the group on the right shows grandparent Luohouzhe (*S. officinarum*) which was crossed with Hainan92-84 (*E. arundinaceus*; note: this was mistakenly written as HN92-9 in the image above) to produce YN2000-117, which was crossed with commercial cultivar F172 to produce BC1 progeny, a sample of which are shown to the right. In YN2000-117, bands specific to the *Erianthus* parent are shown, and these are also apparent in the BC1 progeny, providing evidence of these being derived from *Erianthus*.](image-url)
Table 1—Numbers of crosses made for different types of crosses, showing numbers of crosses with validated true hybrids (ie. not arising from self pollination or pollen contamination).

‘Commercial’ refers to commercial cultivar or elite parent used in commercial breeding program.

In all of the crosses made, half the seed was retained for use in China, and half imported into Australia following strict quarantine protocols. Clones generated from these crosses are now undergoing selection and use in further backcrosses to high-value parents in sugarcane breeding programs in both countries.

Targeted research trials were carried out on a range of progeny derived from S. spontaneum, and some methods and results in this study were reported in detail by Wang et al (2008). This study provided a preliminary evaluation of performance of a range of clones derived from diverse S. spontaneum clones when crossed with S. officinarum or sugarcane clones, as well as some basic statistical parameters that should guide the design of optimal early-phase selection among similar populations in the future.

Overall, the high genetic variation and broad-sense heritabilities (>0.7) observed among progeny for all traits suggests that large gains from selection in these populations could be easily achieved with limited replication (1 or 2 replicates) in small plot trials. For most biomass composition traits, the variation among the families comprised a substantial proportion (over 40%) of the genetic variation.

A selection system involving such initial selection of high-performing families for biomass composition traits, followed by selection among large populations within the best families, would represent an efficient method. Initial selection among families based on measuring a limited random sample of say 10 to 20 clones per family should be effective. For both cane yield and stalk biomass yield, the relatively smaller size of the among-family component suggests that family selection would be limited in effectiveness, and individual clonal selection within families would be important from early stages of selection.

Mid-parent values in an independent trial predicted biomass composition traits (brix, pol, fibre, dry matter %) among the progeny families reasonably well (generally r > 0.6), but less so for cane and biomass yield (0 < r < 0.4), suggesting the importance of non-additive genetic variance for yield traits. For biomass composition traits, moderate to high (>0.5) correlations were observed between the female (sugarcane or S. officinarum) parent and mean progeny performance, but not between the male (S. spontaneum) parent and progeny performance, emphasising the high importance of using high-performing female clones in crosses with S. spontaneum. For cane yield components of stalk number and stalk weight, correlations with progeny performance were high for both female and male parents.
Pol and purity levels in these progeny clones, as expected, were overall much lower than the commercial cultivars included in the trials for comparison, but some clones performing at levels similar to the commercial cultivars were also identified. For cane yield and biomass yields, clones with considerably higher biomass levels relative to commercial sugarcane were identified. However, as emphasised above, results relating to cane and biomass yields should be interpreted cautiously at this stage, since competition effects are important in the small plots used in this study, and further evaluation in large plots is required to substantiate these results. Nevertheless, the performance levels in biomass coupled with large predicted gains from selection suggest that some clones generated from crosses between sugarcane and *S. spontaneum* could offer opportunities for providing high yielding biomass crops. In addition, based on prior knowledge about the contribution of *S. spontaneum* to sugarcane breeding, it may be expected that strong ratooning ability and adaptation to a range of environmental stresses may be expected to be a feature of some first cross progeny involving *S. spontaneum*. These traits were not tested in the current study, but should be a priority for further evaluation.

**Use of DNA markers for introgression breeding**

A large effort was devoted toward determining if and how DNA markers may be used to identify favourable or unfavourable genes or QTL in exotic germplasm, which could be used in subsequent breeding and selection cycles. Scoring the AFLP gels for the large numbers of markers required for QTL mapping in sugarcane was extremely time consuming and prone to error variation, and any future marker work should benefit from a more automated marker system such as DArT (Jaccoud *et al.*, 2001). Several case study populations derived from *S. spontaneum* and *Erianthus arundinaceus* were studied. One population and some results are briefly described here to illustrate the approach used. This population was derived from the cross between ROC25 (a commercial cultivar bred in Taiwan province) × YN02-356. The latter clone was selected from the cross Co419 (Indian commercial cultivar and parent) × YN75-1-2 (a *S. spontaneum* clone collected from the wild in Yunnan province).

It was of particular interest to determine if favourable QTL could be identified from the wild *S. spontaneum* clone, which could then be selected for or against in further breeding cycles. A sample of 300 clones from this BC1 population was evaluated in a trial in Australia in very small plots, with each clone being planted into 4 replicates, arranged in a randomised complete block design with individual plots being a single row × 4 m long. Measurements were made on brix in juice, pol in juice, fibre, CCS, stalk weight, stalk number, cane yield (from product of prior two) and biomass yield. The population of clones was also screened with approximately 40 AFLP primer pairs and 12 SSR primer pairs in labs at YSRI and CSIRO.

Despite the relative sparseness of existing linkage maps, a number of important associations between markers and trait performance were apparent (Table 2). The effects for cane yield are particularly interesting, with these effects representing potentially important effects in a sugarcane breeding program. These results have provided further impetus to utilise selected clones from this population and linked markers for further breeding efforts, as discussed below.

Genotype × environment interactions between countries

A common set of 26 clones was evaluated in multi-environment trials within both Australia and China (24 environments in Australia and 10 environments in China), with trial design and other procedures used described by Jackson et al. (2007).

Despite some major differences among trial environments between China and Australia for climate (especially temperature and solar radiation), and for some diseases, moderate to high genetic correlations between clone performance in China and Australia were observed for sugar content and cane yield. The average genetic correlation between environments in China versus Australia was 0.75 for CCS and 0.65 for cane yield. This is consistent also with results found with families derived from *S. spontaneum* where common families were evaluated in Australia and China and good genetic correlations between countries were observed (reported in Wang et al., 2008). These results are the first to our knowledge documenting genotype × country interactions. The results indicate that selection results in China are relevant to Australia and vice versa. Therefore, ongoing exchange of data, seed and selected clones could be mutually beneficial. This has led to a draft collaborative agreement between institutes in China and CSIRO/BSES for ongoing exchange of data and seed.

Further work and recommendations

Arising from the collaborative program of work, the following activities are planned or recommended:

- Further and more accurate evaluation of promising clones derived from *S. spontaneum* and *Erianthus* in both Australia and China, and further crossing of selected and verified (verified with DNA markers) clones to high value commercial parents.

- Initial selection among families and clones in the above program should be based on phenotype, without marker assisted selection. When a small number (2–3) of the best parents and bi-parental populations are identified, then QTL mapping should be done on one or more high value populations derived from new germplasm sources. Markers linked to favourable QTL introgressed into mainstream breeding programs may then be used in ongoing marker-assisted selection in materials along with other markers already used in the core program.

- There is interest in exploiting the genetic material generated in this collaborative project for emerging energy production systems in both countries. The relative value of fibre and other traits should be reviewed further with a view to informing breeding objectives. However, for the purposes of initial selection, a value of fibre relative to brix is suggested as 40% (ie. 1% increase in fibre content in fresh cane is worth 0.40 of the value of a 1% increase in CCS and brix content). This initial assumption is based on likely biofuel yields from sugars versus fibre and costs of conversion and assumed price parity between sugar and biofuel in the future. Other traits also need to be reviewed to determine optimal selection indices.

- To continue to exchange data and germplasm arising from the project efforts to date between China and Australia, in order to achieve mutual advantage from each other’s efforts in sugarcane breeding in the future.

**Résumé**

recommandée. Un autre résultat significatif qui (à notre connaissance) est une première, est la documentation de l’interaction génotype x pays. Assez surprenant, des corrélations génétiques modérément élevées (>0.6) ont été obtenues entre la performance des familles et les clones entre les essais conduits en Chine et en Australie, en dépit des environnements divergents et une gestion différente. Ces résultats renforcent un besoin de collaboration continue entre la Chine et l’Australie par l’intermédiaire des échanges des résultats des essais de la sélection et du germoplasme.

PALABRAS CLAVES: Erianthus, Saccharum spontaneum,
Introgresión, Mejoramiento Genético, Marcadores ADN.

Resumen

UN PROGRAMA colaborativo de mejoramiento e investigación comenzó en el 2002, procurando utilizar germoplasma silvestre de China para mejorar las variedades de China y Australia. Algunos resultados y recomendaciones que salieron de este proyecto hasta hoy se reportan aquí: El programa tuvo como finalidad de: 1. Caracterizar la diversidad genética de las especies Chinas de S. spontaneum y Erianthus arundinaceus; 2. Conducir cruzas entre S. spontaneum and Erianthus spp. chinos y caña de azúcar cultivada así como una evaluación inicial de las progenies resultantes; 3. Evaluar si los marcadores del ADN pueden ser usados para identificar regiones del genoma de valor positivo o negativo de los clones silvestres, y asistir a los programas para introducir nuevos genes de las cañas silvestres a las cultivadas comercialmente; 4. Identificar las interacciones genotipo × ambiente entre Australia y China. Los estudios de diversidad genética mostraron un alto nivel de diversidad en S. spontaneum y Erianthus arundinaceus en China, y proveen las bases para identificar materiales claves y usar en cruzamientos futuros o formar colecciones núcleo. Se realizaron 202 cruzas de un rango de clones de S. spontaneum y Erianthus con semillas viable y 100 de estos cruzamientos se verificaron como híbridos verdaderos usando marcadores moleculares (hasta hoy). Estos resultados fueron significantes en relación a Erianthus spp. mostrando por primera vez la existencia de híbridos fértiles entre Saccharum × Erianthus comparados con otros esfuerzos del pasado. Varios estudios de caso de poblaciones derivadas de S. spontaneum y Erianthus fueron usadas para estudios y mapeo de locus de Caracteres Cuantitativos (QTLs). Aparentemente, varios QTL importantes parta producción de caña fueron identificados de S. spontaneum. Un método para aplicar marcadores moleculares en trabajos futuros de introgresión en caña de azúcar se recomienda basándose en las experiencias y resultados obtenidos. Otro resultado significante (de lo que conocemos) fue el primer reporte documentado sobre la interacción genotipo × ambiente. Sorpresivamente, las correlaciones genéticas fueron de moderado a alto (>0.6) en el comportamiento de las familias y clones entre los experimentos en China y Australia. Todo esto a pesar las condiciones contrates del ambiente y de manejo. Estos resultados soportan el trabajo colaborativo que está en marcha entre China y Australia a través de intercambio de germoplasma y resultados de los experimentos.
OPPORTUNITIES AND CHALLENGES FOR SUGARCANE BREEDING: A SUMMARY OF THE 9th ISSCT BREEDING AND GERMPLASM WORKSHOP

KEYWORDS: Sugarcane Breeding, Biotechnology and Biomass, ISSCT Workshop.

Abstract

The 9th Sugarcane Breeding and Germplasm Workshop was held from 17 to 21 August 2009 at the Novotel Rockford Resort, Coral Coast Drive, Palm Cove, Cairns, Australia. The workshop was hosted by staff from the BSES Limited’s Meringa Experiment Station. BSES Limited, ISSCT, and the Sugar Research and Development Corporation of the Australian Government were sponsors for the workshop. The Breeding Workshop was attended by 70 delegates from different countries, and was distinguished by its scientific content, its impeccable organisation, and a great spirit of friendliness. Australia was well represented with a contingent of 20 breeders and researchers. Delegates from Argentina, Barbados, Brazil, China, Colombia, Ecuador, Fiji Islands, France, India, Indonesia, Japan, Mauritius, Reunion, South Africa, Sri Lanka, Thailand, Uganda, and USA attended. The presentations covered topics not only on breeding for sugar content but also biomass. There was an interesting analysis from an investor point of view on the advances in traditional plant breeding compared to the use of sugarcane transformation with novel genes. New molecular markers for mapping and genetic diversity studies and novel techniques for sugarcane biotechnology and bioenergy use also were discussed. Finally, an analysis on genetically modified (GM) sugarcane and associated biosafety risk was included. The Workshop demonstrated that traditional plant breeding and the biotechnology tools should work together in order to obtain rapid developments and increase production not only for sugar but also for bioenergy.

Introduction

The 9th Sugarcane Breeding and Germplasm Workshop was held from 17 to 21 August 2009 at the Novotel Rockford Resort, Coral Coast Drive, Palm Cove, Cairns, Australia. The Breeding Workshop was attended by 70 delegates from 19 different countries (Table 1), and was characterised by its excellent scientific content, impeccable organisation, and a great spirit of friendliness. The workshop theme was ‘Sugarcane Breeding: Opportunities and Challenges’. An important delegation of 20 breeders, pathologists, entomologists, biometricians and researchers in general from Australia was present. The Australian researchers showed a commitment for a cooperative research venture and its great achievements accomplished from several threats of devastating diseases to the applications of tools like the informatics and biotechnology to manage information and use of germplasm resources. There were 44 technical presentations during four
days of the workshop. The Wednesday visit to Meringa Station and the clear and practical demonstrations complemented the high scientific component of the Workshop.

Keynote talks and workshop topics
The 9th workshop had four keynote speakers covering topics:
1. ‘Future opportunities for sugarcane biomass use’ by Dr Les A. Edye, Principal Research Fellow, Queensland University of Technology, Brisbane.
2. ‘Sugarcane crop improvement—an R&D investors’ viewpoint’ by Dr Frikkie Botha, Executive Director, Sugar Research and Development Corporation, Brisbane.
3. ‘Global trends in sugarcane improvement—Syngenta’s view’ by Dr Manuel B. Sainz, Group Leader, Sugarcane Research, Syngenta Centre for Sugarcane Biofuels Development, Centre for Tropical Crops and Biocommodities, Queensland University of Technology, Brisbane, and
4. ‘Application of DArT technology and associated informatics to sugarcane crop improvement’ by Dr Andrzej Kilian, Director, Diversity Arrays Technology Pty Ltd, Yarralumla, Canberra, Australia.

The presentations were excellent and covered topics not only on breeding for sugar content but also biomass. The program for presentation was arranged in related groups of topics: 1) Bioenergy, 2) Molecular Breeding, 3) Physiology, 4) Biometrics, 5) Introgression, and 6) Crop Improvement grouped in five sessions.

Breeding for bioenergy
Many countries have initiated projects to exploit the potential of sugarcane biomass. The program of FAPESP-Brazil on bioenergy called BIOEN includes research on sugarcane breeding, ethanol production, and its impacts. BIOEN integrates comprehensive research on sugarcane and other plants. The Caribbean research is focusing on developing new cultivars that combine high sugar with high fibre content as multi-purpose energy canes, which will help to produce sugar as well as sustain energy production.

While traditional sugarcane may constitute the ideal energy cane in some scenarios, Type I (sugar + fibre) and Type II (fibre only) energy canes could have a broad-based impact in the national drive for developing sustainable energy technology. Future breeding of sugarcane for sugar plus energy production would be based on three objectives: 1) Economic analysis of different traits and determining optimal selection indices, 2) Optimal parental germplasm to use, 3) Target environments and selection systems.
Molecular breeding

This topic relates mainly to the use of molecular markers to help breeders to speed up the release of cultivars. Experiences from Australia on the use of molecular markers analysing the progress, lessons, challenges, and prospects, concluded that the impact of the use of molecular markers should be based on three strategies: 1) Association mapping in a broadly-based population of genotypes representing the core breeding program, 2) QTL mapping in one or several related crosses, and 3) QTL mapping in populations derived from wild canes. Results from association mapping indicated that markers correlated with cane yield, commercial cane sugar, and disease resistance can be easily found. A marker-assisted breeding program based on a narrowly based population may be effective for increasing rates of genetic gain compared with existing breeding programs. Comparative mapping of a sugarcane genetic map to the sorghum genome provides an important tool for identifying candidate genes underlying QTL regions that can lead to an acceleration of the breeding process for introgressing genes.

A long and constant research activity in CIRAD, France allowed characterisation of the Bru1 (brown rust resistance) locus and its distribution in sugarcane cultivars. Two PCR markers developed in the course of this mapping project in perfect linkage disequilibrium with Bru1 can be used to identify the presence of Bru1 in sugarcane cultivars. Identification of microsatellite markers associated with brown rust resistance in a sugarcane bi-parental cross is used in breeding programs of Brazil.

Target region amplification polymorphism can be used for studies on genetic variability among sugarcane genotypes. SSR loci have helped to identify the DNA profiling and genetic diversity of sugarcane germplasm. Identification of genes has allowed work on the molecular cloning and characterisation of cytosolic malate dehydrogenase gene SC cyMDH from sugarcane (*Saccharum officinarum* L.).

Molecular and in vitro technologies as adjuncts to conventional breeding are routinely used in South Africa. DNA fingerprinting is used to verify the identity of genotypes selected for bulking, while an in vitro micro-propagation protocol, based on the use of temporary immersion bioreactors, assists in both pathogen elimination and the mass propagation of selected genotypes.

Physiology and cane breeding

Sugarcane physiology related to plant breeding mainly covers photoperiod and flower induction. However, there is an increasing interest in studying the genetic control of some traits controlling sugarcane development and nutrient uptake. Assessing genetic variation in water use efficiency and resistance to water stress in sugarcane cultivars can help breeders to identify cultivars tolerant to water stress, providing direction for more focused and effective breeding and selection of improved cultivars. Efficient use of water is a major determinant of both irrigated and non-irrigated sugarcane production. However, improvement of water use efficiency and/or resistance to water stress has never been specifically targeted within sugarcane breeding programs elsewhere in the past. Breeding for high phosphorus use efficiency in sugarcane is of interest as low availability and high fixation of phosphorus are events frequently occurring either in acid or alkaline soils, which cover more than 30% of the world’s land area. Therefore, phosphorus deficiency is a primary constraint to sugarcane production in the tropics and subtropics. Comparing high and low phosphorus use efficiency (PUE) expression will be possible for screening of candidate genes associated with high PUE by molecular markers and comparative proteomics.

Management of flower initiation in tropical conditions has shown positive results. Modifications in the glasshouse on flowering and crossing efficiency need to be reviewed in a sub-tropical condition, where natural flowering is generally poor and inconsistent. No viable seed is produced under field conditions and breeders rely on artificial regimes of photoperiod and temperature to initiate and synchronise flowering for crossing and production of viable seed. Synchronisation of flowering between wild and hybrid cultivars is necessary for introgressing
genes. Phenology of sugarcane and *Erianthus arundinaceus* (Retz.) Jeswiet and development of a technique to control flowering time of *E. arundinaceus* is being studied in Ishigaki Island, Japan.

**Biometrical tools**

Biometrics has been and will be a major tool for crop improvement. There are several statistical methods to apply in sugarcane considering the different selection stages and applications of family or clonal selection systems. Methods of analysis for family and parent data have been developed for improving the efficiency of estimating breeding values of sugarcane parents to enable breeders to increase the rate of population improvement by better choice of parents and cross combinations. Optimal experimental design and analysis for sugarcane clonal trials with analytical methods have been developed that combine multi-site multi-harvest data in a single analysis. The advantage of such a single analysis is that genetic correlations of testing cultivars over sites and crops can be utilised and proper accounting for the residual correlations between crops at each site can made allowing more accurate selection decisions than the common practice of conducting separate analyses of individual trials and harvests.

An evaluation of new designs for the first clonal stage of selection at Mauritius Research Centre-MSIRI has been tested with an Augmented Latin Square (ALS) design superimposed on the conventional layout at the first clonal (2-m plot) stage in three sub-trials. The ALS design also accommodated a second control variety of wide adaptation with similar ripening pattern as the standard control.

Quantitative genetic analysis of progeny tests to improve selection and genetic gains in sugarcane breeding programs were introduced into the Canal Point sugarcane breeding program to evaluate the benefit of using a combination of between and within-family selection to improve genetic gains for sucrose content and cane tonnage and also as an aid to determine the sample size of the best families for advanced selection.

**Introgression in sugarcane**

Introgressing genes from wild species has been a common practice over the last 50 years of sugarcane germplasm enhancement program in Houma, Louisiana, USA, aiming to develop parental material with an expanded genetic base for the commercial breeding program. Clones with multiple genera and/or species in their background contain: *Erianthus brevibarbis* Michx. × *S. spontaneum* L.; *E. arundinaceus* × *Miscanthus* Anderss. spp.; *Miscanthus*. spp., *E. brevibarbis*, × *S. spontaneum*; *S. officinarum* L. × *S. spontaneum*; *E. arundinaceus* × *S. spontaneum*; and *M. sinensis* Anderss × *Saccharum* spp. hybrids. These wide crosses are being evaluated for cold tolerance, insect resistance, disease resistance, agronomic type, and yield characteristics.

Studies on morphological and genetic characters of the Thai *Erianthus* collection will help to identify materials for introgressing in a wide-crosses program. In China, studies on chromosome genetic analysis for the hybrid progenies of *S. officinarum* L. and *Erianthus arundinaceus* will help to identify the laws of chromosome transmission by chromosome number counts and karyotypic analysis in the hybrids and backcross progenies, and to get some cytological evidence of the use of *E. arundinaceus* in sugarcane breeding. Genetic diversity of sugarcane cultivars in mainland China is very low, as the pedigree analysis indicated using the core parental material which was descended from remote ancestral parents of two to four species of *S. officinarum*, *S. spontaneum*, *S. barberi* Jeswiet, and *S. robustum* Brandes and Jeswiet ex Grassl, with coancestry coefficients varying from 0.012 to 0.387.

**Sugarcane crop improvement**

A BSES-CSIRO joint venture variety improvement program for research and development (R&D), shows important innovations starting from the development of a web-based integrated database and crossing system (SPIDNet), use of mobile weighing equipment; routine use of SpectraCane, a NIR-based system for quality analysis using fibrated cane; a DNA fingerprinting-
based variety audit program for advanced clones and a molecular markers approach for marker assisted breeding. For example, the use of a centralised information management system like SPIDNet has produced benefits including data security, standardised data collection operations, fewer data errors, increased data availability, and the possibility of data exchange between BSES, CSIRO, and other industry partners.

The breeding objectives and its concept, construction, and implementation are based on each major production area with various steps: 1) examining the production system in each production area; 2) collecting all economic data related to each step in the production system; 3) assessing the impact of changes in performance for sugarcane traits on the economic data and 4) deriving economic importance or weight of each trait.

The foreign cultivars in the Australian sugar industry play an important role as parents in the development of new cultivars: 21 of the last 50 ‘Q’ cultivars have at least one foreign variety as a parent. Imported cultivars generally do not yield as well as locally-bred cultivars in selection trials. However, they are an important source of diversity and of new genes for resistance to diseases.

Up until the year 2000, orange rust was only a minor disease in Australia recognised by just a few disease specialists, but that changed when a new strain of the pathogen developed and rendered the widely grown cultivar Q124 susceptible. Fortunately, a high level of resistance was found in the germplasm making the selection of resistant cultivars easier. Disease control has been achieved using resistant cultivars and the disease no longer poses a threat to the Australian sugarcane industry.

A web-based variety management and information resource for the Australian sugar industry will help growers to better manage cultivars by providing specific recommendations and a broad range of information on cultivars, accessing the database in a grower-friendly format.

Parental selection for crosses is performed using the System of Information of Varieties – SIVAR in Colombia. The system designs crosses using trait values such as sucrose (cane %), stalk diameter, height, leaf shading (cover), flowering, tillering, lodging, stalk population, and resistance to smut, rust, and mosaic. The algorithm adds values for certain traits of both cultivars in comparison and if the sum is equal to or below a critical value, the process moves to the second trait and so on until all the comparisons are done for all traits.

If the sum of traits exceeds the critical level then the cross cannot be performed. Each descriptor is weighted according to its importance in the prototype of an ideal variety and this is multiplied by its descriptor to add the value of all weights to generate a value of merit of the variety.

There is a need to identify parental materials of high-sucrose for early harvesting in Ecuador; two groups (G1 and G2) were evaluated. These groups will be the basis to arrange crosses for high sucrose content.

In SASRI, research is being conducted collaboratively with the Sugar Milling Research Institute to determine whether near infra-red spectroscopy can satisfactorily predict colour and pith:fibre ratio of cultivars routinely processed in SASRI’s Mt. Edgecombe millroom.

A method that compares commercial productivity of new and older sugarcane cultivars is being used in Mauritius.

Plant breeders often are concerned about the commercial performance of their newly released cultivars relative to the older ones being replaced. Such a comparison is often difficult unless reliable and comparable commercial data are available.

Results were presented for a new multi-site selection network implemented in Réunion Island, which is designed to serve the very contrasting agronomic zones of the island.

Progress from breeding and variety selection programs in Argentina from 1989 until 2008 has shown a TCH increase of 5.3 t, TRS advanced by 4 kg per tonne milled, and TSH increased 0.85 t.
In China, over 90% of sugar produced is from sugarcane. The sugarcane growing areas are distributed mainly in the developing area of south-west China, where the economy is based on the sugar industry. Recently, sugarcane is grown for use as an ‘energy crop’.

As for all genetically modified crops, any GM sugarcane will have to undergo regulatory processes prior to commercial release, focused on safety to humans and the environment. Research provides baseline information for the decision making for the future deployment of GM sugarcane within the Australian regulatory context. Based on the Australian analysis, the information is applicable for sugarcane industries around the world.

Conclusions

Opportunities and challenges for sugarcane breeding remain intact as many new alternative breeding methods, molecular tools, and most importantly, the need for new cultivars of different usage are in demand. Traditional breeding still remains as the only practical system to release new cultivars, and the sugar industry needs trained crop improvement scientists to ensure future cane production. New genes from wild species are incorporated into the hybrid cultivars to ensure disease resistance and incorporate traits that are important in dry environments or heavy soils with low mineral contents. The 9th Breeding and Germplasm Workshop was a successful meeting in term of presenting a high level of knowledge to those delegates investing the time and money to attend. All the presentations were of scientific merit, with adequate time allowed for discussions.

Acknowledgement

We thank the BSES Limited’s management and staff for supporting the Workshop economically and technically. They shared their knowledge and scientific experiences in a series of presentations and their friendship shown during the Workshop and the social events were greatly appreciated by all participants. The work of the local Organising Committee: Dr. Nils Berding (BSES Limited, Chair), Dr. Michael Cox (BSES Limited), Dr. Phillip Jackson (CSIRO, Plant Industry), Mr. Ross McIntyre (BSES Limited) and Ms. Rhylee Pendrigh (BSES Limited), is gratefully acknowledged, as are the staff of the Meringa Experiment Station who provided excellent support for the field excursion.

MOTS CLÉS: Amélioration Génétique de la Canne à Sucre, Biotechnologie et Biomasse, Atelier de l’ISSCT.

Résumé

Le 9ème atelier d’amélioration génétique de la canne à sucre et du germoplasme de l’ISSCT a eu lieu du 17 au 21 août 2009 au Novotel Rockford Resort, Coral Coast Drive, Palm Cove, Cairns, Australie. L’atelier s’est déroulé à la Station Expérimentale de Meringa du BSES Limited et parrainé par BSES Limited, ISSCT, ainsi que le Sugar Research and Development Corporation du gouvernement australien. Soixante-dix délégués de différents pays ont participé à l’atelier qui s’est distingué par son contenu scientifique, son organisation impeccable et l’esprit de camaraderie qui a régné. L’Australie était bien représentée par un contingent de 20 généticiens-sélectionneurs et des chercheurs. Des délégués étaient venus de l’Argentine, la Barbade, le Brésil, la Chine, la Colombie, l’Équateur, les Îles Fidji, la France, l’Inde, l’Indonésie, le Japon, Maurice, Réunion, Afrique du Sud, le Sri Lanka, la Thaïlande, l’Ouganda et les États Unis. Les présentations ont non-seulement couvert les thèmes concernant l’hybridation de la canne pour la richesse, mais aussi la biomasse. Une analyse intéressante a été présentée du point de vue d’un investisseur sur les avancées en sélection traditionnelle comparé à l’utilisation de la transformation génétique de la canne, avec des gènes nouveaux. Les nouveaux marqueurs moléculaires pour la cartographie du génome, la diversité génétique et les nouvelles techniques de biotechnologie pour la canne et l’utilisation de la bioénergie ont aussi été discutés. La canne génétiquement modifiée (GM) et les risques à la biosécurité ont également été abordés. L’atelier a démontré que l’hybridation traditionnelle et les outils de la biotechnologie devraient marcher de pair afin d’obtenir des développements rapides et augmenter la production, non seulement pour le sucre, mais aussi pour la bioénergie.
OPORTUNIDADES Y RETOS PARA EL MEJORAMIENTO DE LA
CAÑA DE AZÚCAR: UN RESUMEN DEL 9TH TALLER DE LA
ISSCT EN MEJORAMIENTO Y GERMOPLASMA

Resumen

El 9th Taller de mejoramiento y germoplasma de la ISSCT se realizó desde el 17 al 21 de agosto de
2009 en complejo hotelero Novotel Rockford Resort, Coral Coast Drive, Palm Cove, Cairns,
Australia. El Taller fue organizado por los investigadores de la estación Experimental Meringa de
BSES Limited. Los auspiciantes del evento fueron BSES Limited, ISSCT, y la Corporación de
Desarrollo para la Investigación Azucarera (SRDC) del Gobierno Australiano. Participaron en el
evento 70 delegados-investigadores de diferentes países, caracterizado por su alto nivel científico,
impecable organización y un enorme espíritu de amistad. Australia estuvo muy bien representada
con 20 mejoradores e investigadores. Hubieron delegados de Argentina, Barbados, Brasil, China,
Colombia, Ecuador, Islas Fiji, Francia, Indonesia, Japón, Mauritius, Reunion, Sur África, Sri Lanka,
Tailandia, Uganda y USA. Las presentaciones orales cubrieron tópicos no solamente de
mejoramiento para contenido de azúcar, sino también en biomasa. Hubo un importante análisis
desde el punto de vista de los inversores en investigación sobre los avances en el mejoramiento
tradicional comparado con los trabajos de transformación genética con genes novedosos. También
se discutieron nuevos marcadores moleculares para mapeo y estudios de diversidad genética, así
como nuevas técnicas en biotecnología de caña y el uso en bioenergía. Finalmente, se discutió sobre
los organismos genéticamente modificados (GM) y los aspectos de bioseguridad. El Taller, mostró
que el mejoramiento tradicional y las herramientas biotecnológicas deberían trabajar juntas para
obtener desarrollos rápidos no solamente en azúcar sino también en biomasa.
OVERVIEW OF SUGARCANE BREEDING IN MAINLAND CHINA

KEYWORDS: Breeding, Sugar Production, Sugarcane, China.

Abstract

This paper briefly reviews the history of sugarcane breeding in mainland China, major sugarcane research institutes in different provinces, and the development and adoption of new varieties in the past 10 years. It also highlights important benefits and progress in introducing sugarcane varieties from overseas and Taiwan, China. Progress in utilising basic germplasm for sugarcane improvement in mainland China is also briefly reviewed. Challenges facing sugarcane breeding in China and potential ways to address these are proposed.

Introduction

China is currently the 3rd largest sugarcane producing country in the world, following Brazil and India. Sugarcane is mainly grown in south-western China. In the 2007–08 season, 1.47 million hectares of sugarcane was grown in China and produced 13.19 million tonnes of sugar.

Improvement of sugarcane varieties has played a critical role in the Chinese sugarcane industry. The central and local governments have therefore given a high priority to the program of sugarcane breeding, and sugarcane improvement through breeding has made considerable progress in recent years.

History of cane breeding in mainland China

Chinese people have cultivated sugarcane for more than 2000 years. In the early days, (before 1930) of sugar production in mainland China, the principal varieties were Bamboo Cane and Lu Cane, which were Saccharum sinense Roxb (Chen et al., 2003).

From 1932 to 1934, POJ2725, POJ2878 and POJ2883 were introduced from the Philippines, and Badila from Australia, but only POJ2878 and POJ2725 became major varieties for sugar production. F134 and Co419 (originally from India) were introduced to the mainland from Taiwan in 1947. F134 became the most popular variety in the sugarcane growing areas in mainland China until early 1980 (Peng et al., 1990).

In 1953, a sugarcane breeding station was established in Yachen Sanya (formerly known as Yaxian county), Hainan Island. It is located in a tropical region (18°27’N) and sugarcane can flower in the field (Figure 1). Sugarcane seeds from this station were sent to sugarcane research institutes in different provinces (Table 1). This station can make 1200 crosses from 1600 flowers every year. Besides this station, Ruili hybrid station can provide about 100 crosses. The number of seedlings is...
about 0.8 million over the country each year.

Since the 1950s to 1999, more than 100 sugarcane varieties have been bred and released for commercial sugarcane production in mainland China. Of these GT11 (CP49-50 × Co419), YT57-423 (F108 × F134), YT63-237 (Co419 × CP33-310) and MT70-611 (CP49-50 × F134) have became dominant varieties for a period in different provinces (Lin *et al.*, 2004; Tan and He, 2004).
From 1999 to 2009, 42 new sugarcane varieties have been released for commercial sugarcane production (Table 2).

* Variety identified by National means that the variety can be planted in main production provinces. Identified by one province means only can be grown in this province; before extending in other provinces, further testing may need to be done in those provinces.

Cane production and cane yield and quality have been improved very quickly in mainland China in the past 50 years. Cane production in mainland China has risen from 12.4 Mt in 1961 to over 97.5 Mt in 2008, while the harvested area has increased from less than 0.3 Mha to more than 1.5 Mha (Figure 2). Over the same period, cane yield has increased by about 40%, from under 50 t/ha to over 70 t/ha, representing an increase of 40% or an average 0.43 t/ha/year over 47 years. The average sucrose content, over this same period, has increased from under 13% to more than 14.5%,
with some varieties now providing an average over 16% (from October to April) (Figure 3 and Table 3). Success in the improvement of sucrose content is attributed at least partly to the use of introduced varieties with high sucrose, such as CP and ROC varieties, as parents.

**Fig. 2**—Cane yield and area in mainland China 1961–2008.

**Sugarcane varieties introduced and used in mainland China**

A large number of overseas sugarcane varieties have been introduced into mainland China since 1978, such as the CP series of USA, Q series of Australia, PR series of Puerto Rico, RB series
of Brazil and ROC series of Taiwan, China. After quarantine, most of them have been used as parental clones in the breeding program.

The CP and ROC series (Wu et al., 2008), in particular, CP72-1210, CP84-1148, ROC1 and ROC10, were used most frequently.

Some introduced varieties were suitable for commercial production in some cane growing areas and adopted directly as varieties. After assessment trials, such clones have been released as commercial varieties.

The most important of these have been ROC10, ROC16 and ROC22 bred by Taiwan Sugarcane Research Institute in China, and introduced to mainland China in 1980–2000.

The planting area of these three clones has expanded continuously due to their high cane yield, high sucrose content and adaptation to a range of environmental conditions.

In the 2006–2007 season, these three clones accounted for 70 percent of the total planting area of mainland China.

**Basic hybridisation program in mainland China**

China is rich in sugarcane germplasm resources. Since the 1980s, Chinese sugarcane breeders have collected a large number of wild cane resources from different provinces and maintained most of these in the National Sugarcane Germplasm Nursery, Kaiyuan City, Yunnan province (Table 4).

Among them, *S. spontaneum* and *E. arundinaceus* are more prominent than other wild species.

As soon as the Sugarcane Breeding program was set up on Hainan Island, in 1953, Chinese sugarcane breeders began working on a basic hybridisation program by crossing the local *S. spontaneum* with Badila (*S. officinarum*).

This effort produced two high performing F1 hybrids; YC 58-43 and YC 58-47 (Deng et al., 2004), which in turn have produced 5 and 9 commercial varieties, respectively (Figure 4).

In recent years, Chinese sugarcane breeders have used *E. arundinaceus* to cross with *S. officinarum* in order to introduce the characteristics of resistance to disease and vigour in *E. arundinaceus* into sugarcane. Some promising clones have been bred from the cross between *Erianthus* and *Saccharum* (Figure 5).
Selection program in mainland China

The selection programs conducted in China are almost the same in all research institutes in mainland China. Clones are first tested in an experiment station at an institute for 5–6 years. This is followed by testing at multiple sites outside the original institute for 4–5 years. An example of such a program, conducted in Fujian province, is shown in Table 5.

In addition to selection schemes operated by each individual institute, in 1996, China began a new project to evaluate sugarcane varieties in a nationally coordinated series of trials.

The project was named the National Sugarcane Variety Cooperative Regional Test (NSVCRT), and was coordinated by Fujian Agriculture and Forestry University and supported by Crop Variety Examination and Approval Committee, Ministry of Agriculture in China.

Seven series of regional tests have been carried out and more than 110 varieties were assessed in the tests, of which 55 varieties have been approved and released.

Issues in sugarcane breeding in mainland China

An issue of concern in China is that currently the planting areas of three ROC varieties accounted for 70% of the total sugarcane area in mainland China and exceeded 90% in Guangxi. The growing areas of new varieties bred in mainland China only accounted for 30%. Adaptability and yield stability of these newly bred varieties are commonly poorer than that of ROC series varieties. However, many of them have higher sucrose or higher TCH than the ROC series varieties.

It is considered greater progress will be made by increasing the scale of sugarcane breeding in China, which is limited by financial input by the Ministry of Agriculture and the Ministry of Finance of Chinese Government. Substantial financial support from the government for the long term should provide a golden chance for sugarcane improvement.

Resumen

ESTE artículo revisa rápidamente la historia del mejoramiento de caña en China continental, los principales institutos de investigación en las diferentes provincias y el desarrollo y adopción de Variedades en los últimos 10 años. También se destaca los importantes beneficios y progresos al introducir variedades desde otros países y Taiwán. Los progresos logrados al usar el germoplasma básico de China son también brevemente revisados. Futuros retos y caminos potenciales para trabajar en mejoramiento de caña en China también son analizados.
COMPARISON OF BIPARENTAL AND MELTING POT METHODS OF CROSSING SUGARCANE IN HAWAII

Abstract

Sugarcane (Saccharum spp.) breeders at the Hawaiian Sugar Planters’ Association used biparental and melting pot (modified polycross) crossing methods concurrently from 1935 to 1985. While the annual effort expended to make biparental crosses exceeded the effort to make melting pot crosses over this 50-year period, annual viable seed yield from biparental crosses was usually less than 15% of that from melting pot crosses and, hence, the numbers of seedlings planted to the field from those crosses usually accounted for less than 20% of the total seedling population. In 1985, nine of the 10 sugarcane cultivars listed in Hawaii’s variety census originated from melting pot crosses; only one originated from a biparental cross. In the face of a shrinking sugar industry in Hawaii and a smaller work force in the breeding program, the decision was made in 1985 to rely primarily on melting pot crosses for the production of commercial cultivars. From 1985 to 2005, twelve additional clones that were bred prior to 1985 eventually attained ‘commercial cultivar’ status by exceeding 1% of the total cane growing area. All twelve originated from melting pot crosses. Over the 50-year period that the two crossing methods were used, the melting pot method proved to be more labour efficient and ultimately contributed more than the biparental crossing procedure toward the development of new commercial cultivars for the Hawaiian sugar industry. From 1985 forward, the biparental crossing method was used more for introgressing desired traits from exotic germplasm than for the development of commercial cultivars.

Introduction

Since 1935, sugarcane breeders at the Hawaiian Sugar Planters’ Association (HSPA) Experiment Station have employed the melting pot (MP) crossing method. This method was used sparingly until World War II. From 1942 to 1946, the MP method was used almost exclusively because of employee shortages at the Experiment Station; only 32 biparental (BP) crosses were made during this period.

After World War II, MP crossing remained an important method for developing new commercial cultivars in Hawaii. MP crossing was adopted at a few other sugarcane breeding stations around the world. However, it has not become the mainstay breeding procedure at most other breeding stations, including those in the USA.
The term ‘melting pot crossing,’ first coined by Dr. A. J. Mangelsdorf (1953), is a modified polycross. While the MP crossing method was being used in Hawaii, breeders working on other crops in the United States and Europe developed the polycross method for obtaining combining ability information in forage species. Tysdal et al. (1942) proposed the term ‘polycross’ to describe the progeny from a line that was subject to outcrossing with selected lines growing in the same nursery. A true polycross would consist of a collection of selected parents replicated in an isolated nursery in such a manner as to assure random inter-mating through open pollination. Ideally, every clone has an equal chance of being pollinated by every other clone in the polycross (Allard, 1960).

Thus, MP crossing, as conducted in Hawaii, does not constitute a true polycross because tassels from each clone may not be interspersed randomly, unequal numbers of flowers may be used from each clone, and tassels vary greatly in pollen production. Throughout this paper, the term ‘female’ refers to parents that shed little to no viable pollen at anthesis, and ‘male’ refers to parents that shed moderate to abundant viable pollen at anthesis at 20–30°C.

Warner (1953) stated that the MP crossing method was first explored in Hawaii with the object of evaluating the breeding value of a large number of parents at minimum expense. After several years of experience, a number of advantages to the use of the MP method were observed.

**Cost efficiency:** Considering labour, time, physical facilities, and space, the MP method produced a large number of seedlings at minimal cost. In Hawaii, establishing MP crosses is a one-day operation per crossing date. Stalks with tassels at early anthesis are cut and tagged in the field, then brought to the MP crossing shelters where they are interspersed. In contrast, erecting BP crosses is more labour-intensive and requires two days of activity per crossing date. The first day is spent recording numbers of tassels available by clone, determining the level of pollen production of individual parents by examining florets, then determining desired combinations based on individual pollen production and tassel availability. Relatively male-sterile parents (low- to non-pollen producers) are used as females, while moderate to abundant pollen producers are used as males. On the second day, tassels are collected and crosses are erected. In MP crossing, hundreds of tassels are compactly arranged in large shelters to achieve wide distribution of pollen shed from each tassel. In BP crossing, each cross must be kept isolated in order to prevent pollen contamination. Large cloth lanterns, first described by Skinner (1959) in Australia, were adopted on a large scale in Hawaii following the building of new crossing facilities at the HSPA Sugarcane Breeding Station in Maunawili Valley on Oahu 1975 in order to minimise cross contamination (Heinz and Osgood, 2009).

**Seed set:** Substantially more viable seeds per tassel are produced from the MP crosses than from the BP crosses. Low pollen viability of certain parents used as males and mating incompatibilities probably contribute to poor seed set in certain BP crosses. By contrast, a large amount of pollen is dispersed from a wide range of tassels in the MP crosses. Consequently, resulting recombinations obtained in MP crossing must be viewed as biased, rather than random.

**Genetic combinations:** With the same number of parents available, the potential number of possible parental combinations in MP crosses is exponentially greater than in BP crosses. To illustrate, assuming ten male-fertile tassels representing ten different parents were available, as many as 90 crosses \([n*(n-1)]\) or 45 unique genetic combinations \([n*(n-1)/2]\), discounting reciprocal crosses, are possible in a polycross arrangement. With the same number of male-fertile tassels and parents, only five BP crosses could be arranged in a manner that would assure cross fidelity.

The primary disadvantage of the MP crossing method is loss of pedigree information (inability to repeat crosses giving high selection rates, track inbreeding coefficients, determine
specific combining abilities, etc.; Stevenson, 1965) and hence, a theoretically lower level of parent selection efficiency (Empig et al., 1972), since half-sib rather than full-sib progeny are being assessed. Since the HSPA used both the BP and MP crossing methods concurrently for 50 years (discounting the World War II era), sufficient data have accumulated to assess the relative performance of the two procedures in Hawaii in relation to the production of commercial cultivars.

Breeding methodology

Melting pot crosses

The MP crosses, as arranged in Hawaii, consist of tassels from highly selected male-fertile cultivars, with more diverse, less highly selected male-sterile (female) cultivars (Warner, 1953). The number of tassels of individual parents in MP crosses is dependent on breeding interest, availability of tassels, and estimated pollen fertility. Seed is harvested from both male-fertile and male-sterile parents. In Hawaii, four principal MPs have evolved:

**General MP:** This was the largest and genetically most diverse MP. In addition to proven parents, recently tested clones with only limited yield information, as well as vigorous wild-derivative male-sterile (or sterilised) clones were included as parents.

**Leeward MP:** Clones adapted to irrigated leeward environments were included.

**Windward MP:** Clones adapted to rain-fed windward environments were included.

**Quality MP:** Relatively small numbers of elite clones and proven parents were included on the basis of exceptional individual and/or progeny performance in yield tests. Emphasis was placed on those clones with above-average sucrose content.

Special MP crosses were arranged for brief periods, often not greater than five consecutive years, to improve characteristics such as smut (Ustilago scitaminea H. & P. Sydow) resistance, drought tolerance, salt tolerance, and biomass potential. From 1974, wild-derivative MPs began to be made as an efficient method of incorporating into elite germplasm, genes from wild germplasm sources (Meyer and Heinz, 1975). Initially, both male (elite as female, wild derivative as male) and female (wild derivative as female, elite as male) wild-derivate MPs were made. Because very few wild-derivative clones were male sterile, the female wild-derivative MP was discontinued. The male wild-derivative MP was refined by forming three S. spontaneum L.-derivative MPs, namely Spont. 1, Spont. 2, and Spont. 3 (Meyer et al., 1982). These S. spontaneum-derivative MPs received tassels from first-generation (F₁), first backcross (BC₁), and second backcross (BC₂) male-derivative clones. Each derivative MP received tassels from at least 40 male sterile (or emasculated) commercial-type parents.

Biparental crosses

Until 1985, most BP crosses were commercial-type (Saccharum spp. hybrids) x commercial-type combinations. The traditional approach in making such combinations was to match elite parents with complementary traits (windward x leeward environment adaptation, high tonnage x high sucrose, etc.), until tassels were no longer available to make further crosses. A fully computer-driven procedure for determining usage of available tassels in BP combinations, such as the proven cross method used in Australia (Hogarth and Skinner, 1986), was never implemented in Hawaii, although data were electronically organised to assist breeders in arranging optimum crosses among available tassels.

Since 1985, BP crossing was principally used for population improvement, rather than the direct development of commercial cultivars. First-generation hybridisation between wild or foreign commercial clones × commercial-type clones, and early-generation backcrossing toward the commercial type was accomplished using the BP crossing method.
Results and discussion

The mean distribution of crosses made and seedlings produced at generational intervals from 1935 to 1985 is shown (Table 1).

Since 1950, approximately 13% (520) BP and 87% (3480) MP crosses were made per year in spite of the greater effort that was required to erect BP crosses. The highest number of BP crosses achieved in Hawaii in a single year was 1200. The MP crosses could be placed directly from the field into the crossing house where they remained until seed harvest. By contrast, tassels in BP crosses had to be handled two additional times prior to placement in crossing lanterns in the BP crossing facility.

First, they were set in a staging area where the male and female parents were paired, and then they were moved to a temporary location where the desired male and female were secured together with the male tassels positioned approximately 20 cm higher than the female tassels, and the exposed anthers on the female tassels trimmed off.

Numbers of crosses per MP are determined by counting the number of parents used per crossing date, then summing over crossing dates. The General MP usually accounted for about 50–55% of the total MP crosses. Windward and Leeward MPs each accounted for approximately 15%, and the Quality MP for 5%.

Specialty MPs accounted for the remainder of crosses. Since 1972, following the formation of the first specialty MP (Smut Resistance MP), specialty MPs generally accounted for <5% of the total number of MP crosses arranged each year, thereafter.

The number of seedlings planted from BP and MP crosses does not necessarily correspond with the number of crosses arranged for or seed produced from each type of cross. Nearly all seed from BP and Quality MP crosses was planted, as was most seed from the Leeward and Windward MP crosses. By contrast, most seed from the General MP was not planted, unless there was a shortage of seed from other crosses.

During the 1977–1978 crossing season, BP and General MP crosses accounted for 12% and 51% of total crosses, respectively (Table 2). However, BP crosses accounted for nearly 18% of the seedling population, compared with only 32% for the General MP. Selection intensity from Stage 1 (seedling stage) to Stage 4 (preliminary yield testing) appeared to be nearly constant among MP and BP crosses.

From 1950 to 1980, approximately 15 to 20% of sugarcane seedlings planted each year originated from BP crosses. About 33% of all seedlings were from General MP crosses while roughly 50% of seedlings were from Leeward, Windward, Quality MP crosses, and special MP crosses.

Both BP and MP crosses played a significant role in the early production of commercial cultivars. Heinz and Osgood (2009) published a list of major cultivars in Hawaii (along with their parentages) in their review of the history of HSPA from 1946 through 1996. Three of the 22 cultivars they listed (H 37-1933, H 49-5, and H 59-3775) originated from BP crosses. All three pre-dated 1960. By 1985, nine of the 10 cultivars then being commercially grown in Hawaii (representing 97% of the area in sugarcane) were progeny of MP crosses. While there was a trend toward a decreased percentage of seedlings being planted from BP crosses, the proportion never dropped below 15%, between 1947 and 1975, and actually increased during the 1975 to 1985 decade. None of 21 cultivars that became commercial after H 59-3775 came from BP crosses. The under-representation of commercial cultivars originating from BP crosses, relative to the proportion of seedlings planted from 1955 to 1985, would suggest that the MP crosses were more effective in producing clones that would eventually gain commercial status.

In 1985, to investigate whether the lack of cultivars from BP crosses was likely to persist, the origin of clones having the greatest potential of attaining commercial status was investigated. Potential commercial clones were defined as those with a sugar yield per unit area matching or exceeding that of the major cultivar planted at the time in at least two advanced yield tests. Of the 51 clones that had commercial potential, only 4 (8%) were derived from BP crosses. Only eleven (22%) of the potential commercial clones were derived from General MP, suggesting that the more conservative and specialty (MPs) were the most efficient in producing commercial cultivars (70% of total).

Generating a large amount of viable seed from BP crosses is widely acknowledged as being more difficult than from MP crosses. However, the lower productivity of BP crosses, in proportion to their relative representation in the seedling population, is more difficult to explain. Although most parents used in BP crosses were selected primarily on the basis of their own performance, rather than proven parental performance, considerable effort went into making the most desirable combinations possible.

Unless the formation of BP crosses is based on the known specific combining abilities of the parents, the advantages associated with BP crosses are more than offset by their lower relative fertility. While BP crosses involving parents with known high specific combining ability will in theory produce more elite progeny and hence, have a higher probability of producing commercial cultivars, the challenge to the breeder is the time and effort needed to obtain and make use of specific combining ability data.
Results from a combining ability study in which families (rather than individual clones) were planted in yield test plots, indicated that non-additive genetic variation for sugar yield is important in cane harvested at 24 months (Wu and Tew, 1990). The performance of elite x elite crosses is difficult to predict without specific combining ability data. Perhaps the far greater number of combinations represented in MP crosses may be more advantageous than previously acknowledged, especially where selection and yield testing programs are designed to evaluate large numbers of seedlings. In spite of the shortfalls of MP crossing, results of this retrospective study suggest that MP crossing has been the more effective crossing method for exploiting specific combining ability in sugarcane.

Several efforts have been made to refine MP crossing. The most important recent improvement has been the effective hot water (50°C, 5 min) emasculation treatment prior to anthesis (Nagai, 1985). This treatment should permit increased flexibility in the selection of parents entering MPs. For example, lesser-tested new parents could be rendered male sterile before they are entered into an MP, in order to assure a high proportion of pollen from elite clones. With the ability to emasculate, it has become possible to use wild-derivative clones as female parents rather than as male parents, in the derivative polycross scheme. Physical separation of backcross generations during crossing also is no longer necessary. Results from the 1984–1985 crossing season indicate that, even though the emasculation procedure reduces female fertility, nearly half of all wild-derivative clones produced adequate seedlings for effective selection. This demonstrated that a large increase in the number of female parents could be achieved through the use of the emasculation procedure.

Presently, it is difficult to retrace the specific MP origins from which Hawaii’s commercially important sugarcane cultivars were derived. However, the MP origins of those cultivars deemed important enough to have been registered as commercial cultivars are known. Based on the MP origins of registered cultivars, it is apparent that the more elite MPs have been especially productive, particularly since 1960. Cultivars H 62-4671 (Heinz et al., 1979) and H 70-144 (Heinz et al., 1983) originated from the Quality MP. Cultivars H 65-7052 (Heinz et al., 1981a), the current leading cultivar in Hawaii, H 68-1158 (Heinz et al., 1981b), and H 73-7324 (Tew et al., 1992a), came from the Windward MP. Cultivar H 73-6110 (Heinz et al., 1984) came from the Leeward MP. Somewhat surprisingly, three cultivars, H 74-1715 (Tew et al., 1988), H 74-4527 (Tew et al., 1992b), and H 78-4153 (Wu, 2003) originated from a special MP set up shortly after the discovery of smut in Hawaii that involved smut-resistant parents. This MP was referred to as the Smut MP (1972–1978). Cultivar H 78-292 (Tew et al., 1992c) is the only registered cultivar of recent vintage that originated from the General MP.

Conclusions and recommendations

The MP crossing method has been more productive than the BP crossing procedure in the development of new commercial cultivars for the Hawaiian sugar industry. From 1955 to 1985, only one commercially important cultivar was produced from BP crossing compared with 26 cultivars from MP crossing. Without the availability of specific combining ability data, the only demonstrated advantage BP crossing has over MP crossing is the preservation of ancestral information. Obtaining specific combining ability data in Hawaii is difficult because the crop is grown to an average of 24 months of age. After eight months’ age, the crop forms an entangled mat of cane, precluding effective visual evaluation in small plots. The correlation between cane volume at eight months and cane weight at 24 months is negligible (Wu, 1983). Entry of full-sib families, rather than individuals, into yield tests may allow a reliable measure of specific combining ability at harvest (Wu and Tew, 1990), but this procedure is so costly and time consuming as to be impractical. Limited BP crossing for specific purposes, such as conducting genetic studies, or evaluation of specific combining ability among commercially important cultivars, for example, may be justified.
After 2010, there will only be one plantation remaining in Hawaii, namely Hawaii Commercial and Sugar Company (HC&S) on the Island of Maui. It is therefore unlikely that the remaining breeding program, tailored to one plantation’s needs, will accommodate more than one MP in the future. In most breeding programs around the world, including Hawaii’s, the turnover rate of parents tends to be conservative; the majority of parents used in one year will be used the following year.

We recommend the continued inclusion of recently yield-tested clones as experimental parents in this MP. Parents with only preliminary yield data could be emasculated and older proven parents be used as the primary pollen source. This modification should result in an increase in the mean performance of progeny from this MP and allow a more meaningful comparison of the relative performance of the newer clones as parents, since the pollen source is controlled.

Acknowledgements

Acknowledgement is given to: Dr Albert J. Mangelsdorf, whose sugarcane breeding career at HSPA spanned from 1926 to 1961; Dr John N. Warner, whose breeding career at HSPA spanned from 1940 to 1965, with breaks to serve during World War II, and to obtain a PhD degree (HSPA-paid leave); and Dr Don J Heinz, whose breeding, administrative, and consulting career at HSPA spanned from 1961 to 1995, for the important contributions that they made toward the improvement of the HSPA breeding and selection program during the course of their careers.

PALABRAS CLAVE: Cruzas Biparentales, Policruzamientos, Habilidad Combinatoria Específica.

Resumen

Los mejoradores de caña de azúcar (Saccharum spp.) en la Asociación de Cultivadores de Caña Hawaianos, usaron los métodos de cruzamientos biparentales y la fusión de varios parentales o cruzas múltiples (policruzamiento modificado, ‘melting pot’) en forma concurrente desde 1935 hasta 1985. Mientras los esfuerzos usados para hacer cruzamientos biparentales excedieron a cruzas múltiples durante un periodo de 50 años, la producción de semillas viables anualmente de los biparentales usualmente fueron menores al 15% comparados al método de cruzas múltiples, por esta razón el número de plántulas sembradas en el campo de estos cruzamientos generalmente fueron 20% menos en el total de la población de plántulas. En 1985, nueve de 10 cultivares de la lista del censo de variedades Hawaianas se originaron de cruzas múltiples (melting pot); solamente una se originó de cruzas biparentales. Debido a la reducción de la industria azucarera de Hawái y al pequeño grupo de trabajo en el programa de mejoramiento genético, la decisión tomada en 1985 fue depender principalmente de los cruzamientos por cruzas múltiples para desarrollar cultivares comerciales. Desde 1985 al 2005, doce clones adicionales provenientes de cruzas previas a 1985, eventualmente fueron denominados ‘cultivares comerciales’ por exceder el 1% del total del área de cultivo de caña. Los doce materiales se originaron de cruzas múltiples (‘melting pot’). Durante el periodo de 50 años en que los dos métodos de cruzamientos fueron usados, se probó que el sistema de cruzas múltiples es más eficiente en el uso de mano de obra comparado con el sistema biparental en el desarrollo de variedades de caña de azúcar en la industria azucarera Hawaiana. Desde 1985 en adelante, los cruzamientos biparentales se usaron mayormente para realizar introgresión de genes específicos, usando materiales foráneos que para el desarrollo de variedades comerciales.
ROOT DENSITY AND DIAMETER OF SUGARCANE CULTIVARS ACROSS THREE LOCATIONS IN CUBA

KEYWORDS: Sugarcane, Root System
Soil Profile Wall, Genotype By Environment.

Abstract

The objective of the present work was to study the density and distribution of sugarcane root systems in a multi-environment trial. Experiments were planted at three locations in the South-Eastern region of Cuba, with 11 sugarcane cultivars. Measurements of root diameter and root density (root numbers/cm³) for fine (FD), thick (ThD) and total (TD) roots were taken using the profile wall method. The root system was evaluated in squares of 20 × 100 cm up to 80 cm depth below the ground surface. Cane yield data (t/ha) and its relations with root system measurements were analysed. Genotype by environment interaction was identified using the AMMI model. Results showed significant (p<0.05) response for root density across genotypes, locations, depths and all interactions. Root depth was the major source of variation. Percentage of total root density was variable from 42.6–55.5% for 0–20 cm depth, dropping to 5.6-11.7% for 60–80 cm depth. Genotypes C86-12, C86-156, B7274 and C88-380 showed similar patterns for t/ha and TD. Moderate but significant (p<0.01) correlations were found between t/ha and FD, ThD and TD.

Introduction

The root system serves important physiological and biochemical functions. A deep-root system should be a desirable characteristic for sugarcane cultivars for the low rainfall regions because this would ensure an ability to endure depletion of soil water (Smith et al., 2005).

However, quantitative information on root distribution in sugarcane is limited. The objective of the present work was to study the density and distribution of sugarcane root systems comparing genotypes across environments in a multi-environment trial.

Materials and methods

The trial was carried out in the South-Eastern region of Cuba at three locations across the sugarcane production zone (Table 1).

Therefore, data from a multi-environment trial were analysed. Eleven sugarcane cultivars: C86-12, B7274, C323-68, C90-317, C86-156, C86-503, C86-531, C88-380 C90-530, C90-647 and C89-250, released in the last 10 years by the Cuban National Institute for Sugarcane Research (INICA) were evaluated.

Experiments at each location were planted in a randomised block design with three replications.

Data were collected from the plant and first ratoon crops. Root evaluation was performed in the first ratoon crop within 12 months. Cane yields (t/ha) for the first ratoon cropping season were recorded.

For assessing root diameter (mm) and density (root numbers/cm³), the profile wall method was used (Vasconcelos et al., 2003). Evaluations were made at 0.8 m depth and 1.0 m wide trenches (Figure 1). The profile was divided in squares of 20 x 100 cm up to a soil depth of 80 cm below the ground surface (0–20, 20–40, 40–60 y 60–80 cm). Roots were classified as fine (FD) (0.5–1 mm), thick (ThD) (>1 mm) and total (TD = FD + ThD).

Analysis of variance (ANOVA) was performed to determine the significance of the main effects of genotype, environment and depth. The effect of genotype-environment interaction (GE) was also determined using AMMI models (Gauch et al., 2008), and regression analysis.

**Results and discussion**

Results of analysis of variance (Table 2) showed significant differences for all effects (genotypes, locations and depths) and its interaction. For root density (FD, ThD and TD), depth was the most important source of variation accounting for 42.5, 63.1 and 58%, respectively.

Root diameter also showed significant differences for all effects and every interaction. Root diameter was different from root density for magnitudes of the variance terms. Results showed a lower variance contribution for depth for root diameter.

* indicates significant differences at p<0.05, PSS = Percent of total sum of squares.

As shown in Figure 2, the highest mean total root density (TD) was recorded at Enidio Díaz, and this was significantly different to the other locations. Root density and percent of total roots were different for locations and depth. The Enidio Díaz location had the highest percent total root density in the first 20 cm (55.5%), going down progressively with depth to 5.6% at 80 cm, which was the lowest of the three locations.

![Root density and percent of total roots recorded at each location.](image)

Fig. 2—Root density and percent of total roots recorded at each location.

Leyva et al. (2000), found a negative relation between depth and root numbers. Vasconcelos et al. (2003) reported 72% of total roots in the first 40 cm of soil depth. Physical-chemical properties of the soils at the three locations are shown in Table 3. The Enidio Díaz location has the lowest value for bulk density (BD) and the highest concentration of organic matter (OM). These characteristics seem to improve the development of the sugarcane root system. However, the Mella location, with a sandy soil, has the highest value for BD, the lowest concentration of OM and the poorest root system development.

**BD—Bulk density  P—Porosity OM—Organic matter**

A regression analysis for cane yield (t/ha) and root density (FD, ThD and TD) (Figure 3) showed a moderated and significant correlation, with the highest $R^2$ value for ThD. These results demonstrate that sugarcane root densities are influenced by the environment and genotype, as their relation with yield is not completely proportional. This suggests genetic differences for root system efficiency.

![Figure 3](image)

**Fig. 3**—Regression analysis for root density (fine (DS), thick (DP) and total (TD)) and cane yield (t/ha). (** indicates significant differences at $p<0.01$ and * $P<=0.05$)

The pattern of genotype by environment interaction for cane yield and total root density was analysed using the AMMI model. For cane yield (Figure 4a), AMMI analysis indicated differences for the three test locations.

At Mella location, C89-250 was the highest yielding genotype. At Enidio Diaz location, the best yielding genotypes were C90-530 and C88-380. At Paquito Rosales, the best performing genotype was C323-68.

The pattern of GE for total root density (Figure 4b) showed differences between the three locations, but genotypes clustered differently compared to cane yield. Genotypes with the best performance across all locations were the same for cane yield and DT: C86-12, C86-156, B7274 and C88-380.

![Figure 4](image)

**Fig. 4**—Biplot of genotype by environment interaction using AMMI model for (a) cane yield (t/ha) and (b) total root density.
Root diameter (Figure 5) showed differences among locations, genotypes and depth. Enidio Diaz location had the lowest mean value for root diameter, significantly different to the other locations. There were also significant differences among genotypes for root diameter. The highest root diameter values were found in the upper soil layer and reduced with soil depth (see colour scale).

Results indicate differential performance of genotypes for root density (FD, ThD and TD) across location and soil depth. The highest root density is found in the upper soil layer (0–20 cm) and directly below the plant. On the other hand, genotypes with high homogeneity for root system distribution in the soil profile could take advantage of soil water. Relationship between root density and agricultural yield is not always direct. It depends on several environmental factors where it is developed. In the future, we will focus on water uptake and shoot eco-physiological traits such as biomass, leaf area, stalk length, etc.

MOTS-CLÉS: Canne à Sucre, Système Radiculaire, Technique du Profil Cultural, Génotype par Environnement.

Résumé

Le but de ce travail consistait à étudier la densité et la distribution du système radiculaire de la canne à sucre de 11 cultivars dans des essais multi-locaux établis dans trois sites dans la région du sud-est de Cuba. Une mesure du diamètre et de la densité des racines (nombre de racines par cm³) pour les racines fines (FD), épaisses (ThD) et totales (TD) ont été prélevés par la technique du profil cultural. Le système radiculaire a été évalué en utilisant des grilles de 20 × 100 cm d’une profondeur allant jusqu’à 80 cm. Le rendement de canne (t/ha) et sa relation en fonction des mesures du système radiculaire ont été analysés. Les interactions génotype × environnement ont été identifiées grâce à la modélisation AMMI. Les résultats ont démontré une réponse significative (p<0.05) pour la densité des racines à travers les génotypes, les sites, la profondeur ainsi que pour toutes les interactions. La profondeur des racines a été la source principale de variation. Le pourcentage de la densité totale des racines a varié de 42.6–55.5% pour une profondeur de 0–20 cm, déclinant à 5.6–11.7% pour une profondeur de 60–80 cm. Les génotypes C86-12, C86-156, B7274 et C88-380 ont montré une tendance similaire pour le rendement de canne et la mesure des racines totales. Des corrélations modérées, mais significatives (p<0.01) ont été observées entre le rendement de canne et la mesure des racines totales ainsi que pour les racines épaisses et les racines totales.
ESTUDIO DEL SISTEMA RADICULAR DE LA CAÑA DE AZÚCAR EN TRES LOCALIDADES DE CUBA

Resumen
El objetivo del presente trabajo fue el estudio de la densidad y distribución del sistema radicular de la caña de azúcar en experimentos multiambientales. Los estudios se plantaron en tres localidades de la región sur oriental de Cuba, con 11 cultivares. Se determinó la densidad (no. raíces/cm³) de las raíces activas finas (DF), gruesas (DG) y total (DT) y su diámetro (mm). Se utilizó el método del perfil de suelo, dividiéndose en áreas de 20 cm × 100 cm, hasta 80 cm de profundidad. Se determinó el rendimiento del cultivo (t caña/ha) y su relación con las variables analizadas, así como, análisis de interacción genotipo-ambiente (IGE) por el modelo AMMI. Los resultados mostraron, que para todas las variables de densidad de raíces, una respuesta diferenciada y significativa (p<0.05) de los genotipos, localidades, y profundidades, así como de sus interacciones. Para el diámetro, la mayor variación fue debida a la profundidad. Los porcentajes de la densidad total de raíces por profundidad y localidad disminuyen desde 42.6–55.5% para la profundidad de 0–20 cm hasta 5.6–11.7% para los 60–80 cm. Los genotipos C86-12, C86-156, B7274 y C88-380 presentaron similar patrón de IGE para las t caña/ha y la DT. Se obtuvieron correlaciones moderadas y significativas respecto a las t caña/ha para la DF, DG y DT.
THE IRANIAN SUGARCANE SELECTION PROGRAM:
AN OVERVIEW OF METHODOLOGIES

KEYWORDS: Selection Program, Genotype-Environment Interaction.

Abstract
The main sources of genetic variation, G × E interaction, response to selection and heritability values were studied in order to establish methodological bases for the selection in initial stages of the Iranian sugarcane breeding program. A representative sample of 10 bi-parental combinations was evaluated in six environments. The component of variance attributable to environment was prevailing and the genotype-environment interaction was significant. Three types of environment were defined and differences between them contributed to selection efficiency. The greatest genetic variability was obtained in the northern region of Khuzestan, and the best results for selection were registered in Imam Khomeini sugar factory’s locality.

Introduction
It is estimated that the consumption of sugar in the Islamic Republic of Iran is around 30 kg per capita with a total demand of 2 million tonnes of refined sugar annually for direct and indirect use. Iran produces 1 300 000 tonnes of sugar, and imports the remainder.

Sugarcane cultivation has increased in the south of Iran and in Khuzestan province, and Iran aims to be self-sufficient in sugar and develop various by-products. In fact, the Sugarcane and By-Products Development Corporation has been created to produce sugar, animal food, paper, particle boards, pulp paper and other by-products.

This has motivated special interest in the adoption of modern technologies and improved cultivars. Therefore, the National Breeding Program is working under special climatic conditions in Khuzestan to grow sugarcane, with different environmental stress conditions (drought, salinity and freeze). The main commercial varieties are CP48-103, CP57-614, CP69-1062 and NCo310.

The particular growing conditions enabled a study of genotype-environment interaction, its sources of variation and genetic parameters that allow breeders to establish methodologies and bases for the Breeding and Selection of sugarcane in Iran and here we present a summary of the results.

Materials and methods
The experiments were planted between September 2003 and March 2007, in three locations of the Sugarcane Research Center, belonging to Sugarcane and By-Products Development Corporation in Khuzestan province.

Progenies of 10 bi-parental combinations of representative commercial varieties of different geographical origin were evaluated in a randomised block design. Each combination had a
population of 60 seedlings and the evaluations were carried out in plant cane and first ratoon at 10 and 12 months respectively. Data were taken for plant height, stem diameter, number of stems and brix, following procedures described by Jorge et al. (2002) and Hamdi et al. (2003).

Analysis of variance of double classification (clones × locality) was performed to identify the sources of genotype × environment interaction (G × E) using a factorial model (Cochran and Cox, 1965).

The model of simple classification of randomised effect balanced proposed by Kempthorne (1952) was used to estimate the statistical genetic parameters for each of the localities. Heritability estimates in narrow sense (h²e) were calculated from the components of variance (Hogarth, 1968; Milligan et al., 1990).

The approximate standard error was obtained according to Anderson and Bancroft (1952) and Becker (1984) and the genetic coefficient of variation (CGV) according to Falconer (1970). To compare the selection efficiency between localities and characters, the response to selection (R) was utilised and a selection index (ΔG) of 40% of the population selected was utilised (Falconer, 1970; Cesnik and Vencovsky, 1974).

**Results and discussion**

The analysis of variance shows significant differences (p = 0.05) in the G × E interaction in most of the evaluated characters, but not for brix in plant cane and number of stems in first ratoon. This can affect selection efficiency, reaffirming the importance of replication in time and space (Table 1).

Drought stress under these cultivation conditions, with water deficiency combined with high temperatures, might be the reason for the high values presented here. The heritability values estimated in first ratoon confirm the previous results for stem height and field brix as major trends. The genetic coefficient of variation (CVG) had very similar behaviour.

Localities presented the most important source of variation in plant cane and first ratoon for stem height. On the other hand, stem diameter was the character with no location effects. For the remaining characters, experimental error proved to be the main source of variation.

The heritability values and their consistency calculated for each locality were very low for the different environments for cane yield, and the rest of the components of cane yield (Table 2). These results do not agree with Garcia (2004) for conditions of drought stress in Cuba, who found genetic variability for diameter.

Other statistical genetic parameters evaluated were genetic variance (σ²g), genetic coefficient of variation (GCV), response to selection and selection gain, but heritability values might be the best criteria for selection for cane yield in seedling stage in Iran, using stem height and stem diameter. Sugar content might be useful for selection in first ratoon.

Selection efficiency is evaluated using the balance between genetic components and phenotypic expression. The best results of selection were expected at Imam Khomeini in plant cane for three of the four characters (stem diameter, stem height and number of stems).

In terms of the G × E interactions and the main statistical genetic parameters, three types of environments in Khuzestan were confirmed to contribute to selection efficiency, relating to the types of soil and environmental conditions. Environments in the northern Province show great variability where selection in seedling stage will provide better results. A climatic zones classification confirmed differences between Imam Khomeini and Mian Abb localities. The first one shows better efficiency. The southern environment (Amir Kabir) did not show major differences in genetic statistical parameters.

These results show the importance of adopting strategies for selection in the seedling stage, but not assign major importance to evaluation in ratoon, applying low to moderate selection intensity to allow selection of a high proportion of individuals from the population.

$\sigma^2_G$, Genetic variance $\sigma^2_E$, Error variance CVG, Genetic coefficient of variation $h_e^2$. Heritability R, Response to the selection $\Delta G$. Profit for selection.
Conclusion

1. A suitable strategy for the selection will be to conduct it in ratoon with low to moderate intensity and using the length of stalk and refractometric brix as the principal criteria.

2. The environmental effect proved to be the most important source of variation (76-96% of the total phenotypic variation) with a reduction in ratoon.

3. Three types of environments were identified, according to the soil classification, and these contribute to the differences in the efficiency of the selection. Imam Khomeini is the most effective locality for selection.

4. The need to enlarge the genetic base used was ratified for breeding purposes.

KEYWORDS: Sugarcane, Disease Resistance, Brown Rust.

Abstract

The present work is aimed at evaluating rust (Puccinia melanocephala H. & P. Syd) resistance in sugarcane progeny as well as identifying parents able to produce progeny with a high percentage of resistant individuals that can be used as a source of resistance in a breeding program. Ten families derived from biparental crosses were evaluated for rust resistance in a randomised block design with four replicates with 50 seedlings per replication. Rust resistance was evaluated by visually rating on a scale of 1–9 based on infection on all leaves. The lowest means and variances were observed for families 9 (1.82 and 3.05) and 10 (1.06 and 0.5) in which the variety IACSP94-2094 was used as a parent. Individuals in families 8, 9 and 10 showed a 3:1 resistant:susceptible ratio, suggesting the presence of one major gene with a dominant effect. The results identify the varieties IACSP94-2094, IACSP91-2195 and SP83-2847 as sources of rust resistance.

Introduction

Sugarcane brown rust caused by the fungus Puccinia melanocephala H. & P. Syd is considered one of the main diseases of sugarcane with important economic losses in susceptible varieties (Matsuoka et al., 1999).

Rust resistance has been considered a quantitatively inherited trait, with moderate to high heritability. In the past, sugarcane rust evaluation has been based on a subjective rating scale for disease severity (Hogarth, 1987, Asnaghi et al., 2001).

Although sugarcane resistance is considered quantitatively inherited, a 3:1 segregation ratio indicative of a major gene with dominance effect was observed in progeny derived from the self of the variety R570 (Daugrois et al., 1996).

Since the use of sugarcane varieties resistant to rust is the best method for controlling the disease, the present work aimed to evaluate brown rust resistance segregation in 10 sugarcane families and also to identify parents that are able to generate a high proportion of individuals resistant to brown rust for use in a breeding program.

Material and methods

Brown rust resistance was evaluated in 10 families derived from bi-parental crosses between parents with different rust ratings (Table 1).

The experiment was planted in October 2007 at the Sugarcane Center from the Instituto Agronômico Campinas, Ribeirão Preto, SP, Brazil. Each family was composed of 200 individuals derived from hybridisations made in 2007. The experimental design was randomised complete
block with four replicates containing 50 individuals per family. Plots were composed of 5 rows, six metres long, with 1.5 m spacing between rows and 0.6 m between plants. Each replication was planted in a homogeneous area of the field.

Plants were rated in the field for rust, using a scale which ranged from 1 (resistant) to 9 (susceptible) (Amorim et al., 1987).

Scores between one and three were considered resistant, four to six intermediate, and seven to nine susceptible. The SASR (1999) package was used in the analysis of variance, and means and family variance estimations.

The Tukey test was applied to verify statistically significant differences among the family means. To test the hypothesis of a 3:1 segregation ratio (resistant/susceptible), the individuals of each family were separated in two classes: resistant (score = 1.0) and susceptible (score ≥ 2) applying the Chi-square test with 1 degree of freedom.

**Results and discussion**

The lowest means and variances were observed for the families 9 (1.82 and 3.05) and 10 (1.06 and 0.5) in which the variety IACSP94-2094 was used as parent (Table 1).

The low mean and variance values of these two families indicate that most of the individuals are resistant with little phenotypic variability for rust resistance, particularly for individuals from Family 10.

These two families had means that differed significantly from those of families 1, 2, 3 and 4 (Table 1).

</tbody>
</table>

Means with the same letters did not differ significantly at the 5% level (Tukey).

Of the 10 families evaluated, families seven, eight, and nine did not deviate significantly from the 3:1 ratio ($\alpha=0.05$), suggesting the presence of a major gene for resistance in one of the parents (Daugrois et al., 1996).

Family ten did not segregate for susceptibility (1:0 ratio), i.e. all the individuals were resistant (Table 2). This suggests that there is probably a major dominant gene for rust resistance in both parents. According to Hogarth et al. (1993), families derived from crosses between resistant parents are likely to yield resistant progeny.

The deviation in relation to the 2:1 ratio was not significant at (p<0.05) for families 5 and 6. The rest of the families deviated from the expected 3:1 ratio when a single major gene is involved. Families number 1 and 2 showed one resistant individual to each two susceptible ones (1:2) which matches the expected ratio for the presence of minor genes without dominance. Family number 3 had a high severity of rust, with a ratio of one resistant for every three susceptible (Table 2).

p-value < 0.05, $X^2$>=3.84.

Ramdoyal et al. (2000) conducted a study using parents with differential resistance to rust and reported that families derived from crosses between two resistant parents generated mostly resistant progeny while crosses between susceptible and highly susceptible parents produced families with a majority of susceptible individuals.

These results agree with the field observations from this study in which the variety IACSP95-2078 generated progeny with severe disease symptoms with the exception of the cross using this parent with IACSP94-2094.

The results from the current study suggest varieties IAC91-2195, SP83-2847 and, especially IACSP94-2094, are good sources of rust resistance.

Résumé

LA PRÉSENTE étude vise à évaluer la résistance à la rouille brune (*Puccinia melanocephala* H. & P. Syd) dans les progénitures de la canne à sucre, aussi bien que d’identifier les parents capables d’engendrer des progénitures avec un pourcentage élevé des individus résistants. Ceux-ci peuvent ensuite être utilisés dans un programme d’amélioration variétale. Dix familles, dérivées d’un croisement bi-parental étaient évaluées pour leur résistance à la rouille en bloc randomisé comprenant quatre répétitions avec 50 plantules par répétition. La résistance a été évaluée visuellement sur une échelle de 1-9 basé sur l’infection de toutes les feuilles. Les moyennes et les variances les plus bas ont été observées pour les familles 9 (1.82 et 3.05) et 10 (1.06 et 0.5) au sein de lesquels figurait la variété IACSP94-2094 utilisée comme parent. Les individus dans les familles 8, 9 et 10 étaient repartis dans un ratio 3:1 de résistants par rapport aux sensibles, suggérant la présence d’un gène majeur avec effet dominant. Les résultats ont permis l’identification des variétés IACSP94-2094, IACSP91-2195 et SP83-2847 comme source de résistance à la rouille.
EVALUACIÓN DE LA RESISTENCIA ALA ROYA ANARANJADA
(Puccinia melanocephala) EN PROGENIES DE CAÑA DE AZÚCAR

PALABRAS CLAVES: Caña de Azúcar,
Resistencia a Enfermedades, Roya Común.

Resumen

EL PRESENTE trabajo tiene como objetivo principal evaluar la resistencia a roya común (Puccinia melanocephala H. & P. Syd), en progenies de caña de azúcar, así como identificar parentales que muestren una producción de progenies con alto porcentaje de individuos resistentes para que puedan ser usados como fuente de resistencia para los programas de mejoramiento genético. Diez familias derivadas de un cruce biparental fueron evaluados para la resistencia a roya anaranjada en un ensayo de bloques al azar con 4 repeticiones de 50 plantas por replicación. La resistencia se evaluó usando una escala de 1 – 9, basado en la infección de las hojas. Las medias más bajas y las varianzas fueron observadas por las familias 9 (1.82 y 3.05) y 10 (1.06 y 0.5) en las cuales la variedad IACSP94-2094 fue usada como parental. Varios individuos en las familias 8, 9 y 10 presentaron una relación 3:1 de resistencia: susceptibilidad, sugiriendo la presencia de un gen mayor con efectos dominantes. Los resultados presentados, sugieren que las variedades IACSP94-2094, IACSP91-2195 and SP83-2847 pueden ser una fuente de resistencia a esta enfermedad.
REPEATABILITY ESTIMATES IN EARLY MATURING SUGARCANE GENOTYPES

KEYWORDS: Saccharum spp., Repeatability, Maturation, Breeding.

Abstract

The Republic of Brazil (code sign RB) varieties are covering up to 58% of the Brazilian sugarcane cultivated area. The objective of this work was to evaluate the repeatability estimates in twenty two early maturing sugarcane genotypes and to recommend a minimum measurement number for real prediction of performance at the final experimental stage of selection. All these genotypes belong to the Sugarcane Breeding Program of the Federal University of São Carlos/RIDESA and are denominated RB (Republic of Brazil). Seven field trials were established in randomised complete blocks with four replicates. The assayed characters were cane yield, sucrose content, sucrose yield and fibre content. Three statistical methods were applied to obtain the repeatability estimates: analysis of variance (ANOVA), principal components and structural analysis. It was observed that the three methods presented similar performance for all the characters. The lower average value of the repeatability estimate \( r = 0.40 \) for sucrose content, with a confidence around 70%, indicated a major environmental effect on this parameter in the early maturing stage. Fibre content and cane yield showed mean repeatability estimates just over 0.60, with a confidence around 80%. Therefore, this behaviour of early maturing sugarcane genotypes suggests that at least four ratoon crops should be accomplished at this stage to obtain approximate real value predictability of 80% considering all characters.

Introduction

In Brazil, the average sugarcane productivity has increased in commercial fields by about 60% over the last thirty years. This significant increment was possible due to the efficiency of the Brazilian sugarcane breeding programs in the development and release of improved genotypes.

Currently, many sugarcane varieties from different research institutes are used by sugar and alcohol industries, and RB (Republic of Brazil) varieties are covering up to 58% of the Brazilian sugarcane cultivated area.

Maturation is an important aspect in the sugarcane genetic improvement. The selection process of genotypes to release a variety takes many years and locations of experimentation (Mamet and Domainingue, 1999). Varieties must be evaluated in several periods corresponding to the beginning, middle and end of sucrose extraction. Early, intermediate and final maturing sugarcane varieties are the fundamental raw material for sugar and alcohol production in Brazil (Matsuoka, 2001).
Repeatability is an indispensable parameter in the genetic improvement of perennial crops. Repeatability is measured by the correlation for the various measurements of characters between crops and environments (Falconer and Mackay, 1996). Therefore, repeatability enables breeders to consider the characters that are repeated more than once during cultivation and to estimate a minimum measurement number for real prediction of individuals (Vencovský, 1973).

The objective of this work was to evaluate repeatability estimates in twenty two early maturing sugarcane genotypes and to recommend a minimum measurement number for real prediction of performance at the final experimental stage of selection.

**Materials and methods**

Seven field trials were established at different locations (environments) of São Paulo State/Brazil and in randomised complete blocks with four replicates (single row 8 m plots) to evaluate twenty two early maturing RB (Republic of Brazil) sugarcane genotypes. These genotypes belong to the final experimental stage of the Sugarcane Breeding Program of Federal University of São Carlos/RIDESAU.

The assayed characters over three ratoon crops were cane yield, sucrose content, sucrose yield and fibre content. Three statistical methods were applied to obtain the repeatability (r) estimates: analysis of variance (Cruz et al., 2004), which also estimated the genetic variability and the environment coefficient of variation (CV%) for each character; principal components (Abeywardena, 1972), based on the matrix of correlations of the ratoon-crops measurements; and structural analysis (Mansour et al., 1981), considering the arithmetic mean of the phenotypic correlations between genotypes in the ratoon-crops measurements.

The coefficient of determination ($R^2$) was calculated from repeatability estimates obtained of each applied method and location, and the minimum measurement number was obtained based on the expression related by Lush (1937).

**Results and discussion**

The coefficient of variation (CV%) for the characters cane yield and sucrose yield were similar and less than 10% (Table 1), indicating an acceptable precision of the experiments. For the characters sucrose content and fibre content, the CV remained around 4%, an expected value for the characters that are determined under laboratory conditions.

</tbody>
</table>

The results of the three statistical methods for estimating repeatability are presented in Table 1. It was observed that the three methods gave similar results for all the characters. Results of this magnitude were also obtained by Ferreira et al. (2005), who estimated the coefficient of repeatability through the same statistical methods in several sugarcane genotypes over sixteen locations in Brazil.

The analysis of variance (ANOVA) method has been the most used to determine the coefficient of repeatability estimate. However, according to Abeywardena (1972), the principal components method is the most efficient when the characters have considerable genetic variation.
The average estimates of the repeatability (r) and the coefficient of determination ($R^2$) are presented in Table 1. The lower average values of the repeatability estimate considering the three statistical methods ($r = 0.40$; $r = 0.43$; $r = 0.42$) for sucrose content, with a confidence of about 70%, indicated a major environmental effect on this parameter in the early maturing stage. One of the possible reasons for this occurrence would be the various stresses that early maturing varieties are subjected to over the years of cultivation, due to the limited environmental conditions for vegetative growth. Fibre content and cane yield showed mean repeatability estimates just over 0.60, with a confidence of about 80%.

The minimum measurement number for real prediction of individuals is given in Table 2. Three evaluations over the years would be sufficient for the characters cane yield and fibre content, considering a confidence of approximately 80%. In contrast, sucrose content and sucrose yield would have similar confidence after six and five measurements (principal components), respectively. Santos et al. (2004) consider more than five measurements to be unviable economically. Therefore, this behaviour of early maturing sugarcane genotypes suggests that at least four ratoon crops should be accomplished at this stage to obtain approximate real value predictability of 80% considering all characters.

### Table 2—Minimum Measurement Number obtained by the methods of analysis of variance (ANOVA), principal components (PC) and structural analysis (SA) for all characters – average data from seven locations.

<table>
<thead>
<tr>
<th>Character</th>
<th>ANOVA R^2</th>

</tbody>
</table>

Conclusions
The three methods, analysis of variance (ANOVA), principal components and structural analysis, presented similar repeatability estimates. The results obtained for early maturing sugarcane genotypes suggest that at least four ratoon crops should be accomplished to obtain approximate real value predictability of 80% considering all characters.

Résumé
Les variétés de canne à sucre de la République du Brésil (code RB) sont cultivées jusqu’à 58% de la surface sous canne au Brésil. L’objectif de cette étude était d’évaluer les estimations de répétabilité pour 22 variétés hâtives de canne à sucre et de recommander un nombre minimum de variétés pour la prédiction réelle de la performance au stade finale de sélection. Toutes les gènotypes appartiennent au Sugarcane Breeding Program de l’Université Fédérale de São Carlos/RIDESA et portent la domination RB (République du Brésil). Sept essais, disposés en blocks complets randomisés et comprenant quatre répétitions, ont été plantés. Les caractères évalués étaient le rendement en canne et en sucre ainsi que la teneur en saccharose et en fibre. Trois méthodes statistiques ont été utilisées pour obtenir les estimations de répétabilité: l’analyse de variance (ANOVA), les analyses en composantes principales et l’analyse structurale. Il a été observé que les trois méthodes présentaient la même fiabilité pour tous les caractères. La valeur moyenne relativement faible de l’estimation de répétabilité (r = 0.40) pour la teneur en saccharose, avec une confiance autour de 70%, a démontré un effet majeur de l’environnement sur ce paramètre au stade précoce de la maturation. La teneur en fibre et le rendement en canne ont montré une moyenne de l’estimation de répétabilité tout juste au-dessus de 0.60, avec une confiance autour de 80%. De ce fait, le comportement des gènotypes hâtifs tend à démontrer qu’au moins quatre repousses devront être évaluées à ce stade pour obtenir la valeur approximative réelle de prédiction de 80% en prenant en considération tous ces caractères.
ESTIMADOS DE REPETIBILIDAD EN GENOTIPOS DE CAÑA DE AZÚCAR DE MADUREZ TEMPRANA

Resumen

LAS VARIEDADES República de Brasil (códigos RB) actualmente cubren hasta el 58\% del área cultivada con caña de azúcar. El objetivo de éste trabajo fue evaluar los estimados de repetitividad de 20 genotipos de maduración temprana y recomendar un número mínimo de medidas para predicciones reales de individuos en los últimos estados de selección. Todos los genotipos pertenecen al Programa de Mejoramiento de la Universidad Federal de San Carlos/RIDESA llamadas variedades RB. Se establecieron siete ensayos de campo con un diseño de bloques al azar con cuatro repeticiones. Los caracteres evaluados fueron producción de caña, contenido azucarero, producción de azúcar y contenido de fibra. Se aplicaron tres métodos estadísticos para obtener los estimados de repetitividad: análisis de varianza (ANOVA), componentes principales y análisis estructural. Los tres métodos presentaron un comportamiento similar para los tres caracteres. El valor estimado de repetitividad más bajo fue para contenido de sacarosa (r = 0.40), con una confianza cercana al 70\%, indicando un efecto ambiental mayor en este parámetro en estado de madurez temprana. El contenido de fibra y producción de caña mostraron una media del estimado de repetitividad justo arriba de 0.60, con una confianza cercana al 80\%. Por tanto, el comportamiento de los genotipos de caña de madurez temprana sugiere que por lo menos cuatro socas deberían ser evaluadas en este estado de selección para obtener un valor real de predictibilidad de 80\% de los caracteres considerados.
ALLO AND AUTO-COMPETITION IN SUGARCANE EXPERIMENTS

KEYWORDS: Competition, Plot Shape.

Abstract

In Brazil, sugarcane experimental plots for genotype evaluation usually have 3 to 5 rows with 8 to 20 m in length. When an experiment has 5 rows, the central ones (R2, R3, R4) will be in auto-competition in both sides (AUTO) and the rows on the edge (R1 and R5) will be in auto-competition on one side and in allo-competition on the other (ALLO50, with parallel neighbour rows N1 or N5 of adjacent plots). To evaluate AUTO and ALLO50, the rows were individually harvested and weighed (kg per metre) in nine experiments with different environmental conditions as part of the IAC Sugarcane Breeding Program. Each experiment was composed of 5 commercial cultivars and 15 new clones replicated in three blocks. The results showed that the average weight of the five best genotypes at ALLO50 were superior by 4 to 6% compared to the averages at AUTO. Some genotypes show better performances when in ALLO50 than in AUTO, indicating that experiments should have the rows planted mainly in AUTO, since this is how they will be grown on a commercial scale. The superior performance at allo-competition has also been observed in other crops and is probably due to more efficient environmental exploration either by the aerial plant part or by the root system. The correlations between the adjacent rows in the AUTO position as well as those in the ALLO50 position with the respective neighbouring rows N1 or N5 were also evaluated. The correlations between production (free from genotype and block effects) were low in the first harvest but, in the fourth harvest and in ALLO50 condition, reached negative values up to –0.4, suggesting competition, i.e., competitive genotypes damage their less competitive neighbours, an undesired situation for the choice of genotypes that will be planted in AUTO.

Introduction

Sugarcane experimental plots in Brazil are usually planted with 3 to 5 rows with the outside row sometimes being in competition with other genotypes (allo-competition) and the inside rows competing with the same genotype (auto-competition).

On a commercial scale, sugarcane crops are planted in monoculture, and therefore the plants only experience auto-competition. In order to ensure that testing is efficient, it is important to establish if there are differential effects between the competition systems.

Other crops, e.g. maize and eucalyptus have demonstrated that allo-competition can increase the production per area, presumably through more efficient exploitation of the architecture of the roots or above ground plant parts (Perecin et al., 1977; Scarpinatti et al., 2009). It has also been shown that the yields of genotypes can change in relation to one another depending on whether they are grown in allo- or auto competition.
The objective of this work was to collect preliminary data regarding differences in sugarcane response to auto- and partial allo-competition systems.

Material and methods

The data were obtained in 2008 from nine previously harvested experiments from the Bonfim Mill, Guariba-SP-Brazil, as part of the IAC Sugarcane Breeding Program. The experiments were planted in a randomised block design with three replications containing 20 genotypes each (5 commercial cultivars and 15 new clones). The nine experiments included in the study are shown in Table 1.

Experiments were planted in five rows (R1, R2, R3, R4, and R5) eight or ten metres long with 1.4 or 1.5 metres between rows. R1 was adjacent to the R5 row of parallel plot (named N1) with a different genotype and R5 had an adjacent row of a different genotype (named N5) resulting in 50% of allo-competition (ALLO50). Rows R2, R3 and R4 were adjacent to the same genotype on both sides; thus, they were in auto-competition (AUTO).

Each row was harvested and weighed (kg per metre) individually, allowing separate evaluations of those in ALLO50 [(R1+R5)/2] and those in AUTO [(R2+R3+R4)/3]. Correlations between adjacent rows were also determined, including rows N1 and N5.

Results and discussion

The overall average of the production in kilograms of the cultivars in the 9 experiments showed an increase of 10% for rows in ALLO50 when compared to those in AUTO. The ratio (Ratio = ALLO50/AUTO), presented values ranging from 0.65 to 1.49. There were cultivars that had much higher production when in ALLO50, such as RB867515 (Ratio=1.13), SP83-2847 (Ratio=1.23), CTC15 (Ratio=1.25), IACSP95-5000 (Ratio=1.17). Other cultivars showed Ratio around 1, such as RB72454 (Ratio=0.94), RB855453 (Ratio=1.04), SP91-1049 (Ratio=1.07), CTC4 (Ratio=0.91). The differential Ratios of the genotypes suggest that it is not recommended to establish plots with data being taken from rows in allo-competition since the genotypes will not be planted in this arrangement on a commercial scale. Increased production in allo-competition also has been observed in other crops, (e.g. maize, eucalyptus) and has been attributed to more efficient utilisation of resources by either the roots or aerial part of the plant. The increase in production from allo-competitive plants indicates that mixed planting containing different genotypes might be beneficial.

The correlation of the weights between adjacent rows was also evaluated in AUTO (R2R3, R3R4) and ALLO50 (R1N1 and R5N5). In general, these correlations (free from the genotype and block effects) were low (Table 1), but predominantly negative, suggesting that there is some competition, even in AUTO.

In the fourth harvest and in the ALLO50 condition, the correlations achieved negative values up to –0.48, suggesting that more competitive genotypes may slightly damage their less competitive neighbours or take advantage of the low production of the adjacent row to increase their own. This situation is undesirable for choosing the genotypes that will be planted only in auto-competition. For this reason, it is not advisable to work with plots in which there is a predominance of rows in allo-competition (1 to 3 rows).

Conclusions

1. On average, the genotypes in allo-competition (50%) were 10% superior in relation to the same genotypes in auto-competition.

2. The correlations of the weights between adjacent rows generally is low, but predominantly negative, even in auto-competition, indicating some low competition.

3. Some competitive genotypes may damage or take advantage of their less competitive neighbours, across the years (situation not wanted for the choosing of genotypes that will be planted only in auto-competition).
4. The differential reactions of genotypes suggest that it is not advisable to establish research plots with data being taken from rows in allo-competition since the genotypes will not be planted in this arrangement on a commercial scale.

MOTS-CLÉS: Concours, Formulaire Parcela.

Résumé

Au Brésil, les parcelles expérimentales de canne à sucre pour l’évaluation des génotypes sont habituellement de 3 à 5 lignes de 8 à 20 m. Quand un essai a cinq lignes, les rangs centrales (R2, R3, R4) seront en auto-compétition des deux côtés (AUTO). Par contre, les rangs des bords (R1 et R5) seront en auto-compétition d’un côté et en allo-compétition sur l’autre (ALLO50, avec les lignes parallèles voisines N1 ou N5 des parcelles adjacentes). Afin d’évaluer AUTO et ALLO50, les lignes étaient individuellement récoltées et pesées (kg par mètre) dans neuf essais situés dans
des conditions environnementales différentes, qui font partie du programme d’hybridation de l’IAC. Chaque essai était composé de 5 cultivars commerciaux et 15 nouveaux clones, en répétition de trois blocs. Les résultats ont montré que le poids moyen des cinq meilleurs génotypes en ALLO50 était supérieur par 4 à 6% comparé à la moyenne en AUTO. Quelques génotypes ont montré une meilleure performance en situation ALLO50 par rapport à AUTO. Cela démontre que les essais devraient avoir les rangs établis principalement en AUTO, puisque c’est de cette manière qu’ils sont plantés à l’échelle industrielle. La supériorité des performances en allo-compétition a aussi été observée dans d’autres cultures et est probablement due à une exploration plus efficiente de l’environnement soit par la partie aérienne ou par le système radiculaire. Les corrélations entre les rangs adjacents en position AUTO de même que ceux en position ALLO50 avec leurs rangs voisins N1 ou N5 ont aussi été évalués. Ces corrélations entre la production (exempte d’effets du génotype ou de bloc) étaient faibles lors de la première récolte. Toutefois, lors de la quatrième récolte, et en condition ALLO50, des valeurs négatives atteignant –0.4 ont été atteintes, suggérant la compétition. Les génotypes compétitifs endommageaient donc les génotypes voisins moins compétitifs, une situation non-désirée dans le choix des génotypes qui seront cultivés en AUTO.

ALO Y AUTO-COMPETICIÓN EN EXPERIMENTOS DE CAÑA DE AZÚCAR

PALABRAS CLAVES: Competición, Forma de Parcela.

Resumen

Los experimentos en Brasil en caña de azúcar para evaluar genotipos, generalmente tienen 3 a 5 filas de 8 a 20 m de largo. Cuando un experimento tiene 5 filas, las filas centrales (R2, R3 y R4) estarán en auto-competencia en ambos lados (AUTO) y las filas de las orillas (R1 and R5) estarán en auto-competencia a un lado y en alo-competencia en el otro lado (ALLO50, con filas paralelas vecinas N1 a N5 de las parcelas adyacentes). Para la evaluación de filas AUTO y ALLO50 fueron cosechadas invidiamente y pesadas (kg/m) en nueve experimentos de diferentes condiciones ambientales que son parte del Programa de Mejoramiento de IAC. Cada experimento se comparó con cinco cultivares comerciales y 15 nuevos genotipos repetidos en tres bloques. Los resultados mostraron que el promedio del peso de los cinco mejores genotipos en ALLO50 fueron superiores en 4 a 6% comparando los promedios de los AUTO. Algunos genotipos mostraron mejor comportamiento si su condición es ALLO50 que en AUTO, indicando que los experimentos deberían plantarse principalmente en AUTO ya que de esta forma es como se siembra comercialmente. El comportamiento superior en alo-competencia ha sido observada en otros cultivos que probablemente se deba a una eficiente exploración ambiental, ya sea en la parte aérea de la planta o por el sistema radical. Las correlaciones entre las filas adyacentes en la posición AUTO así como aquellas en ALLO50 con sus respectivas líneas vecinas N1 o N5 también fueron evaluadas. Las correlaciones en producción (libres de los efectos genotípicos y de bloque) fueron bajos en primer corte, pero en cuarto corte y en condición ALLO50 alcanzaron coeficientes negativos de hasta –0.4, sugiriendo competencia, por ejemplo de genotipos competitivos que dañan a los menos competitivos de las filas vecinas, situaciones no deseadas al escoger los genotipos que serían sembrados en AUTO.
COMMERCIAL YIELDS AND RAPID ADOPTION OF THE ECU-01 VARIETY IN ECUADOR

By

KEYWORDS: Sugarcane Varieties, Commercial Cane Production, Variety Adoption.

Abstract
THE Ecuadorian variety ECU-01 was released in August 2007, after a 10 year period of clonal selection through four selection stages and evaluations in semi-commercial plots. The variety was derived from the clone ECSP98-169 selected from the cross between SP81-6215 × SP80-1816 performed in COPERSUCAR (CTC) in Brazil. During the selection process, evaluations were performed on sugar content, cane tonnage, and resistance to smut (Ustilago Scitaminea), mosaic (ScMV) and common rust (Puccinia melanocephala). Additionally, a participatory approach of selection was performed with the cane mill’s technicians in order to allow an effective selection. The variety presented averages of cane t/ha of 98 (TCH), sugar t/ha of 9.1 (TSH) and fibre of 13.1% throughout evaluations of stage IV in six localities in plant cane and two ratoons. These values were superior to Ragnar (80 TCH and 7.2 TSH) the leading variety in Ecuador. In commercial production plots in San Carlos Mill, cane plant and first ratoon ECU-01 were on average superior to Ragnar by 2.1 TSH during the 2008-2009 period. A year after its release (2008), the three main sugar mills in Ecuador registered more than 1500 ha planted with ECU-01, and in 2009 the same mills planted 2620 ha. Results from commercial fields during the 2008 harvesting season showed that ECU-01 is superior to Ragnar, CC85-92, CR74-250, B7678, C10571-73 and C87-51.

Introduction
Sugarcane production in the Rio Guayas Valley is dependent on one variety, Ragnar, with more than 70% coverage. This variety was introduced 60 years ago from Australia to Ecuador and has been in commercial production for at least 30 years. Local production has not increased in the past decades, and dependence on a single variety is a permanent risk for a sugar industry settled in tropical conditions.

On the other hand, sugarcane breeding contributes to increased productivity without an increase in growing costs, and disease and insect resistance even reduce the costs of growing the crop (Berding et al., 2004).

The main objective of the Ecuadorian Research Center (CINCAE) is to develop local varieties adapted to the tropical, low sunlight and heavy soil conditions. Support areas of research (plant pathology, entomology, soils and fertiliser and chemistry laboratories) were also established to develop technologies for adequate crop management.

The Ecuadorian varieties should show a combination of cane tonnage and sucrose contents and also fibre for co-generation.
The Varieties Program of CINCAE started in 1998. That year, a sugarcane collection was assembled to have genetic variation for future crosses. Because no facilities were available at this time, an agreement was signed with COPERSUCAR (CTC) from Brazil to make crosses, and the first selection series was planted with fuzz sent from Brazil.

After 10 years of evaluations and selection from Stage I to Stage IV and semi-commercial trials, the best clone was ECSP98-169. The selection trials were planted in several locations to evaluate the performance between locations and years (Castillo et al., 2007).

ECU-01 was named after the clone ECSP98-169 which is a progeny from a cross SP81-6215 × SP80-1816 performed in Centro de Tecnologia Canaviera-CTC (former COPERSUCAR) of Brazil. Fuzz was planted in September 1998 which provided plants to start the selection process from Stage I.

A total of 638 clones were selected to plant in Stage II, ending up with eight clones in Stage IV. After two years of evaluations, three clones were selected to plant in semi-commercial plots in San Carlos, Valdez and La Troncal mills. The best clone of these three was ECSP98-169, named ECU-01 (CINCAE, 2007).

**Results from commercial fields**

ECU-01 showed higher production of cane per hectare (TCH) than Ragnar in all evaluation trials along the selection stages. The same trend of production was observed in the 2009 harvesting season in all three main mills.

An analysis in plant cane and first ratoon of both varieties showed that ECU-01 is 2.1 tonnes sugar per hectare (TSH) higher than Ragnar on average from commercial fields during the 2009 harvesting season (Table 1).

This higher sugar tonnage might be related to the high tonnes cane per hectare (TCH) produced in the different commercial plots. ECU-01 can also be harvested at 12 months of age on average, while Ragnar is a 13 month variety in all commercial plots.

**Table 1**—Production of cane and sugar of ECU-01 in 2009 compared to variety Ragnar in San Carlos Mill.

</tbody>
</table>

The early ripening character of ECU-01 was analysed during the clonal evaluation data collection. Maturity curves were plotted to evaluate the sucrose accumulation through the months before harvesting. Figure 1 shows the differences between ECU-01 and Ragnar in the three main mills where evaluations were performed in semi-commercial fields. In all three cases, the Ecuadorian variety presents higher and earlier sucrose accumulation compared to Ragnar. Therefore, ECU-01 could be easily harvested at 12 months as the commercial fields are demonstrating in 2009.

Managers and farmers at the mills see the variety as important commercial material to diversify cane production in their units. Since the release of ECU-01 in 2007, there has been a rapid increase in commercial fields. The seed stock provided to the mills in 2006 allowed them to plant a total of 613.81 ha in 2007. This number of units increased to 2620.67 in year 2009 (Table 2) and it is expected to keep increasing its planting area in the coming years.

*Personal communication: Glenda Toala (ECUDOS mill), Walter Jara (Valdez Mill), and Edgar Sánchez (San Carlos Mill).

Conclusions

The newly released variety ECU-01 shows outstanding yields in the tropical lowland conditions of Ecuador. Its main feature appears to be its ratooning ability and early ripening. Sucrose accumulation starts at 11 months and the variety can be harvested at 12 months. This is the main advantage compared to Ragnar which is a 13 month variety. ECU-01 is superior to Ragnar with 2.1 TSH in plant cane and first ratoon crops. A rapid adoption is observed in the Ecuadorian industry of this new variety due to its good agronomic characteristics.

**Resumen**

LA VARIEDAD ecuatoriana de caña de azúcar (ECU-01) fue liberada en agosto de 2007, luego de un proceso de selección clonal a través de cuatro estados de selección y parcelas semicomerciales, con una duración de 10 años. Esta variedad fue derivada del clon ECSP98-169 proveniente del cruzamiento entre SP81-6215 × SP801816 realizado por COPERSUCAR (hoy CTC) de Brasil. Durante el proceso de selección se realizaron evaluaciones principalmente de contenido azucarero, producción de caña, resistencia a Carbón (*Ustilago scitaminea*), Mosaico (ScMV) y Roya (*Puccinia melanocephala*). Además, se realizaron evaluaciones participativas en la selección de clones, con el apoyo de técnicos de los ingenios, que permitieron una selección más efectiva. Esta variedad presentó promedios de producción de caña por hectárea (TCH) de 98 toneladas, con una producción de azúcar promedio de 9.1 toneladas por hectárea (TAH), y un promedio de fibra de 13.1%, en evaluaciones en Estado IV en seis localidades y durante tres cortes; superando a la variedad Ragnar, que es la variedad con la mayor área sembrada (66 %), que mostró promedios de 80 TCH y 7.2 TAH. En canteros comerciales del Ingenio San Carlos, en caña planta y primera soca superó con 2.1 TSH a Ragnar en el 2008–2009. Un año después de la liberación de la variedad ECU-01 (2008), los tres ingenios mas grandes del Ecuador registraron una superficie sembrada de 1500 hectáreas, y en el año 2009 alcanzó las 2620 ha. Los primeros resultados a nivel comercial obtenidos en la zafra 2008, indican que la nueva variedad mantiene su superioridad en comparación a la variedad Ragnar, CC85-92, CR74-250, B7678, C10571-73 y C87-51.
GENOTYPE BY ENVIRONMENT INTERACTION FOR YIELD IN SUGARCANE PERFORMANCE TRIALS: A COMPARISON OF FREQUENTLY USED MODELS

KEYWORDS: Genotype-Environment Interaction, Sugarcane, Statistical Analysis, AMMI.

Abstract
The objective of this paper was to apply different multivariate statistical analysis, (cluster analysis, model of main effects additives and multiplicative interaction (AMMI), regression analysis of sites (GGE) and principal coordinates analysis (PCO)), to compare their utility and efficiency in the study of the genotype-environment interaction (GE) in sugarcane cultivars. Performance data of eighteen cultivars evaluated at four locations, in the south-eastern region of Cuba, was used in this study. The experimental design used in each trial was a randomised complete block. The evaluated variable was tonnes of cane per hectare. Analysis of variance showed that effects of genotype, environment and GE were highly significant. Cluster analysis discriminated between four locations, while the GGE method only generated three groups of environments. The biplot indicated that there were similar results between the AMMI and GGE model. The scatter point diagrams obtained from PCO analysis, however, revealed only limited agreement with the results obtained by the AMMI and GGE model. The G+GE captured by AMMI (50.2 %) and GGE (77.0 %) were both more adequate than PCO analysis in quantifying environment and genotype effects.

Introduction
The differential response of a genotype or cultivar for a given trait across environments is defined as the genotype × environment interaction (GE). If this GE is large, it may result in failure to differentiate performance of genotypes across environments, and it can reduce the precision of the selection across the environments.

Therefore, GE is an important and an essential component of plant breeding programs dedicated to cultivar development. Further, effective statistical analysis of yield trials can help breeders to make faster progress (Gauch, 2006).

The objective of the present study was to compare different multivariate statistical techniques for analysis of multi-environment sugarcane cultivar yield trials.

Materials and methods
Data from a multi-environment trial were analysed. The trial was carried out in the south-eastern region of Cuba at four locations across the sugarcane production zone (Table 1). Eighteen sugarcane cultivars released by the Cuban National Institute for Sugarcane Research (INICA) over the last 10 years were evaluated (Table 2). Experiments at each location were planted in a randomised block design using three replications. Cane yield (t/ha) for one cropping season was recorded.

The 18 experimental cultivars were (G1), (G2), (G3), (G4), (G5), (G6), (G7), (G8), (G9), (G10), (G11), (G12), (G13), (G14), (G15), (G16), (G17) and (G18).

Statistical analysis

Repeated measures analysis of variance (ANOVA) was performed to determine the significance of the main effects of genotype and environment, as random effects, and the effect of genotype-environment interaction. With the residuals of GE, a multivariate statistical analyses for GE and phenotypic stability was carried out.

Multivariate statistical techniques

The analysis used for the study of GE interaction and phenotypic stability in sugarcane cultivars were: cluster analysis (Ghadery et al., 1980), additive and multiplicative interaction (AMMI) (Gauch, 2006), regression analysis of sites (GGE) (Yan et al., 2006), and principal coordinates analysis (PCO) (Westcott, 1987). All statistical analyses were performed using the Statistica system (StatSoft, 2003).

Results and discussion

Analysis of variance

Results of analysis of variance for the yield data are presented in Table 3, which gives an overall picture of the relative magnitudes of the genotype, environment, and GE variance. Locations were the most important source of variation, accounting for 65.2%. GE interaction accounted for 25.8% of total sum of squares.

Statistical analysis to study GE interaction effects and phenotypic stability

a) Cluster analysis

Mella was detected as the major contributing location to the GE interaction (Figure 1). This location is characterised by a different soil than at the others locations (Table 1). Removal of Mella from the analysis resulted in a single cluster, containing all other locations, with significance for GE interaction.

Fig. 1—Cluster dendogram showing the relationships among locations and their GE interaction effects for cane yield. Cluster analysis using Ward’s method algorithm.

b) AMMI and GGE models analysis

AMMI analysis indicated that the first multiplicative components explained 50.2% of the GE interaction (Figure 2). Enidio Díaz was detected as the location with the highest yield, with genotype G14 performing best at this location. On the other hand, Paquito Rosales showed the lowest average yield. The G5, G9 and G4 cultivars performed well over all locations.

Fig. 2—AMMI, Biplot: The genotype and environment means are shown on the abscissa, with a vertical line at grand mean. The principal component (PC) 1 scores are shown on ordinate.

The GGE model (Figure 3a) explained 77% of the variance of genotypes and GE interaction. The locations were grouped into three for the region in study: (i) Enidio Díaz, (ii) Mella and Paquito Rosales, and (iii) Manuel Tames. This result is different to the cluster analysis, which revealed significant differences between Mella and Paquito Rosales locations. Vertex genotypes for each location are the most responsive genotypes (Yan et al., 2006) and include G14 in Enidio Diaz; G10 and G5 in Mella and Paquito Rosales; and G17 in Manuel Tames.
Figure 3b shows the mean performance of genotypes (the line that passes through the biplot origin and the environment) and genotype stability (the line that passes through the biplot origin and the genotype), obtaining results similar to AMMI1 (Figure 2).

**Principal coordinates analysis**

In the low cycle (Figure 4a) and for the four locations in the study, the genotypes more distant to the centre of the diagram are G5, G9 and G4, and are regarded as the most stable cultivars. Also, genotypes G7, G1 and G10 are further from the centre, for the first three cycles of low yield. Nevertheless, G7 was more repeatable across all cycles, showing stability for discriminating environments and low yield.

For the high cycle (Figure 4b), the genotypes (G5 and G9) more distant to the centre in the last cycle, are the same as for the previous cycle. G14 was a winning genotype for the first three cycles, showing stability for high-yielding environments. AMMI and PCO analyses were very
similar for identifying G5, G9 and G4 cultivars, as the more stable cultivars. For G14, AMMI and GGE results partially do not agree with PCO. This genotype is mainly associated with high-yielding environments (Enidio Díaz).

The multivariate analyses AMMI and the regression analysis for sites (GGE) were similar to show genotype performance across environments, with differences in the contribution explained in terms of GE interaction variance (GGE>AMMI1). Both these models were better than PCO analysis in quantifying environment and genotype effects for cane yield and can be equivalent for gaining accuracy. Other models, like cluster analysis, did not show a clear tendency to group, and they are a poorer fit to the data observed. In our point of view, GGE and AMMI are ideal models for visualising patterns in yield-trial data.

Résumé
L’OBJECTIF de cette étude était d’évaluer les différentes analyses multivariables (analyse des conglomérats, modélisation additive et multiplicative de l’interaction (Modèle AMMI), analyse de régression des environnements (GGE) et analyse des coordonnées principales (PCO)), afin de comparer leurs utilités et leurs efficacité dans l’étude des interactions génotype-environnement (GE) des cultivars de canne à sucre. Les données de rendement en canne de dix-huit cultivars évalués dans quatre sites dans la région Sud-Est de Cuba, étaient utilisées pour cette étude. Le dispositif expérimental adopté pour chaque essai était un bloc randomisé. L’analyse de variance a démontré que les effets génotype, environnement et GE étaient hautement significatifs. L’analyse des conglomérats a distingué les quatre sites, alors que la méthode GGE en a distingué trois. Le
biplot a indiqué que les résultats pour les modèles AMMI et GGE étaient similaires. Un graphique d’éparpillement des points obtenu de l’analyse PCO, a toutefois révélé un accord limité entre les résultats obtenus par les modèles AMMI et ceux du GGE. Les G+GE obtenus par AMMI (50.2 %) et GGE (77.0 %) étaient tout deux plus précis que l’analyse PCO pour quantifier les effets environnement et génotype.

COMPARACIÓN DE MÉTODOS ESTADÍSTICO MULTIVARIADOS EN EL ESTUDIO DE LA INTERACCIÓN GENOTIPO AMBIENTE Y LA ESTABILIDAD FENOTÍPICA EN CAÑA DE AZÚCAR

Resumen

El objetivo del presente trabajo fue aplicar diferentes métodos estadísticos multivariados como el análisis de cluster, análisis de coordenadas principales (PCO), modelo de efectos principales aditivos e interacción multiplicativa (AMMI) y análisis de regresión de sitios (GGE), para comparar su utilidad y eficiencia en el estudio de la interacción genotipo-ambiente (IGA) y la estabilidad fenotípica en caña de azúcar. Los datos analizados corresponden a cuatro estudios multiambientales conducidos en la región sur oriental de Cuba, con 15 cultivares, sobre la variable tonelada de caña/ha. Se encontró predominio del efecto ambiental en la varianza total (65.2 %), seguido de la IGA (25.8 %). El análisis de cluster sugirió agrupamiento de las localidades, diferenciándose unas de otras, sin embargo, la agrupación realizada por el modelo GGE generó tres ambientes. Resultados similares mostraron los modelos AMMI y GGE en la descripción del patrón de comportamiento de la IGA y la estabilidad fenotípica de los cultivares, correspondiendo la mayor extracción de la varianza al biplot GGE2 (77.0 %), seguido del biplot AMMI1 (50.2 %). Al comparar los resultados de estos dos modelos con el análisis de PCO, no se encontró total coincidencia en sus resultados, por lo que los dos primeros resultaron más adecuados.
MANAGED INITIATION OF SUGARCANE FLOWERING IN KHUZESTAN-IRAN: A STUDY OF DIFFERENT PHOTOPERIODIC TREATMENTS

By

H. HAMDI1, H. GARCIA2, H. JORGE2, M. PARVIZI1, K. TAHERKHANI1 and J. HAMODI1

1Sugarcane Research Centre, Sugarcane & By-Products Development Co., Khuzestan Iran

hectorgp@inica.minaz,cu

KEYWORDS: Flowering Initiation, Photoperiod, Sugarcane, Breeding program, Day length reduction.

Abstract

MANAGED initiation of flowering is a priority of the sugarcane breeding program in Iran, as sugarcane does not flower under natural conditions in this region. Two photoperiod treatments (long and short) were studied at the Sugarcane Research Centre of Khuzestan province. A sample of 18 cultivars from the sugarcane germplasm collection was classified in three groups according to flowering behaviour at their origins. The treatments and natural photoperiods with control of temperature and humidity were effective to induce flowering in different sugarcane cultivars. High flowering cultivars responded less, while the short treatment cycle (104 days) guaranteed the more intense flowering. The results of the experiments suggest a method for artificial initiation of flowering and an expansion of the photoperiod facilities.

Introduction

Khuzestan is located in the south west of Iran and sugarcane areas are between 31–32°N latitude and 48°E longitude at an elevation of 7 to 80 m above sea level. Daily average maximum temperatures in January and July are 8° and 46.5°C, respectively. Annual evaporation is about 3000 mm and relative humidity is low. Most rainfall occurs between November and April with an annual average of only 240 mm. Because of hot and dry weather, sugarcane is fully irrigated and, with suitable agronomic practices, high yields are achievable from plantations.

Khuzestan has been using old varieties and needs new varieties that are adapted to the conditions and are resistant to diseases such as smut and mosaic.

One of the methods to produce genetic variability is hybridisation of the genetic material in germplasm collections, for which flowering is essential. Climatic and natural photoperiodic conditions of the Khuzestan province are not conducive to flowering in sugarcane. Thus, artificial initiation is necessary.

Flowering is initiated by gradually reducing day length of between 12:30 h and 12:45 h by 30–60 s. (Alexander, 1973; Brett and Harding, 1974). We have established methodology for the artificial initiation of flowering for the sugarcane breeding program in Iran, and this is discussed in the present paper.

Materials and methods

The studies were conducted between September 2003 and March 2007, in the Sugarcane Research Centre belonging to the Sugarcane & By Products Development Co.
The photoperiod and glasshouse used for the experiments were built in 2000, and consisted of one dark room of $5 \times 4 \times 6$ m and a crossing house $5 \times 10 \times 7$ m constructed from local material. Night temperature inside the dark room was regulated between 19–22°C and maximum temperature in the glasshouse was maintained between 28–32°C depending on the season. The required relative humidity (70–85%) was regulated by using a semi-automatic system. Eighteen cultivars were chosen from the germplasm collection, and classified according to their flowering behaviour in their countries of origin and the evaluation of the germplasm collection in Cuba (Perez et al., 1997) (Table 1). They were planted in plastic pots of 25 L capacity and five stalks were retained in each pot.

Initiation of flowering in the northern hemisphere occurs between September and October (Moore and Heinz, 1972; Allam et al., 1977). Treatments were initiated on July 23, five weeks before September. To guarantee enough time for flowering to occur, the period was extended to December 10. Day length in Khuzestan varies from 13:51:00 to 10:09:30 h, with an average reduction daily of 94 seconds.

According to the day length and daily reduction in the period of the experiment and also the available information from different countries with similar latitudes for flowering (Anon., 1971; Anon., 1977), two artificial photoperiod treatments, one with 104 days and another with 141 days, were established. Two natural photoperiod treatments, one inside the glasshouse and another in natural farm conditions were carried out as controls.

**Short treatment (104 days)**
This treatment began on July 23 with day length shortening to 12:30:00 hours, using more darkness, and continued till September 9, when the natural photoperiod attained the length desired of 12:30:00 hours. The treatment finished on November 3 and the necessary hours of artificial light were supplied to decrease the day length to 12:00:00 hours.

**Long treatment (141 days)**
This treatment was similar to the previous treatment but the time was extended to December 10 by decreasing the day length to 11:23:00 hours, with extension lighting, by means of two lines of three fluorescent 500 watt and two lines of three incandescent 200 watt light bulbs to guarantee the uniformity of light distribution.

Photoperiod treatments started by moving the trolleys into the dark room by means of a semiautomatic control system on 23 July, half an hour after Almanac sunset, and pulling out the pots from the photoperiodic house to glasshouse after sun rise. This experiment was repeated over four years (2004–2007).

Only the intensity of flowering (%) was evaluated in the experiments according to Jorge et al. (2002) and Hamdi et al. (2003). The statistical analysis was based on use of contingency tables (Chi square), applied to the treatments and cultivars and their interaction.
The influence of maximum and minimum temperatures, thermal oscillation and relative humidity inside and out of the glasshouse were studied and recorded throughout the experiments using automatic instruments.

The artificial photoperiod was compared with natural flowering for the three levels of flowering: group 1 (high flowering, >25%); group 2 (medium flowering 1–25%) and group 3 (null flowering, < 1%).

**Results and discussion**

The short photoperiod treatment resulted in the best flowering overall and had the biggest impact on the cultivars of low flowering propensity, an increase of 19%. This is comparable to the results of Miller and Lii (1995) who showed that short treatments are more effective for the initiation of flowering than continuous and longer treatments (Table 2).

### Table 2—Flowering percentage for the various treatments.  

<table>

<tr>
<td>Long</td>
<td>56.3</td>
</tr>
<tr>
<td>Internal control</td>
<td>54.8</td>
</tr>
<tr>
<td>External control</td>
<td>0</td>
</tr>
</tbody>
</table>

The long photoperiod treatment (141 days) had an inhibitory effect on cultivars of medium and scarce flowering. Nuss and Berding (1999) indicated the inductive period of cultivars becomes shorter in latitudes greater than 30°.

The cultivars of high flowering propensity responded minimally to the photoperiod treatments, probably because their flowering is influenced by other factors such as temperature and humidity.

The characteristics of the managed photoperiod, or day length and daily reduction, during the time of flowering initiation in Khuzestan, are within the ranges of other investigations which also were successful in artificial initiation from flowering.

Miller and Lii (1995), in Louisiana, beginning with 12:21 hours followed by a daily descent between 60–105 seconds achieved initiation in clones of scarce flowering.

**Effect of climatic variables on flowering**

The parameters *Wilks Lambda* and *F* of the Discriminant Analysis (results not presented) indicated that the variables that better discriminated between the groups were the relative humidity (HRELAT) and the thermal oscillation (OSC_TEMP), while the temperatures (TMIN and TMAX) did not enter in the model, although they are included in an indirect way because of the close relation that they keep with the thermal oscillation.

The bigger contrast was in the maximum temperature which differs from minimum temperature and relative humidity according to Coleman (1962, 1963) who said that, in latitudes far from the Equator; the temperature acquires more importance for the initiation of the flowering than photoperiod, which agrees totally with the results shown in this paper.

The importance of these variables in the initiation of flowering has been reported by numerous researchers (Clements and Awada, 1967; Miller and Lii, 1995, Berding, 2005). The discriminating model made possible the correct classification of 100% of the cases and the distances between groups were significant.
Conclusions

1. Short artificial photoperiod treatments (104 days) produce more flowering than long treatments (141 days) with a bigger impact on the cultivars of low flowering propensity.

2. Cultivars of high flowering responded less to the treatments with artificial initiation of flowering and their potential in this regard is largely influenced by other factors.

3. The climatic variables which have more effect in the initiation of flowering in Khuzestan are the relative humidity and the thermal oscillation. They have a bigger importance than the day length and the daily declination.

Résumé

Le pilotage de l’initiation de la floraison est une priorité pour le programme d’hybridation génétique de la canne à sucre en Iran, la canne ne fleurissant pas dans des conditions naturelles dans cette région. Deux traitements photopériodiques (long et court) ont été étudiés au Sugarcane Research Centre de la province de Khuzestan. Un échantillon de 18 cultivars de la collection de la canne à sucre a été classifié en trois groupes selon leurs comportements floraux dans leurs centres d’origine. Les traitements de photopériodes en combinaison avec le contrôle de la température et d’humidité, étaient efficaces pour induire la floraison chez différents cultivars de canne à sucre. Les cultivars avec un fort taux de floraison répondaient moins bien, alors que le traitement de cycle court (104 jours) garantissait une floraison plus intense. Les résultats de cet essai offrent une méthode pour l’initiation de la floraison artificielle et l’expansion des infrastructures photopériodiques.

PALABRAS CLAVES: Inducción de la Floración, Fotoperiodo, Caña de Azúcar, Programa de Mejora, Reducción Diaria.

Resumen
LA INDUCCIÓN artificial de la floración constituye una de las prioridades del Programa de Mejoramiento Genético de la Caña de Azúcar en Irán, ya que naturalmente la caña no florece. En el Centro de Investigaciones de la Caña de Azúcar en la provincia Khuzestán, se estudiaron dos variantes de fotoperiodo artificial con diferentes combinaciones de duración del día y reducción diaria, así como ciclos de exposición, en una muestra de 18 variedades de la colección de germoplasma, agrupadas en tres categorías de acuerdo a los niveles de floración en sus países de origen. Los tratamientos utilizados y el fotoperiodo natural con control de la humedad y la temperatura fueron efectivos en la inducción de la floración. Las variedades de alta floración fueron las de menor respuesta, mientras que los tratamientos cortos (104 ciclos) garantizaron la mayor intensidad de la floración. Se recomienda una metodología para la inducción artificial de la floración, así como la ampliación de la casa de fotoperiodo como aplicación práctica del trabajo.
IMPROVING THE HARVEST SEASON BASED ON THE MATURITY IN FOUR SUGARCANE GROWING REGIONS IN CUBA

KEYWORDS: Harvesting Season, Genotypes, Sugarcane Maturation.

Abstract

CLIMATE change, which has resulted in global warming, has affected cane production and altered the period of harvest. New investigations are necessary to determine the critical periods of harvest, based on the interactions resulting from the combination of different genotypes and land-ecosystems. Forty eight trials were conducted in four contrasting sugarcane growing regions of Cuba with three varieties – C 1051-73 (early), C 86-12 (mid-season), My 5514 (late-season) that differ in ripening period. A combination of month of harvest and ages from nine to twenty-four months, in two crops, soil types and ratoon crops for ripening characteristics were studied. At the age of 13 months (typical harvest time in Cuba), the studied regions produced significant differences, higher than those relating to varieties. Consequently, the harvesting season must be reorganised. The Centre-Eastern Region was more efficient, with any variety, while the Eastern Region showed a better behaviour of genotypes in the March-October period.

Introduction

Productivity of sugarcane in Cuba has regressed as a consequence of global warming, mainly due to the long periods of drought and the change in rainfall pattern. The sugar industry has developed a process of reorganisation, which includes the identification of the best lands to produce sugarcane and the optimisation of the harvest. It is necessary to find the optimal dates to begin the harvest season according to agro-ecological zones, as well as the sugarcane cultivar that can be planted. It is also important to know the possible extension of the crop period, if soil and climatic conditions are favourable.

It is necessary to study the ripening pattern of the main cultivars out of the periods traditionally used to harvest them.

Materials and methods

To meet the proposed objectives, 48 experiments at four cane contrasting regions of the country (west, centre-west, centre-east, east) were established over three crop cycles (plant cane, first and second ratoon), harvested during the whole year, and combining crop age from nine to twenty-four months. Three varieties were studied, C 1051-73, C 86-12 and My5514, classified as early-ripening, intermediate-ripening and late-ripening respectively over the normal harvesting period spanning from November to April. The variable studied was the evolution of sucrose using uni- and multi-variant analyses.

Results and discussion

The best period to harvest the cane according to the historical rainfall distribution is between November and April, when only 14–26% of the total volume of rains is received at the four regions studied (Figure 1).
With an increase in the volume of cane, which will entail a lengthening of the harvest season, an earlier harvest would not be possible, whereas delaying harvest until June is achievable except in the western region, and further until August in the Centre-Eastern and Eastern region (Figure 1).

During the first two months (November and December), sucrose content of variety C 1051-73 is low in the Western and Eastern sectors, and it would be reasonable to delay harvest until January (Figure 2). In the Western region, sucrose content declines from May while in the Centre-West, the variety can be harvested from November until June.
In the Eastern region, the variety can be harvested until August because of the lower rainfall compared to the other sectors.

Sucrose accumulation for the intermediate variety, C86-12, is strongly influenced by environmental conditions. In the Central-Eastern region, it can be harvested early in the season from November to January (Figure 3). Similarly, in the Eastern zone, C1015-73 demonstrates earliness of ripening and it can be harvested from November to March (Figure 2).

Fig. 3—Dynamics of maturation C86-12 variety.

In the Eastern and Western zone, it is inappropriate to harvest My 5514 at the start of the harvest. Its harvest can delayed further in the Eastern region, which confirms previous observation (Milanes and Tejero, 1995) (Figure 4)

Fig. 4—Pattern of sucrose accumulation for variety My5514.
The environmental component of variation exceeded by far the genotypic effect (Table 1) and is highest in May and August, which is in agreement with Bernal (1986), González (1995), and Jorge et al., (2008).

Varieties show specific suitability to harvest dates in the different areas and should be managed individually.

Additionally, a wider range of varieties can be exploited in March in a wider range of environments. Stable varieties are more difficult to obtain.

It is evident that the major effect of the zones is associated on one hand with the chemical properties of the soils, the most significant of which are nitrogen and potassium available in the first horizon, as well as the acidity.

On the other hand, to the climate elements, minimum temperature and relative humidity, variables that account for more than 34% of the total variation in the first component (Table 2).

Other factors that contribute to the variation include the organic matter content, available phosphorus and accumulated rains four and five months prior to the harvest.

</table>

The characterisation of the regions from the functions of components 1 and 2 (Figure 5) enabled the differentiation of the western and eastern regions and the central localities, which represent the best agro-climatic potential. The Central regions were those that contained most of nitrogen and available potassium.
Conclusions

1. Varieties displayed specific adaptation to harvest periods in the different sectors and should be managed individually.

2. Higher Pol % cane was observed at in the East-Centre zone and Western zone at the start of harvest (November–January), compared to the Eastern region. It would be appropriate to start harvest in the East-Central and Western zones.

The environmental effect contributed more to the total variation, and it was associated with the levels of nitrogen and potassium in the first horizon, the acidity of the soil, the minimal temperature and the relative humidity.

MOTS CLÉS: Saison de Récolte, Génotype, Maturation de la Canne à Sucre.

Résumé

Le changement climatique a eu pour conséquence, le réchauffement global qui a affecté la production de la canne à sucre et a perturbé la saison de récolte. De nouvelles études sont nécessaires pour déterminer les périodes critiques de la récolte, basées sur les interactions résultant de la combinaison de différents génotypes et de l’écosystème terrien. Quarante-huit essais ont été établis dans quatre régions contrastées de canne à sucre au Cuba avec trois variétés – C 1051-73 (début), C 86-12 (milieu), My 5514 (fin) qui diffèrent en leur période de maturité. Une combinaison mois de récolte, âges de récolte de 9 à 24 mois, deux saisons de récolte, type de sol et repousses, par rapport aux profils de mûrissement étaient étudiés. À l’âge de 13 mois (période typique pour la récolte au Cuba), les régions ont démontré des différences significatives pour le mûrissement, plus importantes que celles occasionnées par les variétés. En conséquence, la saison de récolte devrait être réorganisée. L’effet du mûrissement était plus prononcé pour la région Centre-Est quelle que soit la variété, alors que les génotypes se sont mieux distinguées dans la région Est pendant la période mars-octobre.

MEJORAMIENTO DE LA ÉPOCA DE COSECHA BASADOS EN LA MADURACIÓN EN CUATRO REGIONES CAÑERAS DE CUBA

PALABRAS CLAVES: Época de Corte, Genotipos, Maduración de la Caña.

Resumen

Los cambios climáticos causantes del caliento global han afectado la producción y alterado el periodo de cosecha de la caña. Nuevas investigaciones son necesarias para determinar el periodo crítico de cosecha, basándose en los resultados de la interacción de diferentes genotipos y ecosistemas. Se condujeron un total de 48 ensayos en cuatro regiones cañeras cubanas contratantes con tres variedades que difieren en su periodo de maduración: C1051-73 (temprana), C86-12 (mediana), My5514 (tardía). Una combinación de mes de cosecha y edades entre nueve y 24 meses, en dos cortes, dos tipos de suelos y dos socas fueron estudiadas para madurez. A los 13 meses (periodo típico de cosechas en Cuba), las regiones estudiadas produjeron un efecto significativo y mayor al dependiente de variedades. Basados en ello, la época de corte debe ser reconocida. La región Centro-Oriental fue más eficiente con cualquier variedad, mientras que la región Oriental mostró mejor comportamiento varietal en el periodo marzo–octubre.
A NEW NOBILISATION SYSTEM IN SUGAR CANE (SACCHARUM SPP.)

R.R. CAMPO ZABALA and G. PÉREZ ORAMAS

National Sugarcane Research Institute (INICA), Carretera CUJAE, Km 2 ½. Edificio IPROYAZ, Boyeros, Ciudad de la Habana, Cuba CP 19390

KEYWORDS: Sugarcane, Nobilisation, Chromosome Number.

Abstract
A new nobilisation system (NSN) in sugarcane (Saccharum spp.) is presented to compare with the traditional style of nobilisation (TSN). A group of parents with 2n+n chromosomes has been used to transmit this character to their progenies. The system has increased the chromosome numbers in some parents of our breeding program. We suggest a new nobilisation system in combination with the traditional one in order to increase the genetic base of sugarcane cultivars in any breeding program.

Introduction
The sugarcane breeding programs in most countries from the beginning of the 20th century, up to the present, have been performing hybridisation processes in a Traditional Style of Nobilisation (TSN) using a few original varieties of Saccharum officinarum, S. spontaneum, and complex hybrids from a similar genetic background.

Therefore, most of the current commercial varieties have a similar genetic base (Campo-Zabala and Pérez Oramas, 2004). The special cytogenetic behaviour of the hybrids between S. officinarum and S. spontaneum throughout generations (G) of nobilisation with 2n female gametes with duplicated number of chromosomes has not been exploited because of the reduced parental material and the use of the conventional crossing system (Price, 1958).

Sugarcane breeders are still searching for complex hybrids with better commercial characteristics. Therefore, the 2n gametes system has not been exploited in all its magnitude.

The aim of this paper is to promote the use of parents with 2n+n genetic endowment to apply in a new nobilisation system to help increase the genetic base in sugarcane breeding programs.

Materials and methods
Information on cytogenetic studies of the Cuban and introduced varieties during sugarcane nobilisation, parental ancestors, commercial varieties, and their progenies was analysed. In addition, results of breeding programs of the main sugarcane countries were compared, including crosses evaluated in different phases of selection, among 2n+n genotypes, commercial varieties and n+n parents (Jorge et al., 2002).

Results and discussion
Varieties from the series POJ from Java were the first commercial hybrids obtained in the world (Figure.1), especially POJ2878, which became, with its relatives, one of the most used parents up to the present. Most sugarcane commercial varieties around the world share their origin due to a continuous use of similar parental materials in the breeding programs by means of a Traditional Style of Nobilisation (TSN). Therefore, most current commercial varieties have a narrow genetic base (Walker, 1987; Campo-Zabala and Pérez, 2004).
Fig. 1—Traditional style of nobilisation (TSN) to obtain varieties of POJ series.

The commercial varieties in production have to be replaced frequently, either for their poor productive stability, or for the high incidence of diseases and insect pests. However, there have been genetic advances which can not be ignored such as the quality of the juice, sucrose percentage, vigour, etc. obtained from TSN.

Results from Java (Bremer, 1962) and Cuba (Campo-Zabala and Pérez, 2004) showed that selecting parental materials after an evaluation of their ancestors (genealogy), origins and chromosomal numbers of type 2n+n made possible a practical use of the New System of Nobilisation (NSN) (Figure 2).

Fig. 2—New style of nobilisation (NSN) for sugarcane.
The basis of the NSN method is to use 2n+n complex hybrids, either as female or male parents, combining with wild relatives, rather than traditional forms of *S. officinarum* and *S. spontaneum*. The benefits of this method are to increase the chromosome number until a generation (G) is reached with good agronomic performance that a breeder is looking for.

The development and application of the NSN in Cuba has allowed selecting a group of parental clones with 2n+n chromosome number. These materials are being used in the sugarcane improvement program, in order to obtain parents with increased number of chromosomes to enrich the genetic base of the future commercial varieties. Table 1 shows several combinations with 2n+n genotypes obtained in the Cuban breeding program.

### Conclusions

The use of 2n+n genotypes and New Style of Nobilisation (NSN) facilitates the increase of the genetic base to improve the use of current germplasm in sugarcane. The system allows the introgression of new wild genes that provide progenies with better disease resistance and adaptation to different stress conditions. In addition, introduced varieties and a group of complex hybrids from the Cuban sugarcane germplasm allowed the development of the NSN and to establish the new hybridisation system. Further, at least 40 parental materials were proven to transmit 2n+n chromosomes to their progenies which enable the identification of crosses with 2n+n in the breeding program.

PALABRAS CLAVE: Caña de Azúcar, Nobilización, Número Cromosómico.

Resumen
UN NUEVO sistema de nobilización (NSN) en caña de azúcar (Saccharum spp.) es presentado para comparar con el estilo tradicional (TSN). Un grupo de parentales con número cromosómico 2n+n se han usado para trasmitir este carácter a sus progenies. El sistema ha ayudado a incrementar el número cromosómico en algunos parentales de nuestro programa de mejoramiento genético. Sugerimos el uso del nuevo sistema en combinación con el sistema tradicional para incrementar la base genética de los cultivares que se desarrollan en un programa de mejora.
EVALUATION OF FUNCTIONAL MICROSATELLITE MARKERS FOR SUGARCANE POLYCROSS PATERNITY ANALYSIS

KEYWORDS: Polycross, Microsatellites, Paternity Verification.

Abstract

POLYCROSSES allow different cross combinations among elite parents to be evaluated in a single family. However, the male parent of the progeny is unknown. Microsatellites are considered the marker of choice for fingerprinting and paternity analysis. In this work, the potential of seven microsatellites derived from expressed sequence tags (EST-SSRs) and one genomic (gSSRs) were evaluated to identify the male parent of four sibs selected from one polycross involving nine different male parents. The four sibs were selected based on their high productivity of sugarcane per hectare at plant cane in the year of 2008 at the Sugarcane Breeding Station of Ribeirão Preto, SP, Brazil. The products of the PCR reactions were separated on 6% denaturing polyacrilamide gels and silver stained. The eight SSRs screened over the female parent, the nine male parents and the four selected sibs produced a total of 62 alleles with an average of 7.75 alleles/locus. The genetic similarity (Jaccard coefficient) was calculated among all the materials evaluated. The average genetic similarity among the female parent and the nine male parents (GS = 0.547) was similar to that among the nine male parents (GS = 0.534) and also to that obtained among the four sibs and the nine male parents (GS = 0.539). For each locus, the female parent alleles that were present in each sib were excluded from the analysis to enable us to identify the origin of the male parent alleles present in the sibs. The male parent was identified excluding, for each locus at time, all the female parent alleles that were present in each sib, enabling the identification of the male parent with the alleles present in the sibs. The male parent identified with this approach showed the highest GS with the respective sib in pairwise comparisons among all male parents and sibs. The microsatellites used in the present work were used to successfully identify the male parent of the sibs evaluated.

Introduction

Sugarcane is an allogamous plant vegetatively propagated through stem cuttings. However, sexual reproduction is used by breeders to generate genetic variability for selection through crosses involving two (bi-parental crosses) or more parents (polycrosses).

Although different cross combinations among elite parents can be evaluated in polycrosses in a single family, the male parent of the progeny is unknown.

Nowadays, molecular markers have proven to be an important tool in breeding programs (Eathington, 2007). Among the different types of molecular markers, microsatellites are considered the marker of choice for sugarcane fingerprinting and paternity analysis (Cordeiro, 2001).

In the present study, the potential of seven EST-SSRs and one gSSRs were evaluated to identify the male parent of four sibs selected from one polycross involving nine different male parents genetically related.
Material and methods

Four sibs (clones) derived from one polycross involving the variety IACSP98-6209 (female parent) and nine male parents (SP84-7017, IACSP95-3028, IACSP94-2111, IACSP94-2094, IACSP97-3313, IACSP97-6671, IACSP99-3012, CTC-1, IACSP96-2036) were selected based on their high productivity of sugarcane per hectare at plant cane in the year 2008 at the Sugarcane Breeding Station (Centro de Cana). Seven EST-SSRs (ESTB312, ESTC05, ESTC48, ESTB130, ESTB07, ESTA48) (Oliveira et al., 2009) and one gSSRs (SMC1047HA) were used. These microsatellites were chosen based on the high quality of the amplification products. PCR reactions and separation of the amplified products were performed according to Oliveira et al. (2009). Markers were scored based on their presence/absence and used to estimate the genetic similarity between all the materials evaluated, adopting the Jaccard similarity coefficient using the NTSYS-PC software, version 2.0 (Exeter Software, NY, USA; Rohlf, 1993).

Results and discussion

The eight SSRs screened over the materials produced a total of 62 alleles (markers) ranging from 2 (ESTB130) to 13 (ESTA48) with an average of 7.75 alleles/locus. The pairwise genetic similarity among all the materials was moderate (0.603) and that among the nine candidate male parents (0.534) was slightly inferior to the average value estimated among the female parent and the nine candidate male parents (0.547).

The identification of the most probable male parent was done for each locus at time, excluding all female parent markers present in the sibs (clones) and analysing only the candidate male parent markers (Table 1).

Table 1—Identification of the probable male parent based on the exclusion of the female parent markers.

With this approach, it was possible to assume that the clones 17, 19, 21 and 30 have, as the most probable male parent, the sugarcane varieties IACSP97-3313, IACSP94-2111, IACSP94-2094 and IACSP97-6671 respectively. Indeed, exclusion of female parent markers constitutes a successful strategy in paternity identification (Buteler et al., 1997) being able, in our work, to indicate the most probable male parent.

As shown in Table 1, the male parent of clone 17 was easily identified, as the EST derived markers ESTC05.2 and ESTA48.7 were exclusively from the variety IACSP97-3313. The same was observed for clone 19, for the markers ESTC05.5 and SMC1047HA.5 that were exclusively from the variety IACSP94-2111.

As expected, the most probable male parent identified by the exclusion of the female parent markers approach, showed the highest genetic similarity with the respective clone (Table 2).

Table 2—Pair wise genetic similarity for female parent, clones and candidate male parents estimated based on 62 microsatellite markers.

Vérification de Paternité.

Résumé
LES POLYCROISEMENTS permettent les combinaisons de croisements parmi les parents élites pour être évalués comme une seule famille. Cependant, le parent mâle des progénitures est inconnu. Les microsatellites sont considérés comme les marqueurs de choix pour établir l’empreinte génétique pour l’analyse de la paternité. Le potentiel de sept microsatellites dérivés des étiquettes de séquences exprimées (EST-SSRs) et un microsatellite génomique (gSSRs) ont été évalués dans cette étude pour identifier le parent mâle de quatre progénitures. Celles-ci ont été sélectionnées d’un polycroisement impliquant neuf différents parents mâles. Les quatre progénitures ont été choisies en 2008 au Sugarcane Breeding Station de Ribeirão Preto, SP, Brésil sur la base de leur rendement élevé à l’hectare en vierge. Les produits PCR ont été séparés sur gel dénaturant de polyacrilamide de 6% suivi de la coloration au nitrate d’argent. Les huit SSRs criblés par rapport au parent femelle, les neuf parents mâles et les quatre progénitures ont produit au total 62 allèles avec une moyenne de 7.75 allèles/locus. La similarité génétique (coefficient de Jaccard) a été calculée parmi le matériel évalué. La similarité génétique moyenne parmi les parents femelles et les neuf parents mâles (GS = 0.547) était similaire à celles des neuf parents mâles (GS = 0.534) et également à celle obtenue pour les progénitures et les neufs parents mâles (GS = 0.539). Pour chaque locus, les allèles des parents femelles qui étaient présents dans chaque progéniture étaient exclus de l’analyse pour permettre d’identifier l’origine des allèles des parents mâles présents dans les progénitures. Le parent mâle a été identifié en excluant, pour chaque locus, les allèles transmis par le parent femelle et qui étaient présents dans les progénitures, permettant ainsi l’identification du parent mâle. Le parent mâle identifié grâce à cette approche a démontré que le GS est le plus élevé avec sa progéniture respective dans des comparaisons par paires parmi tous les parents masculins et progénitures. Les microsatellites utilisés dans cette étude ont été capables de mener à bien l’identification du parent mâle des progénitures évaluées.
EVALUACIÓN DE LOS MARCADORES FUNCIONALES MICROSATÉLITES PARA ANALISIS DE PATERNIDAD EN POLICRUZAMIENTOS EN CAÑA DE AZÚCAR

PALABRAS CLAVE: Policruzamientos, Microsatélites, Verificación Paternal.

Resumen

Los policruzamientos permiten diferentes cruzas entre parentales élites para evaluar en familias, aunque el parental masculino es desconocido. Los microsatélites son considerados marcadores útiles para descifrar su identidad genética, así como para el análisis de paternidad. En este trabajo se evalúa el potencial de siete microsatélites derivado de secuencias expresadas (EST-SSRs) y un genómico (gSSRs), para identificar el parental masculino de cuatro hermanos seleccionados de un policruzamiento que tiene nueve padres masculinos diferentes. Los cuatro hermanos fueron seleccionado basándose en su alta productividad de azúcar por ha en caña planta en el 2008, evaluados en la Estación de Mejoramiento de Ribeirão Preto, SP. Brasil. Los productos de la reacción de PCR fueron separados en un gel de poliacrilamida al 6% y luego teñido con plata. Los ocho SSRs identificados en el parental femenino, nueve del parental masculino y cuatro de los hermanos produjeron un total de 62 alelos con un promedio de 7.75 alelos/locus. Se calculó la similaridad genética (Coeficiente de Jaccard) entre los materiales evaluados. El promedio de similaridad genética entre el parental femenino y los nueve masculinos (GC = 0.547), fue similar al de los nueve parentales masculinos (GS = 0.534), así como el obtenido entre los cuatro hermanos y los nueve parentales masculinos (GS = 0.539). Para cada locus, el alelo del parental femenino que estuvo presente en cada hermano se excluyó del análisis para que permita identificar el origen de los alelos del parental masculino presente en los hermanos. El parental masculino se identificó luego de excluir todos los alelos al mismo tiempo del parental femenino presente en cada uno de los hermanos, para permitir la identificación de los alelos del parental masculino en los hermanos. El parental identificado con este sistema mostró el más alto valor de GC relación a su respectivo hermano en comparaciones pareadas entre parentales y hermanos. Por tanto, los microsatélites usados en este trabajo fueron usados en forma efectiva para identificar el parental masculino del grupo de hermanos evaluados.
SELECTING VARIETIES FROM SEEDLING STAGE IN GPS SUGARCANE ESTATES

KEYWORDS: On-Site Selection, Varietal Adaptation, Contrasting Environments.

Abstract

GROUPEMENT DES Professionnels du Sucre (GPS) is an association that groups three sugarcane estates in central Africa (SOSUCAM in Cameroon, CST in Chad, and SARIS in Republic of Congo) owned by the Group SOMDIAA. In order to improve the performance of selection and to face the challenge of renewing the variety situation, CERF and GPS has developed a strong partnership. Previously, the choice of cultivated varieties was based on a ten-year selection scheme supplied every year with 100 foreign varieties (elites and pre-selected varieties). This raises a major problem: the introduced varieties, selected abroad, are not well adapted to specific agro-climatic conditions of GPS estates. Moreover, previous results obtained by CERF showed that on-site selection increases the probability of identifying promising varieties. So it has been decided to establish a selection program for each estate with fuzz imported from CERF. Since 2005, CERF has made specific crosses for each estate and has dispatched the fuzz to the respective estates. About 4000 seedlings are raised in the respective estates and screened through a selection scheme designed by CERF. Training was provided to the estate personnel for raising and managing the seedlings for propagation. Results on family selection at the first stage (seedling nursery) and individual visual selection at ‘stage 2’ are presented for the first four years of this project.

Introduction

Growing high potential yield sugarcane varieties is a key point to increase field productivity. SOMDIAA owns three sugarcane estates in central Africa (SOSUCAM in Cameroon, CST in Chad, and SARIS in Congo). These estates must take up the challenge to develop an efficient method to identify high-yielding sugarcane varieties. In 2005, GPS (the association of the three sugarcane estates) decided, in partnership with CERF (the research centre responsible for sugarcane breeding in Réunion Island), to restructure its selection programs.

Three contrasting environments

SOSUCAM is situated along the Sanaga River, at 120 km north-east from Yaounde.

The subequatorial climate of SOSUCAM is characterised by two dry seasons, from November to March and from mid-June to mid-August (Figure 1). The annual average precipitation is 1450 mm generally well distributed throughout the year except for the dry months. Temperature varies from 23.5°C in July to 26.5°C in February. Humidity is very high and drops below 70% only during the long dry season. Daily evaporation is low: 3.8 mm/day. Sugarcane is cultivated under rainfed conditions.

The deep soil has good available water capacity and drainage is easy. Chemical properties are not so propitious: acid pH and low organic matter (Viremouneix, 2009).
CST is near Banda, near the Chari River, 600 km south east of N’Djamena. The tropical climate of CST is divided in two seasons: the dry season (from November to April) and the wet season (from May to October).

Monthly mean temperature varies from 24.2°C to 31.4°C. The annual average precipitation is 1023 mm; the average evaporation is 5.75 mm per day.

The humidity is relatively low (~45%). Fields are irrigated by pivot irrigation, by drip irrigation, or by gravity.

Depending on the ground water table depth and soil clay content, subsurface drain pipes are necessary. Although pH is 6, the soil has poor organic matter content and reveals a slight deficiency in phosphorus and potassium (Viremouneix, 2009).

SARIS is situated in Niari Valley, 250 km from Brazzaville.

The climatic year is composed of a wet season (from October to May) and a short dry season (from June to September). Monthly mean temperature varies between 23.8°C and 27.5°C. Evapotranspiration is low (~3.9 mm/day) (Viremouneix, 2009).

Soil is rich with a pH of 5.3, with high phosphorus and organic matter content.

Contrasting agronomic results

The contrasting agronomic data (Table 1) can be explained by the contrasting environments and cultural practices, but they could be improved on each sugar estate. Selecting adapted sugarcane varieties is a key point to achieve this objective.

Fig. 1—Monthly rainfall distribution and mean monthly temperature for GPS estates.

The previous selection program and its results

Since 1984, GPS estates were importing around 100 sugarcane varieties per year from different breeding stations such as, WICSCBS (Barbados), SBI (India), CIRAD (Guadeloupe), SASRI (South Africa), and CERF (Reunion).

The imported varieties could be:
1. Elite varieties i.e. they had better agronomic performance than standards in their original country and were adapted to the agro-ecological zones where they were selected.
2. Pre-selected varieties i.e. they had gone through the first selection trials in the respective countries.

To identify the best performing varieties, GPS has developed a ten-year selection scheme for each site (Figure 2). Figures 3, 4 and 5 show variety distribution at SOSUCAM, CST, and SARIS respectively.
SOSUCAM cultivates mainly two varieties: Co 997 and B 46/364 on 97% of the cane area (Figure 3). B82333 and Fr 81/258 are being multiplied.

More than 57% of CST cane area is planted with Co 997, 21% with SP 701284, 12.5% with N12 (Figure 4). The varieties R570 and N18 are promising for commercial exploitation.

Four major varieties are cultivated at SARIS: B 46/364, NCo 376, Co 997 and R570; each cover around 20% of the cane area (Figure 5). N 19 and Mex73523 are under multiplication (Viremouneix, 2009).

Some old varieties are cultivated on most of the estates. Although a significant effort is being made to renew the cultivar situation, GPS selection programs are not reaping the expected results.

**The new selection scheme**

To improve the selection efficiency, GPS requested CERF expertise. The main weakness of the GPS selection program is its over reliance on imported varieties. Selecting in an environment and expecting similar performance in a different environment is a strategic error (Simmonds, 1991; Bouvet et al., 1985).

Site-specific selection potentially generates local adaptation, and enables the identification of specific elites (Simmonds, 1991; Barau, 2007).

Since 2005, the estates have established a selection program from fuzz imported from CERF and supported with CERF expertise.

The goal is to raise 4000 seedlings per year per estate. As it is not possible to accurately predict cross performance, the only way to identify the best families is testing a large number of crosses.

However, the performance of the parent is a good indicator for targeting crosses (Hogarth et al., 1997). So, parent varieties were identified as the ten best cultivars in each estate.
CERF breeders provided training to the estate personnel in Réunion Island and in Chad:

1. to design a new selection scheme
2. to manage seedling germination and propagation
3. to grow and select the seedling nursery
4. to select ‘stage 2’ where each variety is planted on one 3 m-line.

Fuzz is sown in trays under a plastic tunnel. A few weeks after germination, seedlings are potted. Three months later, seedlings are transplanted into the nursery. About four months after transplanting, the nursery is selected using a visual grade assigned to each family, which defines the selection rate per family.

About 30% of the seedlings are selected and planted into stage 2 (3 m plots) for clonal selection. In first ratoon, clones are evaluated for agro-morphological characters at 10 months, and Brix is measured on the clones with the best visual grades.

About 6% of cultivars (72 clones per site) are selected and screened through the ten-year classic selection scheme (Figure 2). Thus, the complete new selection program lasts around 14 years.

Discussion

GPS emphasises the use of the best varieties in crosses. However, a number of varieties are not available in the CERF germplasm collection. So CERF plans to acquire them from the respective breeding centres. Moreover, the extent of flowering may limit their use in crosses since CERF relies on natural flowering for crossing.

CERF has suggested that GPS increase the number of seedlings raised in order to widen the genetic diversity for the new selection scheme.

In 2009, GPS will establish the first experimental trials as per the new scheme (stage ‘Pre-selection’).

In the process of developing the new selection scheme, GPS is faced with a number of difficulties, such as the reliability of the visual grades and the identification of diseases (with the classical scheme, the diseases were monitored by CIRAD).

Furthermore, the selection would progressively be improved from feedback received from GPS. Data on selection rates would rapidly provide useful information on the best crosses and parents.

MOTS-CLES: Sélection sur Site, Adaptation Variétale,
Environnements Contrastés

Résumé

Le GPS (Groupement des Professionnels du Sucre) est l’association qui regroupe les trois complexes sucriers de la SOMDIAA en Afrique centrale (la SOSUCAM au Cameroun, la CST au Tchad et la SARIS en République du Congo). Pour améliorer l’efficacité de la sélection et pour renouveler la situation variétale, le CERF et le GPS ont développé un partenariat étroit. Jusque là, le choix des variétés cultivées se basait sur un schéma de sélection de dix ans. Ce schéma de sélection était alimenté par une centaine de variétés étrangères (des variétés élites ou des variétés pré-sélectionnées). Le problème principal de cette démarche réside dans le fait que les variétés introduites et sélectionnées ailleurs n’étaient pas adaptées aux conditions agroclimatiques spécifiques des complexes du GPS. De plus, des résultats obtenus au CERF montrent que la sélection sur site augmente la probabilité d’identifier des variétés prometteuses. Il a donc été décidé d’établir sur chaque complexe, un schéma de sélection à partir de fuzz importé depuis le CERF. Depuis 2005, le CERF réalise des croisements spécifiques pour chaque complexe, puis expédie le fuzz ainsi produit. Environ 4000 seedlings par an sont obtenus sur chaque site. Ces seedlings subissent alors un schéma de sélection élaboré en collaboration avec le CERF. Le personnel des complexes a pu suivre des formations sur la germination et l’entretien des seedlings. Cette étude présente, pour les quatre premières années de ce projet, les résultats de la sélection familiale au stade 1 (pépinière de seedlings) et les résultats de la sélection massale et visuelle du « stade 2 ».

PALABRAS CLAVES: Selección en Sitio,
Adaptación Varietal, Ambientes Contratantes.

Resumen

GPS ES UNA asociación que agrupa a tres estados Azucareros en África Central (SOSUCAM en Camerón, CST en Chad, y SARIS en la República del Congo) y son propiedad del grupo SOMDIAA. CERF y GPS han desarrollado un acuerdo importante entre ellos, con el fin de mejorar la respuesta de la selección y renovar variedades. Anteriormente, las variedades se escogían basándose en un esquema de selección de 10 años, que se aplicaba cada año usando 100 variedades introducidas (variedades élites y pre-seleccionadas). Esto causa un problema mayor que es la introducción de variedades seleccionadas afuera y no están bien adaptadas a las condiciones agroclimáticas específicas de los estados del grupo GPS. Más aún, resultados previos obtenidos por CERF mostraron que la selección por sitio incrementa la probabilidad de identificar variedades promisorias. Por ello, se ha decidido establecer un programa de selección para cada estado, usando semillas de CERF. Se han realizado cruzas específicas para cada estado en la Isla de Reunion para luego sembrar en cada estado, desde el 2005. Estas siembras incluyen alrededor de 4000 plántulas en cada estado y seleccionadas dentro de un esquema de selección elaborado en colaboración del CERF. Se ha entrenado al personal de cada estado para el cuidado, propagación y manejo de las plántulas. En este trabajo se resume los resultados de los primeros cuatro años del proyecto, sobre la selección familiar en Estado I y selección clonal visual en Estado II.
BIOCONTROL OF CHILO SACCHARIPHAGUS (LEPIDOPTERA: CRAMBIĐAE) A KEY PEST OF SUGARCANE: LESSONS FROM THE PAST AND FUTURE PROSPECTS

Abstract

BIOCONTROL of sugarcane stemborers using Trichogramma releases is a common strategy used in numerous countries, and the efficacy of such releases has been proven in most cases. On Reunion Island, the key stemborer Chilo sacchariphagus and its egg parasitoid Trichogramma chilonis have been the subject of intensive research for 10 years. From the identification of the best candidate for biocontrol to mass production and experimental releases in sugarcane fields, improvement has been constantly made through the years, with successful results. In this paper, we report some of the important outcomes, problems encountered and questions that have arisen during the field experiments (Reunion) and laboratory rearing activities (Reunion and France). Behind promising results from an eco-friendly technology that is used worldwide, one of the current debates that remain is the cost of such biocontrol to the growers. Since 2008, a new research and development project has been conducted to optimise the technology of field releases as well as to increase the efficacy of mass production and storage at cold temperature. To deal with profitability and quality and establishing a new industrial process for Trichogramma production, a partnership has been formed with a French company, BIOTOP, which has extensive experience in biocontrol of the maize stemborer Ostrinia nubilalis in France.
