The second demonstration was conducted in a bigger capacity plant (8 m$^3$/day) with two membrane stages, which was installed at Greenfield Ethanol plant in Chatham, Ontario, Canada, with start up in October 2008. The objective of this field demonstration unit was to test a two-stage commercial scale membrane system fully integrated with an industrial grain-based ethanol plant.

A simplified process flow diagram is shown in Figure 4. The demonstration unit was fed with an ethanol-water vapour mixture from the beer column with concentration between 40–60 wt% ethanol.

![Figure 4—Process flow diagram of Chatham demonstration unit.](image)
The plant operated with vapour fed at an absolute pressure of 170–175 kPa, and temperature of 105–110°C. Before feeding the membrane, the flow passed through a filter to avoid any liquid or solid in the membrane.

The ethanol concentration was increased to around 90 wt% through the first stage membranes and further to the final concentration through the second stage membranes.

Figure 5 shows the results of a continuous operation, producing ethanol with concentration between 99.2 and 99.8 wt%.

This demonstration unit was integrated with the industrial plant and involved recompression of the first stage permeate from an absolute pressure of 40 kPa to an absolute pressure of 250 kPa that was re-injected in the rectification column, reducing the fresh steam load.

The permeate from the second stage with a low concentration of ethanol was recycled to the beer column for ethanol recovery.

**Dedini demonstration unit**

The third demonstration unit was built in Brazil with the objective to demonstrate the Siftek™ technology for ethanol production from sugarcane.

The plant was designed with flexibility to process three types of feed: 45 wt% ethanol from the beer column, 93 wt% from the rectification column, and 85 wt% from molecular sieve recycle (Figure 6).

This last condition is a very interesting application because it allows an increase of the anhydrous ethanol production in the distillery (this alternative is described further in this paper).

The Dedini demonstration unit (Figure 7) operates with two membrane stages (one membrane in each stage) and has a capacity of 5 m³/day.

The industrial performance tests were carried out at Costa Pinto Sugar Mill in Piracicaba-SP (2008) and São Martinho Sugar Mill in Pradópolis-SP (2009) (Gabardo Filho, 2008, 2009).
The plant operated with vapour fed at an absolute pressure around 160 kPa, and temperature of 115°C. Before feeding the membrane, the flow passed through a knock pot to avoid any liquid or solid in the membrane and in the super-heated system.

A molecular sieve unit (MSU) produces a recycle flow with ethanol concentration between 50 and 70% during its operation and this flow needs to be reprocessed in the distillation (the lower value is the result of the dilution in the liquid ring vacuum pump used). One alternative to the membrane system is to dehydrate this recycle flow to increase the anhydrous production, avoiding the re-processing step. The first operating condition was to process the MSU recycle in a distillation process to increase the concentration to around 85% and then dehydrate it in the membrane system. The second operating condition was dehydration of the hydrous ethanol (93 wt%) from the rectification column producing anhydrous ethanol.
The third operating condition was to process the ethanol-water flow from the beer column with concentration around 45 wt% producing ethanol 99.5 wt% (to be done in November 2009).

Figure 8 shows the results of the dehydration process from the MSU recycle by membrane system (operating condition 1).

The feed concentration oscillated between 76 and 93 wt% ethanol, according to the operation of the industrial distillation column.

The system assimilated this variation very well, providing a flexibility feature for the Siftek™ membrane that is not found in other, conventional technology.

The two black bars in Figure 8 represent the leak of feed from the distillery during rain periods.

The permeate flow, with low ethanol concentration, was sent to be recovered in the distillation process. It represented a recycle between 2 and 2.5% of the feed ethanol, compared with around 15 – 30% from molecular sieve.

Other parameters measured were the acetic acidity and conductivity. Figure 9 shows the behaviour of the acidity during operation.

It shows a small increase of around 2 mg/L in the acidity of the product. This increase is the result of the water reduction in the product and consequent concentration of the organic compounds.

It is more an indicative parameter that confirms the higher selectivity of the membrane to water compared to organics. Although the acidity is increasing, it remains lower than the specification (30 mg/L).

Figure 10 shows the conductivity in the feed and in the product, resulting in an average reduction of 55%, helping to meet the product quality specification value (500 μS/m).
In the second operating condition, the system was fed with 93.0 wt% hydrous ethanol in liquid phase. Figure 11 shows the results where it is possible to see again the stability in product quality, with average of 99.65% wt% ethanol.
Application of the membrane technology

There are some industrial applications where the Siftek™ Technology can be integrated in a bio-ethanol plant. Figure 12 shows the membrane application like a dehydration plant, replacing conventional technology like molecular sieve or dehydration via extractive distillation with cyclohexane in greenfield plants. The Siftek™ membrane is a product that has the advantage of no chemical contamination and high energy saving. The membrane steam consumption is around 0.41 kg steam/L of product, resulting in an energy saving around 35% when compared with MSU (consumption of 0.65 kg steam/L) and around 70% when compared with a cyclohexane dehydration process (1.55 kg steam/L).

Another industrial application of the Siftek™ technology is the treatment of the MSU recycle stream. In a conventional plant, a MSU is regenerated by applying vacuum sweeping with purified ethanol. This stream, containing 50–70 wt% ethanol, is recycled to the rectification column, representing a recycling of about 15–30% of the purified ethanol produced by the plant, resulting in an additional energy consumption for re-purification.

The use of a membrane system for dehydration of the MSU recycle stream can save around 15% energy, with a consumption of 0.55 kg steam/L, and debottlenecking the plant by freeing up capacity in the rectification column and MSU. If these processes are limiting, plant production could be increased by around 20%. This process flow diagram is shown in Figure 13.
Conclusions

Considering the excellent results obtained in the demonstration plants and in the industrial design, the conclusions are:

- The Siftek™ system is a polymeric membrane that can be used to dehydrate ethanol in vapour phase because of its high selectivity of water over ethanol, with benefits of no contamination in the product and lower energy consumption.
- The three demonstration plants showed a high membrane performance in water removal, producing ethanol in a continuous process with concentration higher than 99.5 wt% ethanol.
- The Dedini system showed a high stability in quality product with an average of 99.65 wt% ethanol, with a system flexibility to assimilate variation in the feed concentration.
- Recirculation of ethanol is minimised.
- The membrane technology can be installed in new plants with lower energy consumption, saving around 35% of energy when compared with molecular sieve technology and around 70% when compared with extractive distillation by cyclohexane.
- When used to treat the MSU recycle stream, the membrane results in a reduction of around 15% in energy consumption with increased production capacity of 20%.

Acknowledgments

This project is a partnership between Dedini S/A Indústrias de Base and Vaperma Inc. During the operation in Brazil, the system was supported by Cosan Group and São Martinho Group, two of the biggest sugarcane processors in the world.

Résumé
L’ETHANOL est une énergie renouvelable importante au Brésil et plusieurs sociétés améliorent leurs technologies afin d’accroître les avantages de l’éthanol par rapport aux combustibles fossiles. Les membranes polymériques Siftek™ donnent une technologie qui peut économiser entre 35 et 70% d'énergie par rapport aux processus classiques. La première usine pilote (Tiverton, Canada) a exploité une déshydratation d’éthanol de grain de 80–90% d’éthanol à 99.2 % (masse), démontrant la bonne performance des membranes. Dans le but de tester le système à titre commercial, une deuxième usine (Chatham, Canada) a été construite et exploitée avec succès, utilisant l’éthanol de grain de 40 à 60% d'éthanol à 99.5% (masse). Pour démontrer cette technologie aux producteurs d'éthanol brésiliens, un troisième appareil de démonstration a été construit et exploité dans les usines d'éthanol a partir de la canne. Les résultats ont confirmés l'excellente sélectivité du système de membrane pour l'eau; une déshydratation de 85–93% d'éthanol a été augmentée a 99.5%, avec une faible consommation d'énergie et en préservant la qualité du produit.

Resumen

EL ETANOL es energía renovable muy importante para Brasil y varias compañías están mejorando sus tecnologías desarrollando procesos para incrementar los beneficios del etanol comparado con las fuentes fósiles. La membrana polimérica Siftek™ es una tecnología que puede ahorrar entre 35 y 70% de la energía cuando se la compara con procesos convencionales. La primera planta piloto (Tiverton, Canadá) operó deshidratando etanol de granos desde 80–90% en peso hasta 99.2% en peso, evidenciando el buen desempeño del sistema de membrana. Con la meta de probar el sistema a capacidades comerciales, una segunda planta (Chatham, Canadá) fue construida y probada exitosamente, deshidratando etanol de granos desde 40–60 % en peso hasta 99.5% en peso. Para demostrar esta tecnología a los productores de etanol brasileños se construyó una tercera planta piloto y se operó en las plantas de alcohol a partir de caña. Los resultados confirmaron la excelente selectividad del sistema de membrana al agua, deshidratando desde 85–93% en peso a 99.5%, con un menor consumo de energía y preservando la calidad del producto.
MODELLING THE EFFECT OF THE SRI SWIRL SPREADER BAGASSE COMBUSTION SYSTEM ON FURNACE OPERATION

By

F. PLAZA, A.P. MANN and G.A. KENT
Queensland University of Technology
f.plaza@qut.edu.au

KEYWORDS: Boilers, Bagasse, Furnace, Combustion, Swirl.

Abstract

CONVENTIONAL pneumatic bagasse spreader systems with a plane air jet to feed bagasse into sugar mill boilers have been widely used for over forty years. Being relatively simple and reliable, conventional spreaders have served the cane sugar industry well. However, they do have some significant deficiencies. Firstly, at high bagasse moisture contents, there is usually a significant build up of fuel on the grate which limits steam output and can cause combustion instability. The pressure excursions arising from combustion instability can cause significant damage to the boiler. Secondly, by inspecting the flame in the furnace through any small ports available, it is clear that the flame produced is concentrated towards the back part of the furnace. A significant portion of the furnace volume is underutilised. The swirl spreader addresses the issue of an underutilised furnace volume by spinning the bagasse as it enters the boiler, achieving a better spread of fuel over the furnace grate and reduced deposition of unburnt material. Current swirl spreader installations have made it possible to increase boiler steam output by up to 10% and make the boilers more tolerant of high moisture content bagasse. Further improvements in performance are possible through the use of hot air at the swirl spreader. The Computational Fluid Dynamics (CFD) code FURNACE was used to compare swirl spreaders to conventional spreaders, both cases using hot air, based on modelling the effect on furnace operation. The modelling predicted that the swirl spreaders achieve a more uniform temperature profile in the furnace, with smaller hotter and colder regions, and with the flame located closer to the grate. Lower peak and average gas temperatures and velocities at the furnace exit and convention bank tube inlet were predicted with swirl spreader operation due to the predicted increase in furnace heat absorption.

Introduction

Conventional pneumatic bagasse spreader systems (Dixon and Jorgensen, 1988) with a plane air jet to feed bagasse into sugar mill boilers have been widely used for over forty years. Being relatively simple and reliable, the conventional spreaders have served the cane sugar industry well. However, they do have some significant deficiencies. Firstly, at high bagasse moisture contents, there is usually a significant build up of fuel on the grate which limits steam output and can cause combustion instability. The pressure excursions arising from combustion instability can cause significant damage to the boiler. Secondly, by inspecting the flame in the furnace through any small ports available, it is clear that the flame produced is concentrated towards the back part of the furnace. A significant portion of the furnace volume is underutilised. Previous computer modelling has supported this observation and predicted that a significant increase in heat transfer would occur if the volume in the furnace was better utilised (Dixon and Plaza, 1995). Improved heat transfer in the furnace will result in improved overall boiler steam output and boiler efficiency and, in the longer term, the development of a smaller, cheaper boiler station.
The swirl spreader addresses the issue of an underutilised furnace volume by spinning the bagasse as it enters the boiler, achieving a better spread of fuel over the furnace grate and reduced deposition of unburnt material. Mann et al. (2004) described the history of its development, including the operation of a large sugar mill boiler (MCR 200 t/h) at Proserpine Mill using swirl spreaders of Mark III design. Since that time, relatively small modifications by Proserpine Mill staff have resolved a wear problem, resulting in the current Mark IV design. Observations from boilers where swirl spreaders have been retrofitted have shown that swirl spreaders (using cold air) can increase boiler steam output by up to 10% and make boilers more tolerant of high moisture content bagasse.

It is believed that the use of swirl spreaders with hot air will result in further improvements in boiler performance. Such measurements are not available. Computer modelling can be used to gain some insight into the operation of a furnace with such an installation. Previous work (Woodfield et al., 1997, 1998; Mann et al., 2004) demonstrated that the Computational Fluid Dynamics (CFD) code FURNACE (Boyd and Kent, 1986) successfully predicts general trends and patterns in a furnace, including gas temperature and velocity distributions. This poster paper uses FURNACE to compare the gas temperature and velocity predictions for the Proserpine No. 4 boiler furnace operating with conventional spreaders and with swirl spreaders.

**Predicted results for furnace operation**

The Proserpine No. 4 boiler was modelled with conventional spreaders and with swirl spreaders. Both types of spreaders were positioned on the same centre line. The simulated swirl spreader air temperature was 230°C. In order to compare only the swirl spreader to the conventional spreader, all air for both alternatives was simulated to enter the furnace at this temperature, with the total amount of bagasse and air entering the furnace being identical for both alternatives. The modelling was carried out for operation at a high steam load (210 t/h). A description of the furnace locations referred to in the discussion of the predictions is shown in Figure 1. The results of the simulations are shown in Figure 2, Figure 3 and Figure 4, which respectively show a gas temperature side view near the middle of the furnace, a gas temperature plan view halfway up between the grate and the bottom of the furnace exit baffle, and a gas velocity side view near the middle of the furnace.
Inspection of the gas temperatures shows that, relative to the conventional spreaders, operation with the swirl spreaders results in a larger more even flame which occupies a greater volume within the furnace, with smaller areas of both hotter and colder gases.

The gas velocities with the swirl spreader operation are predicted to have less recirculation downwards at the front top of the furnace, with a more even gas distribution out of the furnace. Peak gas velocities at the furnace exit baffle and at the tubes at the inlet to the convection bank are predicted to be lower for operation with swirl spreaders.

The use of swirl spreaders with hot air instead of conventional spreaders with secondary air at the same temperature is predicted to significantly improve the utilisation of the available furnace volume.
Conclusions

Computer modelling has been used to gain some insight into the operation of a furnace with a swirl spreader installation using hot air, relative to a conventional spreader installation using secondary air at the same temperature. Boiler operation with swirl spreaders is predicted to result in a larger more even flame which occupies more of the volume of the furnace, with smaller areas of both hotter and colder gases, resulting in a significant improvement in the utilisation of the available furnace volume. Peak gas velocities at the furnace exit baffle and at the tubes at the inlet to the convection bank are predicted to be lower for operation with the swirl spreaders due to the predicted increase in furnace heat absorption.

MODELLISATION DES EFFETS DU SYSTEME SWIRL SRI POUR LA DISTRIBUTION DE LA BAGASSE AUX CHAUDIERES

Par

F. PLAZA, A.P. MANN et G.A. KENT
Queensland University of Technology
f.plaza@qut.edu.au

MOTS CLEFS: Chaudière, Bagasse, Combustion, Foyer, Swirl.

Résumé
Le système conventionnel pour l’alimentation de la bagasse aux chaudières a été utilisé pendant plus de 40 ans. Ce système est bien établi et son opération est relativement aisé, mais il présente des désavantages. Une forte humidité de la bagasse, par exemple, cause des problèmes d’alimentation qui réduisent le débit de vapeur et déstabilisent l’opération de la chaudière. La pression devient instable ce qui peut causer des dégâts. On a aussi trouvé que les flammes sont concentrées à l’arrière du fourneau, réduisant le volume utilisé. Le système Swirl évite ce problème en distribuant la bagasse d’une façon efficiente et en réduisant les dépôts de matériel non brûlé. Les systèmes Swirl en opération ont permis une amélioration de 10% au débit de vapeur et facilitent l’opération avec de la bagasse plus humide. On peut aussi améliorer la performance en utilisant de l’air chaud avec le système Swirl. On s’est servi du logiciel FURNACE en «Computational Fluid Dynamics, CFD» pour comparer le système Swirl au système conventionnel, avec de l’air chaud dans les deux cas. Le model montre que le système Swirl donne une température plus uniforme au foyer, avec moins de régions plus froides ou chaudes; la flamme est située plus près de la grille. Le modèle indique que Swirl réduit la fourchette de la température et de la vitesse des gaz à la sortie du foyer et aux tubes, grâce à une absorption de chaleur plus efficace.
MODELAMIENTO DEL EFECTO DEL SISTEMA DE COMBUSTIÓN BASADO EN EL DISPERSOR DE TORBELLINO PARA COMBUSTION DE BAGAZO SRI EN LA OPERACION DEL HORNO DE CALDERA

Por
F. PLAZA, A.P. MANN y G.A. KENT

Queensland University of Technology
f.plaza@qut.edu.au

PALABRAS CLAVE: Calderas, Bagazo, Horno, Combustión, Torbellino.

Resumen

LOS SISTEMAS convencionales neumáticos para el lanzamiento de bagazo con chorro plano de aire para alimentar el bagazo en calderas de ingenios han sido ampliamente usado por cerca de 40 años. Relativamente simples y confiables los lanzadores neumáticos han servido bien a la industria. Sin embargo tienen deficiencias significativas. Primero, con contenidos altos de humedad de bagazo hay amontonamiento de bagazo en la parrilla que limita la generación de vapor y puede causar inestabilidad de la combustión. Las variaciones de presión debidas a la inestabilidad de combustión pueden generar significativo deterioro de la caldera. En segundo lugar, al inspeccionar el hogo por las mirillas es evidente que las llamas se concentran hacia la parte trasera del hogar, dejando una porción importante del volumen del mismo subutilizada. El lanzador de torbellino aborda el tema haciendo girar en torbellino la corriente de bagazo en su entrada a la caldera, logrando una mejor dispersión sobre la parrilla y una menor deposición en la misma de material inquemado. El lanzador de torbellino logra un mejoramiento adicional con el uso de aire caliente en el lanzador. El código FURNACE basado en Dinámica Computacional de Fluidos (CFD) fue utilizado para comparar los lanzadores convencionales y el tipo torbellino, en ambos casos usando aire caliente, y predecir el comportamiento de la operación del horno. Los modelos predicen que los lanzadores de torbellino logran una temperatura más uniforme en el hogar con zonas muy frías o muy calientes más pequeñas y con una llama localizada más cerca de la parrilla. Se obtuvieron predicciones de los valores de las temperaturas y velocidades del gas a la salida del hogar y a la entrada del banco convectivo, tanto pico como promedio, más bajos con el lanzador de torbellino, debido al incremento de la absorción de calor en el hogar.
ENVIRONMENTALLY FRIENDLY LUBRICANTS FOR MILL BRASSES

By

G. PERFETTI and D. ALONSO
LAAPSA, Buenos Aires, Argentina
gperfetti@laapsa.com.ar

KEYWORDS: Brass, Lubricant, Mill, Viscosity.

Abstract

IN SPITE of environmental, safety and hygiene pressures to eradicate their use, large quantities of asphaltic oils are still used for the lubrication of mill brasses in sugarcane mills. Since about 1980, people have been encouraged to find a solution to the contamination resulting from the use of asphaltic oils and, at the same time, have started to identify significant related costs. Lubricant technology has advanced, introducing new products to provide an effective solution to the contamination problem. This paper shows the evolution of technology from asphaltic oils to very high viscosity oils. These high viscosity oils cause very low environmental impact, are used in small quantities, and are considered biodegradable, with low-toxicity. Some products are considered food-grade.

Introduction

In spite of environmental, safety and hygiene pressures to eradicate their use, large quantities of asphaltic oils are still used for lubrication of mill brasses in sugarcane mills. ‘Mill brasses’ is the common name for the large plain bearings (journal bearings) of sugarcane mills.

The mill brass is one of the mill components with the greatest mechanical stress, since it is subjected to:

- Very high load: 5 to 10 MPa.
- Very high operating temperature: up to 100°C.
- Very low speed: from 4 to 7 r/min.

These operating conditions constitute a specific ‘lubrication regime’ and, in this situation, wear by friction is potentially important. It is necessary to know the lubrication regime to design the best lubricant for the application. These regimes can be identified in the Striebeck/Hersey curve, developed by Striebeck (1902) and Hersey (1914). The Striebeck/Hersey curve determines the coefficient of friction as a function of viscosity (Z), velocity (N) and load (P).

Figure 1 shows that, for a velocity close to 0 and with high loads, the viscosity of the lubricant ‘Z’ is the parameter that must increase in order to ideally let us get away from the regime of ‘boundary lubrication’. However, ‘hydrodynamic’ lubrication, in which there is no metal-to-metal contact between the roll shaft and the bearing, cannot be reached. The possibility of providing effective flow of sufficient lubricant is, in practice, between 100 and 200 times inferior to what is required. Consequently, the lubrication regime of mill brasses remains ‘boundary lubrication’ (Hargreaves, 1984).

In addition to the actual operating conditions of mill brasses, as defined by the ZN/P expression, high temperatures of the order of 100°C can also be developed in the roll shaft-bearing interface. Contaminants such as water, cane juice and bagasse add to the problem, and should be counteracted with design of proper mechanical protection arrangements, alignment and adjustment between the roll shaft and the bearing.
Requirements for designing better lubricants

The design of better lubricants primarily requires that ZN/P is as high as possible. Therefore, viscosity Z will be as high as possible. Viscosity, however, is not the only important condition. Other requirements must be taken into account, given the need to improve the environmental, safety and hygiene performance of mill brass lubricants and to extend the useful life of equipment. The guidelines for the design of a suitable lubricant should be as follows:

**Tribologic requirements of lubricant**
1. Very high viscosity at 100°C
2. Must provide metal adherence for longer residence time in the roll shaft-bearing interface
3. Must avoid or minimise water, cane juice or bagasse input
4. Enough thermal stability at high operating temperature
5. In ‘boundary lubrication’ regime, must have EP capacity necessary to prevent micro-welding when the lubricating layer is thin (four-ball test, ASTM D 2783, weld load ≥ 620 kg).

**Distribution requirements of lubricant**
6. Must be fluid so as to enable its handling and pumping in centralised lubrication systems
7. Its structure must be homogenous, without getting dispersed, in view of repeated pressurisation-release cycles

**Chemical resistance requirements of lubricant**
8. Must not attack valve and pump seals
9. Must withstand contamination by water
10. Must withstand contamination by cane juice

![Figure 1 - Coefficient of friction as a function of viscosity (Strubeck, 1902)](image-url)
Requirements for environment and security and hygiene

11. Must enable lubrication with very low application quantity; 10 times less than asphalts.
12. Must be clear and non-irritating
13. Must be highly biodegradable according to environmental international standards
14. Must have low toxicity
15. Must credit food grade certifications, H1 if required
16. Must derive from renewable resources

Evolution of lubricants for mill brasses

After asphaltic oils, there have been two main evolutions in lubricant types: graphite greases with solid lubricants (graphite) that were originally used for lubrication of open gears in mine and cement industries and, in recent years, very high viscosity oils.

Table 1 shows the performance of the different technologies of lubricants for mill brasses. The numbers in the table relate to the 16 lubricant requirements (reproduced below). The white box signifies poor lubrication, the yellow box signifies good lubrication and the green box signifies excellent lubrication.

Table 1—fulfilled requirements of mill brasses of lubricant.

Theoretical calculation of oil viscosity for a mill brass

Assumptions

A mill top roll brass has been analysed for a mill crushing between 4500 and 5000 tonnes of cane per day and the following configuration:

- Diameter main mill brass: 480 mm
- Effective length of brass: 550 mm
- Mean diameter of roller: 1000 mm
- Length of roller: 2000 mm
- Diameter of hydraulic cylinder: 356 mm

Table 2 relates the top roll hydraulic pressure to the pressure on the top roll brass.

Lubrication parameters
The following parameters should be considered when determining the lubricant viscosity:
1. Lubricant viscosity at rating temperature
2. Pressure between contact surfaces
3. Rotational speed
4. Separation between surfaces (clearance)
5. Materials used (very important for effective lubrication)
6. Quality degree of surfaces.
7. \(\text{l/d ratio (bearing length/bearing diameter)}\)

It is quite complex to relate all these terms, and so a simplified formula has been adopted, (Martinet, 1985)

\[ K = \mu \times n \times 10^8 / P \]

\(\mu\): viscosity (kg.s/m²)
\(n\): rotational speed (r.p.s)
\(P\): specific pressure in the main bearings (kg f/m²)

For the purposes of this specific study we will distinguish three types of lubrication:
- Boundary lubrication: metallic rubbing between the journal-brass.
- Mixed lubrication: in some parts, friction is metallic; in others, it is fluid by means of lubricant
- Hydrodynamic lubrication: lubricant layer is installed on the whole mill brass surface.

The method to determine if our case tends to fall in the last mode is by evaluating K value
If \(K < 5\), hydrodynamic lubrication is not possible.
If \(K \geq 5\), superficial termination will be with 0.005 mm roughness and antifriction material.
If \(K \geq 15\), rectified journal and bronze bearing.

Thus, in our case we look for oil for which the K value must be \(\geq 15\)

Comparison: Asphaltic oil - Very high viscosity biodegradable oil
Table 3 shows K values for different values of speed, temperature and pressure in main mill brasses for an asphaltic oil. Note that the unit of viscosity (kg*seg/m²) is the same as that used in the above formula (kg.s/m²). Table 4 shows K values for a very high viscosity biodegradable oil. It is clear that the K values are considerably higher for the very high viscosity oil than for the asphaltic oil.

Case study

Lubricant performance was measured in a sugarcane mill with a milling tandem consisting of five 1981 mm mills crushing 12 000 tonnes of cane per day. The mill brasses were lubricated with 16 500 cSt @40°C very high viscosity biodegradable oil. The lubricant consumption is shown in Figure 2. The average lubricant consumption was 10 litres per day (0.9 g per tonne of cane). This lubricant consumption was 80% less than is typical of black or asphaltic oils.

The operating temperature was kept stable, as shown in Figures 3 and 4 for the first and final mills respectively.
At the end of the first season of operation, the brasses and the roll shafts was both in good condition (Figure 5).

With the new lubricant, there was minimal spillage of lubricant on the factory floor (Figure 6). The absence of spills improves workplace safety.
Conclusion

Asphaltic oil and graphite greases cannot fulfil the requirements of mill brass lubrication. The high K values required can, however, be achieved with very high viscosity oil. The very high viscosity oil causes very low environmental impact, as much less lubricant is required and is considered biodegradable, with low-toxicity.

Résumé
EN DEPIT de l'environnement, de la sécurité et de l'hygiène, de grandes quantités d'huiles bitumineuses sont toujours utilisées pour la lubrification des coussinets de moulin dans les usines à canne. Depuis 1980, le personnel a été encouragé à trouver une solution à la contamination résultant de l'utilisation d'huiles bitumineuses et, en même temps, on a commencé à identifier les coûts associés à cette contamination. La technologie de lubrifiant a progressée et on a lancé de nouveaux produits afin de fournir une solution efficace aux problèmes de contamination. Ce papier montre l'évolution de la technologie d'huiles bitumineuses vers des huiles de très haute viscosité. Ces huiles de haute viscosité provoquent un impact environnemental très faible, sont utilisées en petites quantités et sont considérées comme biodégradables, avec une faible toxicité. Certains produits sont même considérés acceptables comme aliments.

Abstract
A PESAR de las presiones ambientales, de higiene y de seguridad para erradicar su uso, se siguen empleando grandes cantidades de aceites asfálticos para la lubricación de cojinetes de bronce en molinos de caña. Alrededor de 1980 se incentivó la búsqueda de soluciones a la contaminación causada por los aceites asfálticos y al mismo tiempo se comenzó a identificar los costos asociados al tema. La tecnología de lubricantes ha avanzado, introduciendo nuevos productos para proveer una solución efectiva al problema. Este trabajo trata sobre la evolución de la tecnología desde los aceites asfálticos hasta los aceites de muy alta viscosidad. Estos aceites causan un muy bajo impacto ambiental ores cantidades, y se consideran biodegradables, con baja toxicidad. Algunos de estos productos son considerados de grado alimenticio.
FERRITIC STAINLESS STEEL AISI 439
FOR THE SUGAR INDUSTRY

By

B. MEYER

ArcelorMittal Stainless Tubes Europe
Bruno.meyer@arcelormittal.com

Abstract

The objective of this technical paper is to identify the best material for tubes in evaporators, heaters and vacuum pans of cane sugar mills. Several cane and beet sugar processing plants were studied to analyse production conditions. The main considerations in the selection of tube materials were corrosion resistance and its effect on the durability of the tube, mechanical strength and its effect of the structure of the heat exchanger, thermal conductivity and its effect on the amount of energy required, surface finish and its effect on scaling and cleaning. Several materials were tested. AISI 439 ferritic stainless steel gave the best results.

Introduction

Today, major requirements at a sugar processing plant are to reduce equipment and energy costs. One of the main processes at a sugar plant is the evaporation system, which removes water from the cane juice. This system uses a lot of energy, and involves heat-transfer through tubes providing heat-transfer areas amounting to tens of thousands of square metres. The price of tubes directly affects the equipment-cost factor, while the quality of the installed tubes affects energy consumption.

This paper reports on the materials and procedures used for tubes in sugar processing plants all around the world and compares them with AISI 439 produced by Arcelor Mittal.

Analysis and results

The requirement

Figure 1 shows a schematic of a conventional tubular heat exchanger. Shells are usually made of carbon steel, as are the intermediate plates or tube-end plates. The tubes are either expansion-swaged into the plates to ensure mechanical closure and sealing or are held by O-ring seals. In the latter case, tube surface finish is a decisive factor in achieving leak-free sealing.

Fig. 1—A tubular heat exchanger.
Heat flow in a tube

The following equation describes heat transfer through a tube.

\[ R = \frac{e}{\lambda S} \]

where \( \lambda \) is thermal conductivity, \( S \) is heat transfer area and \( e \) is thickness.

To achieve the best thermal flow, there must be the best possible conductivity. The determining factors are:

- the film of water on the tubes (condensation)
- the thickness of the tubes
- the thickness of the scale (variable during the season)
- the conductivity of the material (\( \lambda \))

**How can these factors be improved?**

**Condensation**

This factor is difficult to reduce. By its very nature, heat transfer creates considerable condensation.

**Tube thickness**

Currently, thickness is usually from 1.5 to 2 mm depending on the material used. With ferritic grades of stainless steel, thicknesses are from 1.2 to 1.5 mm (depending on the length of the infrastructure of the evaporators) and from 1.5 to 2 mm for boilers.

**Scaling thickness**

Scale accumulation can have various causes:

*The surface finish of the tube’s internal wall*

Limiting the roughness of the internal surface of the tube to around 0.4 \( \mu \)m is a major factor in limiting scale accumulation when juice is flowing through a tube.

*The weld surface inside the tube*

Depending on the process used, there may be variable weld-bead build up and consequent variable surface smoothness.

For heat exchanger applications, ArcelorMittal uses laser welding for AISI 439 stainless steel (Figure 2), which ensures a highly consistent weld and a very smooth surface.

![Fig. 2—Micrography of a laser weld.](image)
Grade selection factors

The chemical composition of stainless steels

Table 1 compares two materials used in evaporator tubes.

Table 1—Chemical composition of AISI 304 and AISI 439.

Thermal conductivity

Table 2 shows the thermal conductivity of four tube materials. This parameter should be as high as possible, to ensure the least loss of heat. The higher this factor, the less the process consumes energy and the lower are the production costs. Copper seems the obvious choice but its price and the thicknesses used are a handicap. Carbon steel, which has been very widely used in the past, is now used less because of its poor corrosion resistance and the consequent need for thick gauges. Also, its rough surface finish encourages scaling. Austenitic stainless steels have poor thermal conductivity. AISI 439 ferritic stainless steel is the best technical and financial compromise.

<td>Ferritic stainless steel (AISI 439)</td>
<td>24</td>
</tr>
</tbody>
</table>

The physical properties of the materials:

Apart from thermal conductivity requirements, there are other material properties necessary for the evaporator tube application. Tubes:

- are held to the plates by swaging (require ease of deformation)
- pass through intermediate plates (require mechanical strength)
- are subjected to vibration (require mechanical strength)
- are subjected to chemical attack from sugar juice (require corrosion resistance)
- are cleaned by various procedures (require corrosion resistance)

Properties such as the coefficient of linear expansion, strength and corrosion resistance are important. Table 3 presents the physical properties of four different tube materials.

The coefficient of linear expansion has become more important as tubes have become longer. With grade AISI 439, the tubes stay straight at high temperature although tubes are mechanically terminated at both ends.

The absence of bending lessens the rubbing of tubes against each other and reduces premature wear in the intermediate-plate area.

The mechanical properties of AISI 439 are more favourable than those of carbon steel, allowing thinner gauges (i.e. reduced weight) and improved heat flow. In addition, AISI 439 shows excellent stability within the usual operational temperatures (Figure 3).

It can be seen that the mechanical characteristics are relatively stable at temperatures found in sugar processing (up to 200°C).

Fig 3—Changes in mechanical characteristics of grade AISI 439 depending on temperature (ArcelorMittal, 2009).

**Corrosion**

The corrosion properties of four tube materials are also shown in Table 3. The corrosion properties were rated by ArcelorMittal with a scale from 0 (poor corrosion resistance) to 100 (good resistance), based on the performance of the different materials in corrosion tests.

With the grade AISI 439, the corrosion resistance level is very good.

**Cleaning recommendations for AISI 439**

The cleaning of AISI 439 stainless steel tubes in evaporators was examined in tests with KEBO France. The best solution is to use a caustic solution and to clean by high pressure water or mechanical brushing.
Tube life

Since 1974, AISI 439 stainless steel tubes have been installed in many cane and beet sugar refineries in Europe, Africa and South East Asia. Their expected service life is about 20 years in evaporators\(^1\) and 30 years in vacuum pans\(^2\).

Financial factors

The absence of nickel in AISI 439’s chemical composition means that this grade is much less affected by speculation on the global money markets. Consequently, it is possible to:

- Offer a product with qualities identical or superior to AISI 304 or copper, at a lower price (10–15% less expensive than AISI 304, depending on the current nickel price);
- Offer longer price-validity periods, thanks to the relative stability of the price of chromium.

A financial analysis was conducted to compare the different types of tubes. The analysis was conducted over a 20 year operating cycle, corresponding to the expected life of the AISI 439 tubes.

For each material, an operating cost was determined. The operating cost included the purchase price of the tubes, the cost of cleaning (frequency, chemical products used, workforce required), and the lifespan of the tubes.

The results are shown in Figure 4.

---

![Operating cost based on 20 years](image_url)

Fig. 4—Calculated operating costs for different materials.

The overall cost of the AISI 439 stainless steel is lowest. AISI 304 has a higher purchase price. The cost of carbon steel is lower in terms of purchase price per tonne but the thicker gauge (2.5 mm instead of 1.2 mm, for example) reduces this direct-cost benefit.

---

\(^1\)AISI 439 tubes used in evaporators in Zambia (Zambia Sugar plc.), Philippines (Central Azucarera San Antonio), Guadeloupe (Garde), La Réunion (Bois Rouge, )

\(^2\)AISI 439 tubes used in vacuum pans in Mauritius (Savannah, Medine, F.U.E.L, FivesCail continuous vacuum pans), Colombia (Incauca), Philippines (Cotabato), Thailand (Mitr Phu).
Conclusions

This study showed that AISI 439 grade stainless steel has advantages in all the following key factors in a ‘sugar-processing evaporation’ application:

- Thermal conductivity (30% better than an austenitic grade)
- Surface finish
- Mechanical properties
- Corrosion resistance
- The price of the material

KEYWORDS: 439 stainless Steel, Ferritic,

Abstract
The objective of this technical paper is to identify the best material for tubes in evaporators, heaters and vacuum pans of cane sugar mills. Several cane and beet sugar processing plants were studied to analyse production conditions. The main considerations in the selection of tube materials were corrosion resistance and its effect on the durability of the tube, mechanical strength and its effect of the structure of the heat exchanger, thermal conductivity and its effect on the amount of energy required, surface finish and its effect on scaling and cleaning. Several materials were tested. AISI 439 ferritic stainless steel gave the best results.

Introduction
Today, major requirements at a sugar processing plant are to reduce equipment and energy costs. One of the main processes at a sugar plant is the evaporation system, which removes water from the cane juice. This system uses a lot of energy, and involves heat-transfer through tubes providing heat-transfer areas amounting to tens of thousands of square metres. The price of tubes directly affects the equipment-cost factor, while the quality of the installed tubes affects energy consumption.

This paper reports on the materials and procedures used for tubes in sugar processing plants all around the world and compares them with AISI 439 produced by Arcelor Mittal.

Analysis and results
The requirement
Figure 1 shows a schematic of a conventional tubular heat exchanger. Shells are usually made of carbon steel, as are the intermediate plates or tube-end plates. The tubes are either expansion-swaged into the plates to ensure mechanical closure and sealing or are held by O-ring seals. In the latter case, tube surface finish is a decisive factor in achieving leak-free sealing.

Fig. 1—A tubular heat exchanger.
Heat flow in a tube

The following equation describes heat transfer through a tube.

\[ R = \frac{e}{\lambda S} \]

where \( \lambda \) is thermal conductivity, \( S \) is heat transfer area and \( e \) is thickness.

To achieve the best thermal flow, there must be the best possible conductivity. The determining factors are:

- the film of water on the tubes (condensation)
- the thickness of the tubes
- the thickness of the scale (variable during the season)
- the conductivity of the material (\( \lambda \))

**How can these factors be improved?**

**Condensation**

This factor is difficult to reduce. By its very nature, heat transfer creates considerable condensation.

**Tube thickness**

Currently, thickness is usually from 1.5 to 2 mm depending on the material used. With ferritic grades of stainless steel, thicknesses are from 1.2 to 1.5 mm (depending on the length of the infrastructure of the evaporators) and from 1.5 to 2 mm for boilers.

**Scaling thickness**

Scale accumulation can have various causes:

- *The surface finish of the tube’s internal wall*

  Limiting the roughness of the internal surface of the tube to around 0.4 µm is a major factor in limiting scale accumulation when juice is flowing through a tube.

- *The weld surface inside the tube*

  Depending on the process used, there may be variable weld-bead build up and consequent variable surface smoothness.

For heat exchanger applications, ArcelorMittal uses laser welding for AISI 439 stainless steel (Figure 2), which ensures a highly consistent weld and a very smooth surface.

Fig 3—Changes in mechanical characteristics of grade AISI 439 depending on temperature (ArcelorMittal, 2009).

Corrosion

The corrosion properties of four tube materials are also shown in Table 3. The corrosion properties were rated by ArcelorMittal with a scale from 0 (poor corrosion resistance) to 100 (good resistance), based on the performance of the different materials in corrosion tests.

With the grade AISI 439, the corrosion resistance level is very good.

Cleaning recommendations for AISI 439

The cleaning of AISI 439 stainless steel tubes in evaporators was examined in tests with KEBO France. The best solution is to use a caustic solution and to clean by high pressure water or mechanical brushing.
Tube life

Since 1974, AISI 439 stainless steel tubes have been installed in many cane and beet sugar refineries in Europe, Africa and South East Asia. Their expected service life is about 20 years in evaporators\(^1\) and 30 years in vacuum pans\(^2\).

Financial factors

The absence of nickel in AISI 439’s chemical composition means that this grade is much less affected by speculation on the global money markets. Consequently, it is possible to:

- Offer a product with qualities identical or superior to AISI 304 or copper, at a lower price (10–15% less expensive than AISI 304, depending on the current nickel price);
- Offer longer price-validity periods, thanks to the relative stability of the price of chromium.

A financial analysis was conducted to compare the different types of tubes. The analysis was conducted over a 20 year operating cycle, corresponding to the expected life of the AISI 439 tubes.

For each material, an operating cost was determined. The operating cost included the purchase price of the tubes, the cost of cleaning (frequency, chemical products used, workforce required), and the lifespan of the tubes.

The results are shown in Figure 4.

![Operating cost based on 20 years](image)

The overall cost of the AISI 439 stainless steel is lowest. AISI 304 has a higher purchase price. The cost of carbon steel is lower in terms of purchase price per tonne but the thicker gauge (2.5 mm instead of 1.2 mm, for example) reduces this direct-cost benefit.

KEYWORDS: Water, Ethanol and Sugar Plants, Stillage.

Abstract

FRESH water is becoming one of the most important natural resources in the world. It is fundamental to human beings, for their own consumption, in industries, agricultural irrigation, electrical power production, and also in leisure and amusement activities. For industries, the availability of fresh water may represent a decisive factor in choosing the location of a new enterprise. In the case of Brazilian sugar and ethanol production, sugarcane culture traditionally does not use irrigation, which is an important factor from the environmental viewpoint, because it uses less fresh water, and avoids the entrainment of nutrients and agricultural toxic residues, and soil losses. In sugar and ethanol production, according to average data for the State of São Paulo in 2005, water consumption was 21 m$^3$ of water/tonne of sugarcane (180 litres per litre of ethanol), and intake of 1.83 m$^3$ of water/tonne of sugarcane (nearly 22 litres per litre of ethanol). The increasing demands of fresh water consumption and the shortage of this resource on a worldwide level is a concern to several sectors of society, as they are becoming more critical, demanding more responsible attitudes from companies, while the latter endeavour to follow a sustainable development policy to consolidate their companies and their products.

Introduction

Fresh water is a very precious asset and, as time passes, it becomes scarcer. One cannot imagine life without water. In an industrial society, the need for intensive food production has accelerated the consumption of this resource. Associated with water consumption, large volumes of effluents are generated. The rational use of water has become a question of fundamental importance to the survival of humanity. Its turn, industry is a large water consumer.

For illustrative purposes, according to ABIQUI M, the Brazilian Chemical Association, the use of water in the beer industry is between 15 and 25 L/L beer; for gasoline manufacture, between 7 and 10 L/L gasoline; polyethylene around 231 L/kg polyethylene; paper pulp 300 to 800 L/kg paper pulp and fine paper 900 to 1000 L/kg paper. In the sugar and alcohol industry, water consumption has been reduced, as illustrated by the data in Table 1. Nevertheless, there is a large potential for reduction.

(1) Data from the State water resources plan (‘PERH - Plano Estadual de Recursos Hídricos’) 1994/95.
(2) CTC Survey (Sugar Cane Technology Center), 34 sugar mills in the State of São Paulo.
(3) UNICA/ CTC Survey – (‘CTC - Centro de Tecnologia Canavieira’) in 2005.
As will be demonstrated in the course of this paper, there is an enormous potential in the sugar and alcohol industry for changing from being a water importer to becoming a water exporter.

To get an idea of the production volumes involved in Brazil’s sugar and alcohol sector, according to DATAGRO, the 325 plants in operation in the 2006/07 season processed 427 million tonnes of sugarcane, which were cultivated in an area of 5.3 million hectares (8.8% of the arable area in Brazil), producing 18 million cubic metres of bioethanol and 31 million tonnes of sugar. For the production of these volumes of sugar and alcohol, it was necessary to take around 768 million cubic metres of water (1.8 m$^3$/t cane) and around 214 million cubic metres of stillage (12 m$^3$/m$^3$ ethanol) and 17 million tonnes of filter cake (40 kg/t cane) were generated.

**Technological options**

**Conventional mill**

A traditional sugar mill normally takes water from rivers, wells and/or reservoirs in the magnitude of 1.0 and 2.0 m$^3$ of water per tonne of sugar cane processed. When also considering the amount of water contained in the cane, which is typically 70% of the cane mass, then the total amount of water available is 2530 kg/tonne of cane (Figure 1).

![Figure 1—Water balance in a traditional mill.](image)

Water exits the factory with various products such as finished goods like sugar and ethanol, but also with the filter cake, bagasse (130.21 kg/t cane) and stillage (570.14 kg/t cane). The biggest quantity evaporates during cooling of condensing water (1052.00 kg/t cane) and cane washing, where applied, consumes 694.52 kg/t cane. There are other smaller quantities required for floor washing, restrooms, canteens, etc.)

**Self-contained mill**

An important step would be minimizing or even bringing the need for in-take water to zero and only utilise the water available with the cane; Measures to be implemented are to replace cane washing with dry cleaning. The water balance for a self-contained mill is shown in Figure 2.
By using vapours from the last effect of the evaporators and the vacuum pans for heating purposes (mixed juice heaters) the quantity of condensing water reduces from 1052.00 kg/t cane to 136 kg/t cane.

Water savings can also be made through improved design of the fermentation process. The alcohol content in the beer can be increased from 9.0 to 12.0 vol. % with newer designs. The process can be operated at lower temperatures (less than 30°C).

Less steam is required at the distillation columns and the stillage quantity reduces from 10.0 kg/L ethanol to 6.0 to 7.0 kg/L ethanol, which is 291.00 kg/t cane instead of 570.14 kg/t cane.

The spent wash, from the bottom of the rectification column, can be used in various sectors of the plant for cleaning equipment with good results.

**Water exporting mill**

The final step in water preservation is to move to water generation in the ‘Hydro Mill Plus’ (Figure 3).

The use of process steam and alcohol vapours from the rectification column as heating media in an energy optimised process should be considered. Resulting vapours would be sent to the juice concentrators for fermentation.

Concentrated stillage mixed with filter cake, boiler soot and ash with addition of other nutrients results in an ‘organomineral biofertiliser’ (BIOFOM). It contains 4.66 kg water/t cane.

The result of these measures allows the export of some 290.71 kg water/t cane, which is about one third of the water introduced with the cane.

Utmost extraction of energy contained in the various condensates contributes to the overall energy balance of the factory resulting finally in increased production of exportable electricity.
In summary, the following are required:
- Use of condensates as imbibition water;
- In preparation of mixed juice for fermentation, utilisation of energy from cooling the clarified juice (heat exchange), flash vapours and vapour condensates;
- Washing filter cake with condensate;
- Applying multi-effect juice evaporation with vapour bleeding for distillation and heating purposes;
- Exhaust condensate to be returned as feed water to the boilers, minimising heat losses;
- Utilising last vapours for mixed juice heating;
- Depending on the proportion of juice for ethanol and the quantity of molasses, there may be no need for pre-concentration of clarified juice for ethanol;
- Sugar boiling only with vapour;
- Utilising heat exchangers with condensates and/or vapours throughout the process;
- Producing a fermented beer with the highest possible alcohol content;
- Using vapours from juice or stillage evaporation in distillation;
- Concentrating stillage to 60% solids using vapours from juice evaporation and alcohol distillation;
- Drying stillage and mixing it with filter cake and boiler soot and ash to obtain ‘organomineral fertiliser (BIOFOM)’;
- Heat the beer for distillation with heat exchangers;
- Recovering of all condensates.
It is recognised that reused water will require pre-treatment and increased operating costs to achieve it.

Progress and conclusions

Dedini has taken an important step towards economic, social and environmental sustainability of the Biosugar and Bioethanol plants and, in 2008, has launched self-sufficient water mills and Biowater - water production mills. These plants are self-sufficient in water, and do not demand external supply from water sources. The water in sugarcane alone is sufficient to meet the requirements of the internal processes of the plant.

The further development of this concept is the optimisation of this technology, so that the Biosugar and Bioethanol mill saves water from sugarcane than it will use in the internal process, and will thus be in a position to export BIOWATER as excess water for industrial use.

MOTS-CLEFS: L'Eau, Production d'Éthanol et de Sucre.

Résumé

L'EAU douce est devenue une des plus importantes ressources naturelles dans le monde. Elle est fondamentale pour l'homme, pour leur propre consommation, dans les industries, l'irrigation agricole, la production de l'alimentation et de l'électricité et également dans les activités de loisirs et d'amusement. Pour les industries, la disponibilité de l'eau douce peut représenter un facteur décisif dans le choix de l'emplacement d'une nouvelle entreprise. Dans le cas de la production de sucre et d'éthanol au Brésil, la culture de la canne traditionnellement n'utilise pas d'irrigation, qui est un facteur important du point de vue environnemental, parce qu'elle utilise moins d'eau douce, évite l'entraînement de nutriments, de résidus toxiques agricoles et les pertes de sol. Dans la production de sucre et d'éthanol, conformément à la moyennes de données pour l'état de São Paulo en 2005, la consommation d'eau était 21 m³ d'eau par tonne de canne (180 litres par litre d'éthanol) et un apport de 1,83 m³ d'eau par tonne de canne (près de 22 litres par litre d'éthanol). Une demande croissante de la consommation d'eau fraîche et la pénurie de cette ressource à un niveau mondial sont des préoccupations pour plusieurs secteurs de la société. Devenant de plus en plus critiques, ces problèmes exigent des attitudes plus responsables par les entreprises, tout en faisant des efforts pour suivre une politique de développement durable afin de consolider leurs produits et leurs existences.

Plantas de Azúcar y Etanol, VInazas.

Resumen

El agua fresca se está convirtiendo en uno de los recursos naturales más importantes en el mundo. Es fundamental para los seres humanos, para su propio consumo, en industrias, irrigación agrícola, producción de energía eléctrica, y también para actividades de recreación. Para las industrias, la disponibilidad de agua fresca puede representar un factor decisivo en la escogencia de la ubicación de una nueva planta. En el caso de la producción brasileña de azúcar y etanol, el cultivo tradicional no usa irrigación, lo cual es un factor importante desde el punto de vista ambiental debido a que usa menos agua fresca y evita el arrastre de nutrientes y residuos agrícolas tóxicos así como las pérdidas de suelo. En la producción de azúcar y etanol, de acuerdo a datos promedio para el Estado de São Paulo en 2005, el consumo de agua fue de 21 m$^3$ de agua/tonelada de caña (180 litros por litro de etanol), y un gasto de 1.83 m$^3$ de agua/tonelada de caña (aproximadamente 22 litros por litro de etanol). La creciente demanda de consumo de agua fresca y la escasez de este recurso a nivel mundial son una preocupación para varios sectores de la sociedad, en la medida que asumen una posición crítica, demandando más actitudes responsables por parte de las compañías siguiendo una política de desarrollo sostenible para consolidar sus empresas y sus productos.
ENERGY CYCLE IN CANE SUGAR MILLS: CONTROL AND OPTIMISATION

KEYWORDS: Cane Sugar Mill, Control, Optimisation, Energy Cycle.

Abstract

Energy has become one of the most sensitive costs in industry. Cane sugar production is no exception. Real time energy control systems (RETEC) are the ideal tools for cutting down generation and production costs, and also preventing downtime and expensive repair jobs, improving savings. Information so obtained can be used for predictive maintenance purposes. When the energy control model was fed with real time data (standard analysis available in the mill), information was processed instantly, showing steam generation and consumption data, the whole energy cycle. As the model improved, it gradually became a guideline for controlling the process, resulting in lower incidence of low steam pressure and improved sugar production processes. On the equipment side, analysis allowed modifications and tuning on the run. The system also enhanced training of operators and engineers. Obtained benefits are: developed energy control system helped achieve more stable milling, as a better quality of steam was generated; energy specific consumption reduced from 0.810 to 0.461 tonnes of steam per tonne of cane; auxiliary fuel was unnecessary; Savings obtained were almost 10% of sugar price; less stressed boiler operation resulted in reduced amount and intensity of repairs, generating a second stage benefit; developed model defined some new energy indexes, for better understanding and control of energy generation. The stack became clear as combustion improved, reducing emissions of CO₂ and CO. A factory can adopt RETEC in its own way and obtain significant savings in fuel and repairs and less air pollution.

Introduction

Energy costs have increased in recent years as a result of global warming, oil prices and environmental regulations. Bagasse is the preferred fuel option, reducing fuel costs for a mill.

Today many applications are available to add value to sugarcane processing. Trash and tops are also burned. Diversifying bagasse utilisation is becoming a new profitable business.

With green harvesting and proper milling of trash and other crop residues, more bagasse can be processed for other applications and less greenhouse gases are introduced to the atmosphere. The Kyoto Protocol has established conditions for this ‘green’ market.

This paper proposes five systems and technologies for improving energy efficiency.

Systems and technologies for improving energy efficiency

Combustion adjustment

The way to improve a boiler’s performance is to set all air and fuel controls in such a way that every dampener and valve responds to control with precision and repeatability to allow the best
possible operation, keeping combustion at its best efficiency at all possible generating loads. Flue gas analysers are used to determine the positions of air dampeners and fuel valves.

**Very low excess air combustion based on CO/O₂ control**

As bagasse and residuals vary in their oxygen demand, combustion control based on fuel characterisation does not allow very low excess air operation.

CO increases as oxygen content in flue gases diminishes. High CO content results in a significant energy loss as only 72% of carbon energy is liberated. O₂ and CO measurement are the basis of combustion control. Figure 1 shows an energy relation between O₂ and CO content in flue gases.

Very low excess air operation requires intelligent online O₂ and CO analysers to control combustion of fuels with different and variable air demand. Figure 2 shows the location of analysers inside a boiler.

![Fig. 1—CO, excess air and heat losses.](image)

![Fig. 2—O₂ and CO analysers inside a boiler.](image)
Post combustion process

Traditional processes burn up to 70% of pith, as small particles cannot be retained in the boiler’s furnace for enough time to be completely burned. Energy losses are high. Pith has 19.2 MJ/kg and long fibre 15.1 MJ/kg. As result of incomplete combustion, average caloric value drops from 17.4 to 14.2 MJ/kg.

Incinerating pith in a Heavy Fuel Oil (HFO) pilot flame increases the caloric value from 14.2 MJ/kg to 16.7 MJ/kg, providing 17.9% of additional heat.

Thermic reforming of bagasse

With properly set fluidised bed air, bagasse burning temperature can rise enough to convert lineal carbon chains into benzene rings, liberating some hydrogen atoms that burn at a much higher temperature inside the boiler’s furnace, increasing steam generating speed rate and capacity. It is shown as a temperature jump of about 300°C. The boiler’s efficiency is then improved.

Real Time Control (RETEC).

The RETEC operates with four different fuels: solid, viscous liquids, light liquids and gas; continuously reducing O₂ when steam consumption is stable until the CO maximum limit is achieved. Very low excess air operation, post combustion and reforming are integrated to RETEC.

The RETEC includes control algorithms for Post combustion and Thermic reforming processes.

The RETEC monitors and controls each boiler and the equipment using steam, advises when equipment requires maintenance before failure, preventing undesirable shut downs.

Analyses conducted once a month:
- Caloric values and elementary analysis of bagasse, large fibre and pith, other vegetable residue,
- Caloric value and elementary analysis of auxiliary fuel,
- Isokinetic analysis of flue gases

Analyses conducted each hour and required process data:
- Bagasse moisture content,
- Flue gases composition, and
- Fibre exiting factory (bagasse and/or fibre and/or pith).

Real time data:
- Cane entering mills;
- Flow, pressure and temperature fed to each boiler of generated steam and water; auxiliary fuel and air (primary and secondary);
- Flow, pressure and temperature of steam in: main; to each turbine; to juice heaters, pans, crystallisers, centrifuges, sugar dryers and others;
- Flow of sugar exiting dryers.

Energy ratios obtained from collected data are the basis of efficiency analysis and can explain cost variations:

CenM: Energy per milled cane, [kJ/tonne].
CenAz: Energy per produced sugar, [kJ/tonne].
Cesp: Generated steam per milled cane, [steam tonne/cane tonne].
EnVa: Fraction of energy converted to steam, [%].
VaAz: Generated steam per produced sugar, [steam tonne/sugar tonne].
CoM: Auxiliary fuel per milled cane, [litres/cane tonne].
CoAz: Auxiliary fuel per produced sugar, [litres/sugar tonne].

These ratios are to be analysis guidelines, either solving problems or improving processes, and helpful in understanding energy costs of each alternative.

Using an Energy Balance Board, engineers and operators can see at a glance energy inputs (fuels) and outputs (steam and losses) per source, and bagasse surplus (fibre or fibre plus pith). An example computer screen board is shown in Figure 3.

Using a Mass Balance Board, all fluids entering and exiting boilers, steam flow balance can be observed (Figure 4).
An application of the energy efficiency techniques

In Santa Clara cane sugar mill after Combustion Adjustment and Post Combustion System, excess air reduced to 20% (Figure 5) and achieved 94% pith burning. Efficiency improved dramatically.
Because of the increased efficiency, a bagasse surplus was achieved. Benefits of excess bagasse included starting the milling season with no auxiliary fuel, selling electricity to the grid; and providing bagasse to new biotechnology processes to obtain cellulose without chemicals.

MOTS-CLEFS: Moulins, Contrôle, Optimisation, Cycle d'Énergie.

Résumé
L'ÉNERGIE est devenue un des coûts industriels importants et la production du sucre ne fait pas exception à la règle. Les systèmes de contrôle d'énergie en temps réel (RETEC) sont des outils pour réduire les coûts de génération et de production, et également pour éviter les interruptions de service et les réparations onéreuses, amélioration ainsi les économies. Les informations obtenues peuvent être utilisées à des fins de maintenance prédictive. Lorsque le modèle de contrôle d'énergie fonctionne avec des données en temps réel (analyses standards de l'usine), les informations sont traitées instantanément, montrant des données de production et la consommation de vapeur, donc le cycle entier d'énergie. Comme le modèle s'améliore, il permet le contrôle du processus: cela réduit les incidences de vapeur de basse pression et la production du sucre est meilleure. Pour l'équipement, l'analyse a permis des modifications. Le système a également amélioré la formation des opérateurs et ingénieurs. Les avantages obtenus sont les suivants: Un bon contrôle d'énergie, une opération stable aux moulins et une meilleure qualité de vapeur générée; la consommation spécifique d'énergie réduite de 0.810 à 0.461 tonnes de vapeur par tonne de canne; pas de carburant auxiliaire; économies de presque 10% du prix du sucre; chaudières moins stressées réduisant l'intensité des réparations, donc un deuxième avantage; le modèle a défini certains nouveaux indices d'énergie, pour mieux comprendre et contrôler la production d'énergie.; les gaz de cheminée sont devenus clairs grâce à la combustion améliorée, réduisant les émissions de CO₂ et CO. Une usine utilisant le RETEC peut obtenir d'importantes économies de carburant et de réparations et peut réduire la pollution de l'air.

PALABRAS CLAVE: Ingenio Azucarero, Control, Optimización, Ciclo Energético.

Resumen

La energía se ha convertido en uno de los costos más sensibles en la industria. La producción de azúcar de caña no es la excepción. Los sistemas de control de energía en tiempo real (RETEC) son las herramientas ideales para recortar los costos de generación y producción, y también para prevenir paradas y costosos trabajos de reparación, mejorando el ahorro. La información obtenida puede ser usada para fines de mantenimiento predictivo. Cuando el modelo de control de energía se alimentó con datos de tiempo real (análisis estándar disponible en el ingenio), la información se procesó instantáneamente, mostrando datos de generación de vapor y consumo, el ciclo energético total. En la medida que el modelo se mejoró, se convirtió en una guía para el control del proceso, resultando en menor incidencia de eventos de baja presión y procesos mejorados de producción de azúcar. Por el lado del equipo, el análisis permitió modificaciones y sintonía sobre la marcha. El sistema permitió el mejoramiento del entrenamiento de operarios e ingenieros. Los beneficios obtenidos fueron: el sistema desarrollado para control de energía contribuyó a obtener una molienda más estable con una mejor calidad del vapor generado; el consumo específico de energía se redujo de 0.810 a 0.461 toneladas de vapor por tonelada de caña: no fue necesario el consumo de combustible auxiliar; los ahorros alcanzados fueron casi del 10% del precio del azúcar; la operación menos esforzada de las calderas representó menor cantidad e intensidad de reparaciones generando beneficios de segundo nivel; el modelo desarrollado definió algunos nuevos índices energéticos, para una mejor comprensión y control de la generación de energía; en la medida que la combustión mejoró se redujeron las emisiones de CO\textsubscript{2} y CO. Una fábrica puede adoptar RETEC a su manera y obtener ahorros significativos en combustibles y reparaciones con menor contaminación del aire.
GREEN CANE IMPACT ON SUGAR PROCESSING: ISSCT PROCESS WORKSHOP 2008

By

R.J. STEINDL

Queensland University of Technology, Brisbane, Australia
r.steindl@qut.edu.au

KEYWORDS: Green Cane, Trash, Extraneous Matter, Losses, Workshop.

Abstract

The ISSCT Process Section workshop held in Réunion 20–23 October 2008 was attended by 51 delegates from 10 countries. The theme was Green cane impact on sugar processing. The workshop provided a valuable and timely opportunity to review and discuss the impact on factory operations and performance from a green cane supply that could include significant levels of trash. It was particularly relevant to those mills that were considering options to boost their biomass intake for increased co-generation capacity. Several of the speakers related their experiences with processing ‘whole of crop’ cane supplies through the factory. Speakers detailed the problems and increased losses that were incurred when processing cane with high trash levels. The consensus of the delegates was that the best scenario would involve a cane-cleaning plant at the factory so that only clean cane would be processed through the factory. The forum recommended that more research was required to address the issues of increased impurities in the process streams associated with high trash levels. Site visits to the two factories and a cane-delivery station were arranged as part of the workshop.

Introduction

The Process Section Workshop was held at the Hotel Mercure Créolia, Saint Denis, Réunion from 19 to 23 October 2008 and was hosted by CERF (Centre d’Essai de Recherche et de Formation).

The theme for the workshop was Green cane impact on sugar processing. The workshop provided a valuable and timely opportunity to review and discuss the impact on factory operations and performance from a green cane supply that could include significant levels of trash. It was particularly relevant to those mills that were considering options to boost their biomass intake for increased co-generation capacity.

It was attended by 51 delegates representing 10 countries including some delegates who had travelled from as far away as Brazil, Nicaragua and Japan. All of the organisational matters for the workshop were handled extremely well by CERF and, in particular, by Laurent Corcodel and Carmille Roussel.

Opening session

The opening session of the workshop included presentations by Jean-François Moser, President of CERF, and Laurent Corcodel.

Moser’s presentation provided an insight into the sugar industry in Réunion and its significant importance to the local economy. He described how infrastructure had been developed to allow water collected on the eastern side of the island to be transferred to the western side to irrigate the crops. A modernisation program had resulted in the closure of all but two mills. Cogeneration plants using both bagasse and coal were established at each factory and both had been upgraded to handle the full crop. Cane delivery stations were developed in several areas (mostly on old mill
sites) to allow farmers to deliver the cane to local collection points. Each load is sampled on arrival before being transferred to semi-trailers for transport to one of the mills.

Corcodel reviewed the performance of the cane sugar industry in Réunion since 1984. Some of the important changes to the industry have included:

- The sugar industry in Réunion was consolidated to two factories (Le Gol and Bois Rouge), each processing about 1 000 000 t per year between July and December and producing 100 000 t of raw sugar each;
- The cane crop comprises two main varieties: R570 (high trash) and R579 (self trashing);
- Each field can be ratooned up to nine times;
- All cane is harvested green and much of the trash is included with the cane supplied to the factories;
- Cane is delivered to one of 12 transfer stations or directly to one of the two factories;
- Only 10–30% is mechanically harvested;
- The true purity of the mixed juice ranges between 86 and 90;
- Ash % brix in mixed juice trends down from about 5% at the start of the milling season in July to less than 4% in December;
- Reducing sugars % brix range from about 3% in July to 3.5 to 4.0 in December; and
- Plant reliability has improved significantly over the 20-year period from about 12% downtime to an average of 4% breakdown rate in 2007.

Technical sessions

Session 1—Sugar losses in storage: green cane versus burnt cane

_Determination of sucrose loss in storage of green billet cane (Michael Saska, Stuart Goudeau, Irina Dinu and Mike Marquette. Presented by Rod Steindl)_

Tests measured sucrose loss during 24-hour storage of green billet cane. Several tests were also organised in a sugar factory where, in addition to the storage on the ground, some damage or loss of cane may be expected from handling the cane with front-end loaders. The mass loss of sucrose in storage of green billets of 24 hours or less was adequately represented by a linear model based on the length of time (hours) within three temperature ranges: <17°C, 17–27°C and >27°C, representing cold, moderate and warm conditions, respectively. The predicted relative sucrose change (tonnes of sucrose lost or gained for each 100 tonnes of initial sucrose per hour) in the three temperature ranges are 0.022 (gain), –0.017 (loss) and –0.323 (loss), respectively.

An analogous model applied to the cane weight loss during storage of green billet cane. The predicted relative cane weight loss (tonnes of cane per 100 tonnes initial per hour) in the three temperature ranges <17°C, 17–27°C and >27°C was 0.02, 0.02 and 0.26, respectively. The six factory cane yard tests broadly agreed with the conclusions from the pilot storage tests done at Audubon Sugar Institute, indicating that the cane and sucrose mass losses from handling the cane in the cane yard were relatively small compared with the losses from the enzymatic and microbial action within the stored cane.

It was uncertain whether the small sucrose gain predicted by their model for cold storage of green billets was related to enhanced activity of sucrose synthesising enzymes, or suppressed invertase activity in post-harvest cane as a reaction to low temperatures, or was an artefact of the experimental technique.

The financial impact of the sucrose loss predicted for storage of cane at high temperatures
(3.2% in 10 hours at over 27°C) is serious, and consideration should be given to improving through their design the natural or forced ventilation of cane wagons and piles, and to the scheduling of harvest and storage of cane.

### Cane deterioration: Comparison green cane versus burnt cane – Researching a green cane deterioration indicator (Camille Roussel, Arnaud Petit and Laurent Corcodel)

During 1990–1995, the Process Department of CERF compared cane deterioration of whole cane and burnt cane to find a criterion to gauge cane deterioration. Those studies showed that ethanol was a good criterion in burnt cane, but not in green cane. As cane is no longer burnt in Réunion, deterioration trials undertaken since 1995 have dealt only with green cane. Decreases in weight, sucrose content and purity mean that growers lose about €1/tonne of cane per day from post-harvest delays.

Biochemical measurements were undertaken during deterioration trials in 2005 and 2007. In 2005, aconitic acid ratio appeared to be a good indicator of deterioration. In 2007, other deterioration criteria were tested using chromatography (HPIC and HPLC) to measure organic acids, polyols, and amino acids. Of particular interest was 1-kestose, which increased linearly with post-harvest delays. Results showed also that citrate, alanine, proline, cysteine, isoleucine, and leucine correlated well with the post-harvest delay.

### NIR evaluation of the post-harvest deterioration of sugarcane quality (M. Ueno, E. Taira, Y. Kawamitsu, K. Kikuchi and Y. Komiya)

All Japanese sugarcane is harvested green, because burnt cane is not accepted by the mills. The trash is transported with the cane and separated at the factory. About 60% of the sugarcane is harvested manually. Mechanical harvesters include small machines that load billets into bags on the back of the harvester through to large machines that load directly into trucks. Manual harvesting requires considerable labour, is hard work, and 1–3 weeks is required to load the transport truck. Deterioration that occurs in this period results in sugar losses and deteriorated cane affects the milling process and lowers the efficiency of the mill.

To measure the quality of sugarcane for payment, a 5 kg sample of cane is collected by the core sampler from every vehicle at the entrance of each factory. These samples are fibrated and a near infrared spectrometer (NIR) is used to measure the pol in cane (PIC) as a quality index. If the mill staff can quickly and easily know the degree of deterioration, the information becomes very useful for process control. An NIR calibration equation to measure the ethanol content was investigated as an index of deterioration of cane. VIS/NIR absorbance spectra (570 to 1848 nm) were measured using an NIR instrument (Foss InfraXact), and the calibration equation for ethanol was developed by partial least squares (PLS) regression analysis. As a result of PLS regression, the values of $R^2$, standard error of calibration (SEC), and standard error of cross validation (SECV) were 0.908, 0.09%, and 0.11%, respectively. The developed calibration equation successfully measured the ethanol concentration of deteriorated cane with simultaneous measurement of PIC. Ethanol concentration was examined by the developed calibration equation for 0, 21, 28 and 36 days after harvesting. Although ethanol was not detected in fresh cane, ethanol content increased dramatically as the delay increased. Ethanol content of all sugarcane samples of 11 sugar mills in Okinawa Prefecture were calculated by the developed calibration equation. About 5% of all samples showed more than 1% ethanol content. It was concluded that the NIR method gave information of the sugarcane deterioration to support the operation of all sugar mills in Okinawa without any chemicals or apparatus.

### Session 2—Mill de-trashing equipment: Design, operation, optimisation

**Development of a prototype factory-based trash separation plant (Phil Hobson. Presented by Rod Steindl)**

Several sugarcane industries are actively seeking an efficient way of bringing the biomass to
the factory to increase the co-generation potential. As well, some countries have or are about to ban the burning of cane. This has increased the interest in trash separation plants located either at the factory or in centralised locations closer to the cane supply areas. This presentation discussed investigations by Sugar Research Institute (SRI) to separate the trash at the factory.

Trash left in the field after harvest constitutes a large, currently untapped source of available biomass. Harvesting the whole cane plant and subsequently separating the trash from the cane stalk in the cane supply entering the factory could potentially double the amount of fuel available for power generation. The Queensland Treasury (Office of Energy), Stanwell Corporation Ltd, and the NSW Sugar Milling Co-operative funded the development by SRI of a commercial scale prototype cane-cleaning plant. Funding by the Australian Greenhouse Office assisted with the installation of a fully commercial cane-cleaning plant at Condong Mill. Preliminary trials carried out at SRI in 2000 provided much of the basic information for the design of the prototype cleaning plant. Construction at Condong Mill of the prototype trash separation plant was completed by, and initial commissioning began, in early December 2000. Extensive testing and further development of the plant was continued through 2001. The performance testing program showed that the plant was able to achieve high levels of trash separation at low levels of cane loss (less than 1%), at commercial pour rates. Trials with an industry standard shredder indicated that the shredder could reduce the trash to approximate bagasse like consistency, but with a power requirement of about 12 kW/t of trash per hour. Conventional cyclone technology removed at least 99% of the air-borne trash that flowed from the cleaning chamber.

Cane field residues as supplementary boiler fuel (Kassiap Deepchand and A.F. Lau)

Cane field residues (CFR) consist of the dry cane trash and the green leaves left in the field after harvest and last for about 6 months of the year (June to Nov/Dec). CFR confers a certain number of agronomic advantages such as soil moisture conservation in dry areas, control of soil erosion and maintenance of soil organic matter, but it also imparts a number of disadvantages in that it harbours pests and affects cane re-growth especially in areas with high rainfall. Investment was made in a dry cane-cleaning plant with a capacity of 150 tonnes of whole cane per hour and operated next to a sugar factory. The concept was to reduce sugar loss in bagasse and minimise sugar manufacture difficulties due to the CFR adhering/brought together with cane while, at the same time, targeting the long term additional CFR recovery to increase fuel availability for power plants and thus displace coal. Difficulties were encountered in continuous operation of the plant due to a lack of a constant flow of cane and of an inefficient separation of the trash from the long cane. Subsequently, some modifications were made to the plant, but it could not run beyond 90 t/h, although an improvement in the separation process was noted.

An alternative approach of using CFR as an additional fuel to bagasse is being looked into, and the objective is to increase and extend electricity generation period from these resources by displacing coal. The total amount of CFR (which normally contains around 25% moisture depending on climatic conditions prevailing at harvest and in the subsequent days) is around 15 t/ha. The project aims to collect up to 50% of the CFR from the fields under ratoon crop and almost all the CFR from fields which are to be replanted after 7–8 year crop cycle. Whereas equipment for collection (windrowing and baling – square or cylindrical) and transport are available for industrial applications, those for debaling/shredding have still to be identified or developed for such applications. The emphasis on current R&D has thus been focused on this particular aspect. Analysis of naturally dried CFR shows that it has a moisture content of 9–11%. Its caloric value at 10% moisture is about 15 MJ/kg. Industrial-scale trials using existing conventional mills have shown that such naturally dried CFR can conveniently be burnt in existing boilers. However, in view of the fact that the naturally dried CFR has a relatively higher ash content (8%) compared to bagasse (2.5%), it is proposed that it will, after preparation, be mixed with bagasse in a proportion of up to 25%.
Preliminary estimates indicate that, if 30% of the CFR is collected, prepared and mixed with bagasse from an annual cane production of 5.0 million tonnes, it can potentially generate 250 GWh of electricity. This will replace 150 000 t of coal and avoid the generation of 400 000 t of CO$_2$ and 30 000 t of coal ash. In monetary terms, the foreign exchange saved will be US$30 million assuming a projected future coal price of US$200/t.

Session 3—Effects of trash on factory operations

Ledesma’s green cane project (Mario Rostagno, Carlos Bada, Federico Knauff, Miguel Ullivarrí, Juan Carlos Mirande and Rodolfo Dofonzo. Presented by Rod Steindl)

Ledesma, a cane sugar factory in Argentina, has recently seen a significant increase in mechanised harvesting of cane. In 2007, 85% of the cane was harvested mechanically. The progression to mechanised harvesting has seen the proportion of green cane delivered to the factory increase from 11% of the crop in 2002 to more than 50% in 2005. The proportion of green cane has remained static in the following years. As part of their effort to maintain factory efficiency and product quality, factory staff have undertaken a number of investigations to quantify the effects of the increased proportion of green cane in the raw sugar factory, refinery, distillery and on their energy production. During the 2005 season, trials were undertaken to determine the green cane effect on milling capacity, sugar losses and bagasse moisture. The results can be summarised as follows:

- Final bagasse moisture increased by 7.3%;
- There was an increased frequency in chute blockages along the milling tandem due to the extra trash;
- Pol loss in bagasse increased from 0.64% to 0.70%;
- Throughput capacity of the milling tandems decreased by 7%;
- Although the molasses % cane remained relatively steady at about 3.66, pol loss in molasses increased by 8%;
- Raw sugar colour increased by 10%; and
- Because of the higher starch content of the trash, the consumption of $\alpha$-amylase increased from 40 kg/day to 120 kg/day.

In the refinery, the consumption of chemicals such as decolorant, phosphoric acid and filter aid increased significantly. In the distillery, the total production of ethanol increased by 5.8% as a result of the higher sugar content in the molasses. However, the efficiency decreased to 79% because of the problems associated with the higher ash levels in the fermentation broth. The additional bagasse for combustion allowed the factory to reduce its consumption of supplementary fuel (natural gas).

New laws in São Paulo state and a new agreement between the state and the mills have started a green revolution in the Brazil sugarcane business. By 2014, the cane fields where the harvesters will be able to operate must be harvested as green cane. By 2017, all the cane fields will be harvested as green cane and cane fires will be eliminated.

This green revolution impacts on both the growing sector and the mills. The crop of green cane has a strong impact in the agriculture and industry areas. The challenges for the agricultural sector will include:

- Varieties that withstand the impact of cutter blades on harvesters;
- Effects of trash blanketing on ratooning ability and pest activity;
- Increasing the row spacing to 1.5 m;
- Changes to farm implements to better cultivate the soil and apply fertiliser through the trash blanket; and
• Adoption of 100% mechanical harvesting.

The impact on the factory processes will include:
• Increased impurity loading from the higher extraneous matter in the cane supply;
• Reduced milling throughput;
• Increased dirt loading in the bagasse going to the boilers;
• Potential for lower sugar quality;
• Higher costs for maintenance and chemicals; and
• Greater sugar losses in the mud and bagasse.

The option being favoured is to transport the cane and trash to the factory and separate the trash through dry cleaning plants. The cleaning plant is based on pneumatic separation of the trash followed by cleaning of the trash to remove soil and then shredding of the trash. However, the cane cleaning technology was still only in its infancy.

Clarification properties of stalk and trash tissues from U.S. sugarcane varieties (Gillian Eggleston and Michael Grisham. Presented by Barbara Muir)

The effect of the U.S. change from burnt to unburnt or green sugarcane harvesting on processing has not been fully characterised. Furthermore, the current trend to investigate sugarcane trash (leaves and tops) as biomass for the production of bioproducts has made the processing quality of trash more important.

Sugarcane whole-stalks were harvested from the first ratoon crop of five commercial sugarcane varieties (LCP85-384, HoCP96-540, L97-128, L99-226, and L99-233) with varying yield and harvest characteristics. Four replicated tissue samples of brown, dry leaves (BL), green leaves (GL), growing point region (GPR) or apical internodes, and stalk (S), were separated. Juice from each tissue type was clarified following a hot lime clarification process (operated by most U.S. factories). Only GPR and GL juices foamed on heating and followed the normal settling behaviour of global sugarcane juice, although GL was markedly slower than GPR. GPR juice was critical to clarification. S juice tended to ‘thin out’ rather than follow normal settling, and much more upward motion of flocs was observed. Most varietal variation in settling and clarified juice characteristics occurred for GL.

The quality and not the quantity of impurities in the different tissues affected the volume of mud produced. Tissue juice brix (% dissolved solids) had no relationship with the amount of mud produced. After 30 min settling, mud volume per unit tissue juice brix varied markedly among the tissues (S=1.09, BL=11.3, GPR=3.0, and GL=3.1 mL/brix). Heat transfer properties of tissue juice and CJ were described. Clarification was unable to remove all BL cellulosic particles. GL and BL increased colour, turbidity and suspended particles in the clarified juice with BL worse than GL. This would cause difficulty downstream in the factory boiling house and make the future attainment of Very Low Colour (VLC) raw sugar more difficult. Strategies to reduce the delivery of green and, especially, brown leaves to the factory need to be identified and implemented urgently.

The effects of extraneous matter on factory operations (Rod Steindl)

Several separate investigations that considered the effects of extraneous matter (tops, trash, roots and soil) on the composition of mixed juice and the downstream processes were summarised. The objectives in each case were to quantify the effects of green cane harvesting with increased levels of trash on factory throughput and sugar quality so that economic models could be developed. Although different methodologies were used, the outcomes were similar.

In the first investigation, estimates were determined for the composition of a cane stalk by separating the stalk into clean cane, trash, tops and top leaf components. The averaged values for a number of varieties were:
• Clean cane 81.2%;
• Trash 7.1%;
• Tops 6.1%; and
• Top leaf 5.6%.

It must be accepted that these quantities depend on many factors and can only be used as a guide.

In laboratory trials, composite samples of clean cane and added tops and trash were milled and samples of mixed juice and clarified juice were analysed. As expected, the samples of ‘dirty’ cane had higher levels of non-sugars, ash and colour. In another series of trials conducted at a factory, paired tests of dirty and clean cane were milled and the factory process streams were analysed to provide data to determine the economic impact of the trash content. Trash levels were up to 15% of the cane supply. Statistically significant effects included reductions in the sugar content for cane payment, crushing rates and syrup quality and an increase in the production of final molasses.

In a further series of factory trials, harvesting operations were organised into clean and dirty cane periods of up to 6 days each and the effects measured in the factory operations. The main effects were statistically significant increases in the starch, phosphorus and mud solids content of juice from dirty cane. The filter cake % cane increased by up to 37% and the pol loss in cake % pol in cane increased by 16%. The A massecuite quantity dropped marginally while the B massecuite % cane increased by 7% and the final molasses % cane increased by about 20%.

Interestingly, there was no statistically significant difference in the quality of the sugar produced. It should be noted that the factories involved in these trials only produced raw sugar with a typical pol of 98.8 to 99.0.

**Improving the exhaustion of C-sugar magma through on-line measurements of the crystal content (Teddy Libelle, Michael Benne, Bridgitte Grondin-Perez and Jean-Pierre Chabriat)**

On-line measurements and supervision tools become essential when trying to optimise the boiling crystallisation process and limit the impact of the variability of incoming feed streams. Here, on-line measurement of the crystal contents of the sugar magma (massecuite) was based simply on the comparison between the brix of the massecuite (BxMC) and the brix of the mother liquor (BxML). Thus, its implementation was simplified due to the fact that both these types of sensors are often present at industrial sites. The complete mass of crystals in the C-sugar magma, Cm, depends on the crystal contents. From industrial measurements collected at Bois Rouge sugar mill (Réunion), we showed that Cm can increase, decrease or be stable during a boiling crystallisation. When analysing the evolution of Cm, we proposed some methods to optimise the exhaustion of C-sugar magma.

**Impact of trash and high fibre cane on sugar recovery: CERF preliminary results (Laurent Corcodel, Camille Roussel, Eslyne Lemoine, Audrey Thong Chane and Laurent Barau)**

The effect of cane composition on sugar processing has been discussed worldwide. With the development of high-fibre cane, an investigation into the high-fibre effects on sugar processing was considered important. A high-fibre, elite variety was at the end of the CERF breeding program, and the effect of this variety on the sugar milling processes had to be investigated. Firstly, the theoretical impact in sugar plants (sugar losses and milling capacity) was described and secondly, laboratory extractability trials were done. Those experiments were conducted jointly between the CERF breeding department and the sugar processing department.

Different CERF cane varieties were pressed at different pressures (50–250 bar) by a hydraulic press to calculate their extraction rate. Results showed significant differences between
those varieties which could be explained by their pith/fibre ratio. Those indicators will be studied further with the aim to integrate them into the CERF breeding program to select high-fibre clones with a good milling ability.

**Factory trials to determine the effect of green trash on downstream processing (Barbara Muir, Gillian Eggleston and Bryan Barker)**

There is a worldwide shift to green cane from burnt cane harvesting. In South Africa 89% of the cane is still burnt and most of it is hand-cut. Some areas are changing to green cane harvesting due to environmental pressures, increasing labour costs and the current trend to investigate sugarcane trash as biomass for the production of bio-products. This paper reports on the effects of harvesting green billeted and/or whole-stalk sugarcane compared to burnt billeted and/or whole-stalk sugarcane at three South African mills that operate either a tandem mill or diffusers. Sufficient cane of each treatment was harvested and processed at each mill to purge the extraction plant of other cane. Trash tissues, shredded cane, juice and bagasse samples in the front end were collected and analysed. A bulk sample of mixed juice was then transported to the SMRI in Durban and further processed in the SMRI pilot plant to clarified juice, syrup, A massecuites, molasses and raw sugar.

Some of the differences reported include:
- There was a 6–10-fold increase in trash for mechanically harvested burnt and green cane over manually cut burnt cane;
- Cane and juice purities decreased with increasing trash content;
- RS/ash ratios in juice, syrup, massecuite and A molasses increased from burnt billets to green billets in some cases or were similar in other cases; and
- At one factory, there was a slight increase (~10%) in affined sugar colour while the samples from another factory showed a decrease of ~22% in affined sugar colour from burnt to green cane.

**Session 4—Whole crops**

**Whole crop harvesting and processing (Michael Saska and Nicolas Gil Zapata. Presented by Rod Steindl)**

This report presents results from tests done in 2006 in a Louisiana factory with harvesting and processing of the whole crop or ‘complete cane’ (stalk plus trash). The objective was to determine if there was any benefit if the whole crop was harvested green and transported to the factory and then to process the cane with or without the extraneous matter.

For complete cane (CC), the mill harvested green cane with the extractor turned off on the harvester, and the normal green cane (NC) was harvested with the fans on as usual. On December 15, 2006, 367 tonnes of CC were processed in about 4.5 hours at an average of 82 t/h. Sampling of normal cane as a reference could not be done on the same day, because cane delivery problems delayed the start of processing the cane. Sampling of the normal cane (NC) was therefore done on December 20 for a total of 7 hours. The mill operation was interrupted because of boiler problems for about 2 hours, about 2 hours into the test. Based on the information regarding the code and weight of the wagons that arrived at the mill, an estimated 974 tonnes of cane were processed within the period of the test, for an average rate of 139 t/h. The code, weight, and core lab analysis of the cane wagons delivered during each test were averaged and compared with the analysis of prepared cane taken at regular intervals during the test. Because of the time difference between the two tests, the variations reported here between NC and CC may be due in part to other factors than the trash content, e.g. cane and processing conditions, etc. Freezing temperatures at the start of December affected the cane quality, and the four-day delay between the tests probably resulted in further deterioration of the freeze damaged cane and skewed the comparison between complete and normal cane.
No problems were noted when processing whole green cane although the mill operated well below capacity at the time of both tests for other reasons.

An Excel model was used to estimate the economic viability of harvesting, transporting and processing cane with a variable amount of extraneous matter, including the case of whole crop processing, with co-generation with the extra bagasse. Other factors included in the model were the cane composition, sugar content and price, extra cane yield above the 'normal cane' case, the power generation efficiency and sale price, and harvester fuel requirements, with the extractor fans either on or off. The field-to-factory distance and the fuel cost were the decisive factors whether whole-crop harvesting could be profitable. The model also shows the critical effect of pol in bagasse, when milling cane with increased amounts of extraneous matter.

**Experiences gained from whole crop milling (David Moller)**

Whole cane milling (WCM) has been undertaken at two of the factories in the NSW Sugar Milling Co-operative to supply enough biomass to power a co-generation boiler of 30 MW during the 6 months of the non-crushing season. Whole crop milling is the supply of the whole crop (cane billets, leaves and trash) to the factory for processing through the milling tandem.

The initial plan was to transport the whole crop to the factory and then separate the leaf and trash material from the billets prior to milling. However, the prohibitive capital costs were such that this proposal was later rejected. After a short trial, it was decided that all the material would be processed through the milling train. This method of processing was trialled for three weeks during the 2007 crushing season before the factory returned to burnt cane processing.

In the 2008 crushing season, the factory has been processing whole cane for the first eight weeks. Due to an extreme frost in the 2007 growing period, the cane supply during this eight week period has included approximately 30% of frost-affected cane. Assessing the effects of processing the whole crop has been complicated by the inclusion of this frosted cane. Processing whole cane has impacted on every part of the factory. Changes have been made in the feeding, milling and boiler stations, but no changes have been made to the clarification, evaporation, pan or fugal stages until the effects of whole crop processing can be better determined. The observed effects in the factory include:

- Cane feeding – lower bulk density, trash binds together more than billets alone;
- Milling – the fibre rate increased from 40 t/h to 77 t/h and with greater variability;
- New cane payment formula needed;
- NIR system needed to measure fibre in each sample for cane payment;
- Clarification – lower settling rates, additional phosphate not effective in assisting clarification, and higher turbidity of clarified juice;
- Evaporation – poor HTC, faster scaling rate and scale harder to remove;
- Pan boiling – pans operating at only 60–70%, poor circulation (it is possible that frost affected cane contributed to this);
- Sugar quality – higher colour in molasses layer, no real impact on refinery operations; and
- Recovery – pol recovery dropped by 9%, bagasse loss increased by 4%, and molasses loss increased by 5%.

**Composition of non-stalk components of sugarcane and field residues and their effects on composition of mixed juice (Michael Saska and Nicolas Gil Zapata. Presented by Rod Steindl)**

This presentation summarised four independent investigations, carried out at different times and following somewhat differing methodologies. However, the objective was the same: add to the understanding of the composition of the various components of the sugarcane plant, with a focus on
the effects of non-stalk components on the composition of the mixed juice, and to some degree on the potential new industrial uses for field residues after cane harvest, or after separation from stalk billets.

Specifically, the various facets of the work included the 2002 tests in Louisiana of the cane composition during the growth and harvest period, a one-time sampling and determination of composition in 2003 of non-sugars in a major sugar cane variety grown in Colombia, determination of the effects of a commonly used chemical ripener on non-sugar composition of the cane in 2005, and a 4-year (2002 to 2006) test to determine the chemical composition of both the biomass remaining in the field after harvest and the juice extracted from these field residues using laboratory milling equipment.

It is well known that the non-sucrose content of the juice (e.g. ash, reducing sugars, starch, and colorants) extracted from cane trash is higher when expressed on the dry solids basis, than in juice from clean stalk, and, therefore, the purity of the industrial mixed juice is lower than it would be if only clean stalks were milled. However, even though the present data are far from complete and may have been affected by various experimental factors, it is quite apparent that the ratio of reducing sugars over the sum of concentrations of potassium and aconitate (the two major contributors to ash in cane juices) tends to be larger in juices from tops and leaves, than in the juice in the clean billets. This would seem to indicate that cane trash (tops and leaves) in commercial cane supplies may increase the overall RS/Ash ratio and therefore lower the target molasses purity.

**Session 5—Forum review and discussion**

**Processing of green cane through sulphitation process (J.J. Bhagat)**

An overview of the Indian sugar industry was presented that included:

- Importance of the sugar industry to the national economy;
- Value-added products that are generated from the 260 Mt crop of sugarcane;
- Major constraints being faced by the industry; and
- Strategies being adopted to improve productivity including new varieties, sustainable farming systems, extensive upgrades and modernisation of factories and energy conservation, optimisation and power export.

Indian factories produce a bold grain sugar with a very low colour of 50–150 IU typically. The process includes double sulphitation and usually syrup clarification. Trash and other extraneous matter that would cause an increase in the sugar colour are avoided. Mixed juice colour can vary from about 14 000 IU for clean cane up to more than 30 000 IU for cane plus tops and trash.

Some of the disadvantages of the high extraneous matter present in the cane supply when all the biomass is delivered to the factory include:

- Reductions in grinding capacity and sucrose extraction;
- Mill efficiency reduces by 5% and milling capacity by 10–15%;
- Lower quality clear juice (increases in turbidity, residual CaO and PO₄, lower purity, and additional consumption of chemicals);
- Leaf matter introduces an extra high loading of colorants, ash and RS;
- Increases the purity of final molasses; and
- Net benefit to a factory processing 0.5 Mt of clean cane rather than cane with extra trash was estimated at US$1.3m (without a co-generation facility).

**Literature review of burnt/green cane effects on factory processing (Laurent Corcodel)**

A brief summary of some papers to past ISSCT and SASTA conferences was presented. The summary highlighted the difficulties confronting current technologists when trying to reconcile the range of previous investigations because the focus of individual investigations is usually different
and this makes comparisons difficult.

**Poster papers**

_A pilot plant developed in-house for yield and quality increasing of sugar crystallisation_  
(Cédric Damour, Patrick Jeanty, Yannis Hoarau, Michel Benne, Brigitte Grondin-Perez and Jean-Pierre Chabriat)

Crystallisation process is the key stage of sugar production. Increasing demands for yield and quality created a need for optimisation and control of the process. To reduce the influence of variations in cane quality and changes in agro-climatic conditions on the process efficiency, it is essential to perform manufacturing protocols and to develop predictive control strategies. These steps require a series of experiments to reach the best trade-off. In an industrial context, each experiment could damage or stop the production.

Development of a pilot offers the opportunity to run many tests and experiments in the same experimental conditions but at a reduced scale. This poster describes a 1:1000 scale pilot plant for sugar crystallisation developed in-house at the Laboratory of energetic electronic and processes (LE2P) at University of La Reunion. This pilot plant should allow us to test and implant some new advanced control methods that have not been tested _in situ_. Results obtained on C-sugar crystallisation and experimental design of the seeding point study justify the scientific interest in the pilot plant development.

**Site visit to Casernes cane delivery and transfer station**

Cane is delivered to one of the 11 transfer stations by the farmer, usually as single trailer loads towed by a tractor. A core sample is taken from each delivery to the station on arrival. The cane is then transferred to a stockpile if whole stick or transferred directly to a waiting 20 t trailer if billet cane.

The core sample is then sub-sampled into a 5 kg lot and analysed at the site. The subsample is shredded and a 1 kg aliquot is placed into a press at 200 bar for 90 s to provide a juice sample for pol and brix. The fibre is calculated from a regression equation and the weight of the press plug.

**Concluding forum**

The forum discussed the use of the word ‘trash’ and what it represented. This arose because there were variations between research groups on what constituted trash and what was extraneous matter. The consensus within the workshop delegates was:

- **Trash**—the fibrous non-stalk material from the cane plant. This includes all leaf matter and the growing point of the cane stalk.
- **Extraneous matter**—everything left in the field or delivered to the factory that is not processable stalk.

There was general agreement that the best practice for factories to produce good quality sugar was to process clean cane. However, it was also recognised that future economic conditions will dictate that factories will need to maximise the amount of biomass brought into the factory for energy and bio-commodities. Individual conditions will define the most economical and sustainable balance for each organisation.

There was some discussion about future research needs. Papers delivered to the workshop identified a range of problems that factories have faced when processing cane with high levels of trash. The forum concluded that more research should be directed towards:

- An economical trash separation system to handle a cane supply with high levels of trash;
- Identification of suitable chemicals that would assist to alleviate the problems associated with the additional impurities in trash when processing a ‘whole of crop’ cane supply through the factory; and
Consideration of a joint workshop for both agricultural scientists and factory engineers to consider the operating constraints of each sector of the industry and to consider options that benefit the operations of both the field and the factory.

Acknowledgements

The contributions of CERF for hosting the workshop and the organisational efforts of the staff of CERF were greatly appreciated. Other organisations that provided financial support for the workshop included Sucrière de La Réunion, Sucrerie de Bois Rouge, SFSR (Sugar Producers Associations of Reunion Island), RTAS (Association of Sugarcane Technologists of Reunion Island), REI (Réalisations Electroniques & Informatiques), Département de la Réunion, and IRT (Ile de la Réunion Tourisme).

ATELIER FABRICATION ISSCT: LES EFFETS DES CANNES VERTES SUR LA FABRICATION A LA SUCRERIE

Par

R.J. STEINDEL

Queensland University of Technology, Brisbane, Australia

r.steindl@qut.edu.au

MOTS CLEFS: Cannes Vertes, Paille, Non-Canne, Pertes, Atelier.

Resume

L’ATELIER de la section Fabrication de l’ISSCT, «Effets de la canne verte sur le process», a eu lieu à la Réunion; 51 délégues représentant 10 pays étaient présents. On a discute les effets des cannes vertes avec de la paille en quantités variables, sur les performances et l’opération a l’usine. Ces discussions ont été particulièrement intéressantes pour les sucreries ou la cogénération est une option. On a aussi discute les difficultés associées au traitement des cannes vertes entières et des cannes avec beaucoup de paille. On a pu conclure que la meilleure façon de résoudre les problèmes est l’installation d’un système de nettoyage des cannes vertes, produisant des cannes propres pour la sucrerie. On a aussi conclu qu’il faut continuer à faire des recherches sur les effets des impuretés contenues dans la paille sur la fabrication. Deux sucreries et une station de stockage des cannes ont été visitées.
TALLER DE PROCESO DE LA ISSCT—IMPACTO DE LA CAÑA VERDE SOBRE EL PROCESAMIENTO DEL AZUCAR

Por

R.J. STEINDL

Queensland University of Technology, Brisbane, Australia

PALABRAS CLAVES: Caña Verde, Material Extraña, Pérdidas, Taller.

Resumen

EN REUNIÓN se realizó un taller sobre proceso organizado por el ISSCT, al cual asistieron 51 delegados de 10 países. El taller fue una ocasión importante y oportuna para revisar y discutir aspectos relacionados con el impacto en las operaciones de la fábrica y su desempeño por el suministro de caña verde que podría incluir altos niveles de materia extraña. Fue particularmente interesante escuchar las experiencias de aquellos ingenios que estaban considerando incrementar su contenido de biomasa con el objetivo de incrementar su capacidad de cogeneración. Muchos de los delegados relataron sus experiencias procesando ‘caña completa’ en la fábrica. Los delegados detallaron los problemas e incrementos en las pérdidas que incurrieron durante el procesamiento de caña con alto contenido de materia extraña. El consenso de los delegados fue que el mejor escenario podría involucrar un sistema de limpieza de la caña en la fábrica de forma tal que solo caña limpia podría ser procesada. El foro recomendó más investigación sobre el efecto del incremento de impurezas en las corrientes de proceso asociada con los altos niveles de materia extraña. Como parte de las actividades del taller, se realizaron visitas a dos ingenios y una estación de entrega de caña.
CLARIFICATION OF CANE JUICE FOR FERMENTATION

By

R.J. STEINDL
Sugar Research & Innovation, Queensland University of Technology, Australia
r.steindl@qut.edu.au

KEYWORDS: Juice, Clarification, Fermentation, Turbidity, Insoluble Solids.

Abstract
Fermentation feedstocks in the sugar industry are based on cane juice, B molasses or final molasses. Brazil has been producing ethanol by directing sugarcane juice to fermentation directly or using lower quality juice as a diluent with B molasses to prepare the fermentation broth. One issue that has received only limited interest particularly from outside Brazil is the most appropriate conditions for clarification of the juice going to fermentation. Irrespective of whether the juice supply is the total flow from the milling tandem or a diffuser station or a part of the total flow, removal of the insoluble solids is essential. However, the standard defecation process used by sugar factories around the world to clarify juice can introduce unwanted calcium ions and remove other nutrients such as phosphorus and nitrogen that are considered essential for the fermentation process. An investigation was undertaken by SRI to assess the effects on the constituents of cane juice when subjected to the typical clarification process in an Australian factory and what conditions would be needed to provide a clarified juice suitable for fermentation. Typical juices from one factory were clarified in laboratory trials under a range of pH conditions and the resulting clarified juices analysed. The results indicated that pH had a major effect on the residual concentrations of key constituents in the clarified juice and that the selected clarification conditions are determined by the nominated quality criteria of clarified juice feedstock for fermentation. Further trials were conducted in overseas factories to confirm the results obtained in Australia. It became apparent that the preferred specifications for clarified juice going to fermentation varied from country to country. Each supplier of fermentation technology had criteria applying to clarified juice feedstock that would have a major impact on the standard of clarification required to achieve compliance with the criteria.

Introduction
Although the sugar industry in Brazil has been producing ethanol by directing sugar cane juice to fermentation for many years and has developed significant process technology and experience in this field, the sugar industries in other countries are just embarking on this option. The impetus for the change from crystal sugar to a combination of crystal sugar and ethanol includes the continuing low prices for raw sugar, the rising operating costs and the increasing worldwide demand for biofuels to replace fossil fuels.

One issue that has to be addressed is the most appropriate conditions for clarification of the juice going directly to fermentation. Irrespective of whether the juice supply is the total flow from the milling or diffuser station or a part of the total flow, removal of the insoluble solids is essential.

However, the defecation clarification process used by sugar factories around the world introduces unwanted calcium ions and removes other nutrients such as phosphorus and nitrogen that are considered essential for the yeast.
A review was undertaken by SRI to assess the effects on the constituents of cane juice when subjected to the typical clarification process in an Australian factory.

**Optimum juice conditions**

There is not a lot of information available in the public domain that defines the optimum conditions for clarified juice going to fermentation. However, it is generally agreed that:

- The juice should be free of all insoluble solids;
- The maximum concentration of nutrients should be retained within the juice;
- The turbidity of the clarified juice may not be relevant although one fermentation technology provider has specified a maximum turbidity of about 15 (based on ICUMSA method GS7-21);
- Inversion of sucrose in acidic conditions to fermentable monosaccharides is beneficial; and
- Juice should not be contaminated with bacteria.

As an example, the clarified juice shown in Figure 1 (left) would be unsuitable for a sugar manufacturer but is considered to be suitable for fermentation by some fermentation technology and equipment suppliers.

![Fig. 1—Samples of turbid clarified juice suitable for fermentation (left) and clear clarified juice suitable for sugar production (right).](image)

Fermentec Ltda of Brazil (A. Godoy, 2008; *pers comm.*) provided the data shown in Table 1 on optimum conditions for clarified juice going to fermentation.

| Table 1—Optimum conditions for fermentation juice as specified by Fermentec, |
|---------------------------------|--------------------------|
| Parameter                      | Nominated value          |
| pH of limed juice              | 5.8–6.0                  |
| pH of clarified juice          | 5.0–5.5                  |
| Insoluble solids               | <0.2%                    |
| Calcium                        | As low as possible (<800 mg/kg) |
| Manganese                      | 2.0 mg/kg                |
| Zinc                           | 2.0 mg/kg                |
| Magnesium                      | 200 mg/kg                |
| Phosphorus                     | 50–65 mg/kg              |
| Nitrogen (as NH₃OH)            | 60–70 mg/kg              |
| Turbidity                      | Not important            |
Another fermentation company in South America provided the information shown in Table 2 for the required quality of clarified juice going to fermentation.

However, there is considerable variation in the target values of quality parameters at factories that are already sending juice directly to fermentation. A survey of some factories in Central and South America (see Table 3) indicates a wide range in pH of the feed juice.

In South America, one new factory with a cane diffuser has eliminated the clarification step. The justification relies on the assumption that the fermentation process and the viability of the yeast can tolerate an insoluble solids level of up to 0.2%. The installed process removes gross solids by filtration before sending the juice to fermentation.

The quality criteria are set to maximise the efficiency of the fermentation process and the viability of the yeast cells but appear not to consider the scaling potential in the evaporator or distillation columns.

**Experimental**

Settling rate tests were conducted on samples of mixed juice that were collected from an Australian factory to examine the effect of different pH levels on the settling rate, turbidity and residual impurities of the resulting clarified juice. The tests involved the following procedure:

- Heat the juice to either 75°C or 90°C;
- Adjust the pH of each one litre sample using lime saccharate to a selected value between 5.8 and 7.6 (the raw juice pH was 5.3);
- Heat the limed juice to boiling;
- Transfer the juice to a settling tube and measure the settling rate and settled mud volume; and
- Collect subsamples for analyses.
Mitsui Superfloc flocculants were tested at 3 mg/kg of juice. These flocculants had molecular weights of $24 \times 10^6$ and hydrolysis levels ranging from 24% to 38% and covered the full range of hydrolysis levels normally used in raw sugar manufacture.

The samples of clarified juice were analysed for turbidity (ICUMSA GS7-21), total phosphorus (ICUMSA GS7-15), calcium by inductively coupled plasma mass spectrometry and total organic nitrogen (Kjeldahl).

**Results**

**Settling tests**

The settling rates were very similar for each test. There appeared to be no effect of pH on the settling rates. Most settling rate results were in the range of 47–52 cm/min. The flocculants used were:

- Sample 1: A2120, A2130
- Sample 2: A2120
- Sample 3: A2120
- Sample 4: A2120, A2115 and A2125

As expected, the mud volume increased as the pH of clarification increased. The results are shown in Figure 2. Juice sample 3 contained less mud solids than the other juice samples. This is reflected in the lower mud volumes shown in Figure 2. Sample 3 also had higher settling rates of 61–64 cm/min because of the reduced effects of hindered settling.

![Figure 2](image)

**Fig. 2**—Results showing the increase in mud volume as more lime saccharate is added to raise the pH of the juice.

Figure 3 shows that the turbidity decreased as the pH of clarification is increased. Under normal clarification conditions when the pH of the feed juice is 7.6 to 7.8, the turbidity would be expected to be less than 10. The results suggest that there was little or no reduction in turbidity between 6.5 and 7.6 pH. Usually there is a much larger reduction in turbidity over this pH range. These results are more a reflection of the properties of the particular juice rather than a typical response.
Fig. 3—Results showing the turbidity reduction as the pH of clarification increases.

Analyses of the clarified juice

Analyses of the clarified juice for calcium, phosphorus and nitrogen showed significant effects of pH as illustrated in Figures 4, 5 and 6.
The reason for the different levels of nitrogen in sample 1 is unknown. The clarified juice samples were not analysed for insoluble solids as the levels were estimated to be significantly below the 0.2% limit suggested by Fermentec.

Visually, the clarified juice samples appeared to contain no insoluble solids. This observation was supported by the relatively low turbidity values of 30 and lower for pH levels of 6.0 and above.

Another series of tests was conducted in an overseas factory using the juice from a bagasse diffuser. Characteristics of this juice include:
• Very low mud solids loadings;
• Low brix;
• Higher levels of impurities; and
• Low phosphorus content.

The implication is that clarifying this juice separately becomes very difficult.

The same test procedure was used but only settling rates, turbidity and mud volume data were collected.

Settling rates were difficult to measure because the mud flocs were relatively light and tended to be affected by any flow currents inside the cylinder. The low number of flocs made it difficult to identify any interface between the juice and the settling mud flocs. The best estimate of settling rate was that it varied between about 15 and 40 cm/min. The settled mud was of lower density than that normally expected from juice flowing from a milling tandem or even from a cane diffuser. The results are shown in Figures 7 and 8.

![Fig. 7—Mud volumes from bagasse diffuser juice for different flocculant types.](image1)

![Fig. 8—Turbidity data from the bagasse diffuser experiments.](image2)
For the samples tested, increasing the pH just between 7.0 and 7.6 made a large difference in the turbidity of the clarified juice. The criteria for clarified juice at this distillery were for a pH of not more than 6.8 and a maximum turbidity of 15. The results suggest that it would be difficult to achieve compliance with the criteria.

Discussion

It is clear from the results obtained that the pH of clarification should be maintained at values below 6.2 if the criteria set by Fermentec are to be maintained. This is primarily to satisfy the minimum phosphorus criterion as compliance with other criteria is maintained at pH levels up to about 6.5.

An advantage of maintaining a pH below 6.5 is that alkaline degradation of reducing sugars to organic acids is avoided. According to Fernando Perez (pers comm., 2008) concentrations of organic acids above about 5000 ppm are detrimental to the fermentation process.

Previous experiments by SRI determined that the residual calcium levels in clarified juice started to rise once the pH was increased above about 6.5. Those experiments also determined that other inorganic ions such as manganese, magnesium and zinc were not affected by the normal defecation process used for the clarification of cane juice. The present data support that conclusion with respect to the residual calcium level. The clarified juice samples collected during the investigation reported here were not analysed for magnesium, manganese or zinc. At pH levels below 6.5, all the calcium added as calcium saccharate reacted with phosphorus in the juice to form calcium phosphate precipitate. There was no increase in residual calcium above the base level provided the pH of clarification remained below about 6.5.

Precipitation of calcium phosphate by the addition of lime to react with the phosphorus that occurs naturally in the juice is an essential pre-requisite to the standard clarification process. The calcium phosphate forms a bridge between the anionic flocculant and the insoluble solids. The large flocs formed by this linkage ensure high settling rates and provide an effective mechanism for the removal of other solids from the juice. Without the calcium phosphate precipitate, more expensive processing options would be required to remove the insoluble solids from the juice.

The option of avoiding a clarification step for diffuser juice takes advantage of the low initial solids level in the juice, typically 0.1 to 0.25%. Potentially most of the remaining solids could be removed by self cleaning rotary filters with small aperture (<100 µm) screens. Heating and evaporation steps are still required and higher scaling rates in the evaporator and distillation columns are expected.

When these results are applied to a decision on the type of clarifier and the residence time built into that clarifier, the obvious conclusion is that the installation of a clarifier with a long residence time offers no advantage. This conclusion is based on the following:

- The settling rates are high, even at the low pH levels.
- There are no chemical reactions (except sucrose inversion) that occur in the clarifier that could benefit the performance of the clarifier or the subsequent fermentation process.

The SRI NG clarifier with its short residence time can be applied to the clarification of juice for fermentation. The latest design has been developed through the application of computational fluid dynamics to examine the trajectories of floc particles under a range of operating scenarios to provide optimum conditions that will ensure the effective separation of the insoluble solids from the juice. Other clarifier designs can also be used for this application provided they are operated efficiently.

The experimental data are applicable to the juices being processed at the various factories during the period when the samples were collected. The results may not be fully applicable to other
factories although the trends should be similar irrespective of the source of the cane supply. The settling rates of other juices will vary depending on a number of properties including mud solids content, phosphorus concentration and the flocculant being added.

It is most likely that some juices will have lower settling rates, particularly when operating at the low pH levels or when the mud solids content is higher. Low settling rates can also result when the juice pre-treatment conditions deviate from set points. In these cases the risk of carryover of small mud particles will increase.

The settling rate of the mud is the most important parameter to be used when selecting the appropriate size of clarifier for a nominated juice flow rate. Realistic settling rate data must be used when selecting the diameter of the clarifier so that clarification standards are maintained during periods when low settling rates exist. Thus it is important for the design team to work with the client to determine the most appropriate size of clarifier to suit their particular application.

Maintaining a balance between the charge density on the mud particles and the flocculant is an important consideration irrespective of the destination for the clarified juice. When operating at low pH levels, it becomes more difficult to achieve a consistently high clarification standard because the charge density on the mud particles can be much lower.

Conclusions

Experiments conducted by SRI have shown that the optimum pH for the clarification of juice going to fermentation is below 6.2 if the criteria nominated by fermentation technology providers are to be maintained.

The results indicate that the short residence time clarifiers such as the SRI NG clarifier are also suitable for this application irrespective of the specification applied to the clarified juice. Where clarified juice of low turbidity is required, it is important to get the chemistry of the clarification process correct. If tight control of the chemical conditions is not maintained, it will be difficult to comply with the nominated standards.

Depending on the specification of the clarified juice, treatment of diffuser juice may not require a clarification step. This presents an opportunity to investigate other processes that may satisfy the requirements for fermentation feedstock.
monde entier afin de clarifier les jus peut introduire des ions calcium indésirables et supprimer les autres éléments nutritifs tels que le phosphore et azote qui sont considérés comme essentiels pour le processus de fermentation. Une étude a été entreprise par le SRI pour évaluer les effets sur les constituants du jus de canne lorsqu'il est soumis au processus de clarification typique dans une usine australienne; on a aussi étudié les conditions nécessaires pour fournir un jus clarifié adapté à la fermentation. Des jus typiques provenant d'une usine ont été clarifiés dans le laboratoire sous un éventail de conditions de pH et le jus clarifié résultant analysé. Les résultats ont révélé que le pH avait un effet majeur sur les concentrations des constituants principaux résiduels dans le jus clarifié et que les conditions de clarification sélectionnées sont déterminées par les critères de qualité nécessaires pour les jus destinés à la fermentation. Des essais complémentaires ont été effectués dans des usines à l'étranger pour confirmer les résultats obtenus en Australie. On a trouvé que les spécifications préférées pour les jus clarifiés destinés à la fermentation varient d'un pays à l'autre. Chaque fournisseur de technologie de fermentation se sert de critères pour le jus clarifié qui ont un impact majeur sur le processus de clarification.

CLARIFICACION DE JUGO DE CAÑA PARA FERMENTACION

Por

PALABRAS CLAVES: Jugo, Clarificación, Fermentación, Turbiedad, Sólidos Insolubles.

Resumen

La materia prima para la fermentación en la industria azucarera está basada en jugo de caña, mieles B o miel final. Brasil ha estado produciendo etanol fermentando jugo caña o usando jugo de calidad para diluir la miel B y preparar el caldo de fermentación. Un tema que ha recibido poca atención particularmente en países diferentes a Brasil ha sido el de encontrar las condiciones más apropiadas para la clarificación del jugo que posteriormente se va a fermentar. Independiente si el flujo total del jugo es suministrado por un tándem de molinos ó por una estación de difusión, es esencial la remoción de los sólidos insolubles. Sin embargo, el proceso estándar de defecación usado por las industrias azucareras alrededor del mundo para clarificar el jugo puede introducir iones de calcio indeseados y remover otros nutrientes tales como fósforo y nitrógeno que son considerados esenciales en el proceso de fermentación. El SRI realizó una investigación para valorar los efectos en la composición del jugo de caña cuando es sometido al típico proceso de clarificación en un ingenio australiano y las condiciones que podrían ser requeridas para suministrar un jugo apto para la fermentación. Los jugos de caña de un ingenio fueron clarificados en ensayos de laboratorio bajo un rango de pH. Los jugos clarificados fueron analizados. Los resultados indicaron que el pH tiene un efecto importante en las concentraciones residuales de los constituyentes claves del jugo clarificado y que las condiciones bajo las cuales se realice la clarificación debe ser seleccionadas de acuerdo con los criterios de calidad requeridos para fermentar el jugo clarificado. Se pudo establecer que aparentemente las condiciones deseadas para un jugo clarificado que se va a fermentar varían de un país a otro. Las empresas que suministran las tecnologías de fermentación han establecido criterios para el jugo clarificado que podrían tener un mayor impacto en el nivel de clarificación requerido para lograr el cumplimiento de estos criterios.
LOW MOISTURE MUD FROM SOLID BOWL DECANTERS

By

R.J. STEINDL, T.J. RAINEY and F. PLAZA

Sugar Research & Innovation, Queensland University of Technology, Australia
r.steindl@qut.edu.au

KEYWORDS: Clarifier Mud, Solids, Moisture, Filter, Centrifuge.

Abstract

The high moisture content of mill mud (typically 75–80% for Australian factories) results in high transportation costs for the redistribution of mud onto cane farms. The high transportation cost relative to the nutrient value of the mill mud results in many milling companies subsidising the cost of this recycle to ensure a wide distribution across the cane supply area. An average mill would generate about 100 000 t of mud (at 75% moisture) in a crushing season. The development of mud processing facilities that will produce a low moisture mud that can be effectively incorporated into cane land with existing or modified spreading equipment will improve the cost efficiency of mud redistribution to farms; provide an economical fertiliser alternative to more farms in the supply area; and reduce the potential for adverse environmental impacts from farms. A research investigation assessing solid bowl decanter centrifuges to produce low moisture mud with low residual pol was undertaken and the results compared to the performance of existing rotary vacuum filters in factory trials. The decanters were operated on filter mud feed in parallel with the rotary vacuum filters to allow comparisons of performance. Samples of feed, mud product and filtrate were analysed to provide performance indicators. The decanter centrifuge could produce mud cakes with very low moistures and residual pol levels. Spreading trials in cane fields indicated that the dry cake could be spread easily by standard mud trucks and by trucks designed specifically to spread fertiliser.

Introduction

Mud from the mud filters contains nutrients making it of value as a soil conditioner and substitute for commercial fertilisers but it also contains a large proportion of moisture (typically 75–80% in Australian factories).

Following an extensive assessment of the nutrient value of mill mud versus the application of commercial fertilisers, Qureshi et al. (2000) concluded that, for farms within 25 km of mills in the Central Queensland region, it was economical for farmers to apply mill mud (at 75% moisture) at rates up to 150 t/ha for substitution of commercial fertilisers.

The development of mud processing facilities that would produce a low moisture mud that could be spread onto cane fields with existing or modified spreading equipment will:

- Improve the cost efficiency of mud redistribution to farms broadly across the mill area;
- Provide an economical fertiliser alternative to more farms in the supply area; and
- Reduce the risk of environmental impact from farms.

It was proposed to investigate whether a solid bowl decanter could reduce the moisture of the final mud product without any extra loss of pol in the cake and without any increase in the level of mud solids recycled back to process with the filtrate.

Previous investigations
Hale et al. (1974) conducted factory trials on a decanter supplied by Sharples-Stokes. They concluded that one of the biggest problems was maintaining a high level of mud solids retention in the cake. They investigated feed conditioning options including the addition of lime to raise the pH, dilution of the feed and addition of flocculant and bagacillo to improve the retention. The most significant improvement was achieved with a high pH (~10) feed.

Stewart et al. (1974) conducted trials on a MercoBowl solid bowl centrifuge at another factory. This machine had facilities to add wash water at several positions along the inclined beach section.

A maximum pol recovery of 91% was achieved when dilution water was added to the feed. A higher pol recovery was possible when wash water was applied to the cake on the beach section but at the expense of reduced retention.

The amount of fibre in the mud affected the mud solids retention. Increasing the fibre ratio from about 0.27 to 0.4 improved the mud solids retention from 45–50% up to about 65%. The addition of flocculant improved the mud solids retention but did not affect pol recovery.

Stewart et al. (1975) showed that as flow rate through a solid bowl centrifuge increased, mud solids retention decreased. The pol loss was two to three times higher than that achieved by a rotary drum vacuum filter (RVF).

Stewart et al. (1976) investigated the effect of the finer bagacillo on the performance of the centrifuge. The performance of the MercoBowl was found to have improved significantly during the 1975 season compared with previous performances.

This improvement was shown to be a direct result of the finer bagacillo supply available from the new heavy duty shredder. Mud solids retention improved to above 90% even at high feed rates and the pol loss was reduced by about one third.

Danish Sugar & Sweetener Engineering (DSSE, 2004) was developing a decanter specifically for use on clarifier mud. Results provided by DSSE indicated the following:

- Cane quality and concentration of suspended solids had a significant effect on the capacity and pol loss;
- The use of a suitable flocculant was essential;
- The centrate was a clear lemon yellow juice;
- No bagacillo was necessary;
- The cake moisture averaged 58% over all tests; and
- The average cake pol was 3.2%.

**Methodology**

Factory trials were conducted to assess the potential of a solid bowl decanter centrifuge (SBC) to produce low moisture mud.

Two SBCs were tested. The first series of trials was conducted on a model P3400 SBC supplied by Alfa Laval.

The initial results of the P3400 indicated higher than acceptable pol losses and poor retention of the mud solids in the SBC so a second series of trials was conducted in the following year on a skid-mounted G2 40 decanter centrifuge unit also supplied by Alfa Laval.

The arrangement of the pilot plants for the factory trials is illustrated in Figure 1. The feed for the SBC was bled from the mud feed to the existing RVFs.

Hot flushing water was supplied at the top of the supply pipe. A magnetic flowmeter and resistance thermometer measured the flow rate and temperature of the mud feed to the SBC.
The centrate from the SBC was discharged to a small tank and then pumped to the secondary juice tank. The mud product was removed by a conveyor, stockpiled and finally removed by a front end loader at appropriate intervals.

Trials were conducted on both SBCs over a range of processing conditions. Some trials were conducted by collecting filter cake from the RVF, adding water to reconstitute the mud and then pumping the mud through the SBC. The mud was reconstituted in the mixer bowl of a concrete truck. Just enough water was added and mixed with the cake from the RVF to make the reconstituted mud fluid enough to flow to the SBC. The concept was to simulate conditions where a factory with limited filter area would process thicker cakes than optimum through the existing filter station and then reprocess the reconstituted mud through a SBC as a two-stage process to recover more sucrose and to produce a drier mud product.

The reconstituted mud was continuously discharged from the concrete truck and pumped to the centrifuge (as shown in Figure 1). Each batch from the concrete truck contained around 2.5 t of reconstituted mud and was sufficient to run the centrifuge at maximum rate (around 10–11 t/h) for about 15 minutes.

Stockpiled mud product from the centrifuge was loaded into a fertiliser truck and spread onto a nearby cane field to determine if there were issues with the transportability and spreadability of the low moisture mud.

Samples of feed and mud product from the RVFs and SBCs were collected during the trials and were analysed for pol, moisture, fibre and mud solids. Samples of centrate from the SBCs were also collected and analysed for pol, brix, purity and insoluble solids. During each trial, the bulk density and slump of the mud product was also tested. The slump was measured using concrete slump testing equipment (Anon., 1978; Anon., 1998). The slump of the mud product was measured to provide indications of the angle of repose and how easily the mud would flow from a mud truck.

**Pilot equipment**

The model P3400 decanter centrifuge supplied by Alfa Laval shown in Figure 2 had a rated capacity of 11 t/h of mud feed at 10% mud solids. The mud feed was introduced through a rotating
scroll into a rotating bowl. The scroll rotated at a small differential speed to the bowl. The bowl was driven by a 30 kW motor at around 3200 r/min and the scroll was driven by a 4 kW back drive motor connected by a vee-belt to the gearbox. The unit had no facilities for internal washing of the mud product.

Fig. 2—The P3400 pilot centrifuge used during the factory trials.

The skid-mounted G2 40 decanter centrifuge unit supplied by Alfa Laval for the second series of trials is shown in Figure 3. The skid was a turnkey system and just required connection of three phase power and connections for water, mud feed and centrate and a conveyor to remove the mud cake.

Fig. 3—The G2 40 decanter centrifuge used during the factory trials.
The G2 40 decanter had more instrumentation than the P3400 unit including an automatic polymer dosing rig, mud feed pump and magnetic flowmeters. It also had an internal baffle arrangement which was designed to press the dried mud product against the stator prior to discharge to achieve a further reduction in the final moisture content.

During the trials, the feed rate was adjusted between 3.7 and 8.0 t/h; however, for the majority of the trials where the effect of flow rate was not the object of investigation, the mud feed pump was set to deliver the maximum feed rate of 7–8 t/h. This was the capacity limit of the mud feed pump rather than the capacity limit of the centrifuge. The speed differential between the bowl and the scroll ranged between 8 and 27 r/min.

The most significant facility of the G2 40 was the torque monitoring instrumentation. The torque provides an indication of the degree of separation between the solids and the liquid within a centrifuge; the higher the torque, the better the separation.

By altering variables that increase the torque (usually speed differential between the bowl and the scroll), the operator is able to improve separation of the solid component from the liquid component for any given set of operating conditions.

The flocculant pump fed into a manifold which allowed the flocculant to be added into the feed at a number of locations prior to the centrifuge.

**Factory trials**

**Solid bowl decanter centrifuge trials**

**P3400 centrifuge**

A total of 33 trial conditions investigating combinations of speed differential (5 to 20 r/min), feed rate (2.6 to 8.7 t/h) and flocculant dose (Superfloc A2115 at 0 to 1320 ppm on mud solids in feed) were tested.

**G2 40 centrifuge**

During the trials on the G2 40 centrifuge, there was an emphasis on maximising the mud solids retention. The variables adjusted included the flocculant addition rate (600 to 2500 ppm on mud solids in the feed), the fibre ratio of the mud feed (0.25 to 0.6), the feed rate (3.7 to 8.0 t/h), and the differential speed between the bowl and the scroll (8 to 27 r/min). The centrifuge was used to process mud from the mud mixer and reconstituted mud from the RVF.

Sucrafloc 2320 flocculant was added to the mud feed at 89 to 336 litres per hour to achieve 600 to 2500 ppm on mud solids. It had been found that Sucrafloc 2320 was better suited for flocculating the mud than the Superfloc 2115 used for the P3400 trials.

**Results and discussion**

**Rotary vacuum filter**

Table 1 provides a summary of the results collected during the RVF trials. When dilution water was added to the clarifier underflow and wash water was turned off, a visible reduction in the moisture content of the cake was achieved. The final moisture of the cake reduced from 77–79% to 69–72%.

It appears that there is a distinct limit to the amount of water that can be removed. As the cake dries, the cake starts to crack and air passes through the cake and into the filtrate pipes. Once air starts passing through the cake, the vacuum reduces since the drum is no longer sealed.

In one test, the vacuum dropped to –15 kPa g compared to the typical vacuum of –70 kPa g. During this test, the cake thickness also increased from 6–8 mm under normal operation to 11–13 mm. Composite cake samples collected during the trials indicated that the pol % mud solids increased by an average 6.5 times when the wash water was off.

**Solid bowl decanter centrifuge trials**

#### P3400 centrifuge trials

The trials with the P3400 centrifuge focussed on determining the minimum moisture content of the mud product achievable with a decanter centrifuge. Initial results indicated that 51.8% moisture was achieved but with a mud pol of 8.2. These results were obtained without attempting to minimise pol loss. The mud product was promising since it was highly spreadable but further work to improve the properties of the mud (pol and bulk density) was required.

The centrifuge also had poor retention of mud solids (around 50%). This meant that the fibre ratio of the mud product was high (around 0.7) and the bulk density was low. Increasing the mud solids retention and maintaining a high recovery of sugar is necessary to ensure the economic viability of the process.

Feed rate and weir depth settings in the decanter were found to be the most important variables affecting final moisture content. The driest mud product had a high proportion of fibre and was generally of low bulk density (median of 327 kg/m³). The trials showed that the centrifuge could produce mud product between 47% and 61% moisture. Selected results of the trials with the P3400 centrifuge are shown in Table 2.

A summary of the results of the trials on the P3400 centrifuge follows:

- By decreasing the differential speed between the bowl and the scroll, a drier cake can be achieved but the solids loading of the centrate is increased. It was found that adjusting the differential speed had only a minor impact on the performance of the centrifuge.
- It was found that adjusting the weir depth had a profound effect on the moisture content of the cake and the mud solids loading in the centrate. By decreasing the weir depth, a drier cake could be produced but the resulting centrate had a higher solids loading as a consequence.
- The feed rate appeared to have a moderate effect on the performance of the centrifuge. The maximum feed rate was limited by the ability of the filtrate pump to
remove the centrate. The feed rate was measured by a magnetic flowmeter while the mud product rate was determined by weighing the cake falling from the conveyor with a large bucket and a stopwatch.

- The mud solids retention of the mud product was particularly poor; ranging between 47 and 90%. The average retention was 60.1%. The pol% mud solids was too high (28.6–42.5%) due to the absence of any facility to wash the cake.

The mud product generated from the centrifuge appeared to be attractive as garden compost. During the trials, stockpiles of mud disappeared, taken by various mill staff as compost. There seems to be an opportunity to value-add to the mud produced by the centrifuge as a feedstock for granulation or pelletising.

Many mills are battling with insufficient filter area to process adequately the mud flow. One option is to implement a two-stage process where the existing rotary drum filters comprise the first stage. The second stage would consist of a reconstitution phase where the cake is mixed with water and then fed to a decanter centrifuge. It was expected that the final mud pol could be significantly reduced.

Results from the mud reconstitution trials are shown in Table 2. The tests were successful in reducing the pol % mud solids to well below 1.0%. During the reconstitution trials, there was an increase in the moisture content of the mud product to 58–65%. This increase in moisture compared to trials with fresh mud from the mud mixer was in spite of the low weir setting which would normally be expected to provide the driest cake.

### G2 40 centrifuge trials

The P3400 trials gave good results for final product moisture but poor results for mud solids retention and pol loss. The high pol loss was overcome by reconstituting the mud (albeit at the expense of product moisture).
Data from the trials by Stewart et al. (1974) indicated that greater than 97% mud solids retention was possible under certain conditions.

Averaged results of the trials with the G2 40 centrifuge are shown in Table 3 including results from the mud reconstitution trials. The main conclusions of the results for the G2 40 centrifuge are:

- When fed with mud from the mud mixer, the centrifuge was able to achieve 53–58% moisture cake;
- The cake moisture was low in spite of the high weir setting;
- Mud solids retention was close to 100%;
- The high mud solids retention is reflected in the low solids level in the centrate;
- The fibre ratio of the cake product reduced from 0.77 for the P3400 to 0.49 for the G2 40 because of the much improved retention of mud solids;
- The cake moisture and retention were independent of the feed rate;
- The pol loss remained at an unacceptably high level;
- Flocculant usage to achieve these results was high; and
- All centrates would be suitable for forward processing.

A large amount of flocculant was used during the G2 40 trials even though Stewart et al. (1976) found that around 400 ppm gave adequate mud solids retention.

Increasing the fibre ratio, while improving the mud solids retention, had a detrimental effect on the final cake moisture as shown in Figure 4.

The following equation was developed to predict the final moisture content of the mud product.

\[
\text{Final cake moisture} \% = 100 \times (0.455 \times \text{FR} + 0.417)
\]

where FR = fibre ratio of the mud feed to the centrifuge (dimensionless).
Observations from the trials on reconstituted mud feed to the G2 40 include:

- Reconstituting the mud reduced the final pol loss significantly;
- The moisture of the cake was higher than the moisture achieved when fresh feed from the mud mixer was used; and
- Although there was a decline in the retention, the retention level was still acceptable.

**Field distribution trials**

The mud cake from the centrifuges appeared to have excellent spreadability characteristics. It was arranged to load a truck normally used to distribute gypsum and fertiliser with typical cake product from the centrifuge (i.e. 52–58% moisture) and spread it onto a nearby cane field (see Figure 5).
One of the concerns of the spreading trials was that the mud would be blown away because the mud resembled a relatively fine powder. When the trial was performed, it was particularly windy; however, a good uniform layer of mud product remained on the ground.

The truck operator was satisfied with the spreading performance of the cake and considered this distribution method to be viable.

There was interest in how a standard mud truck would handle the dry cake from the SBCs. Truck operators would normally ensure that the cake was wet to prevent any difficulties during spreading operations.

Approximately 8–10 tonnes of cake generated by the centrifuge were loaded into a 15 tonne mud truck. The truck was then driven 10 km to a local farm where it was unloaded. It was thought compaction of the mud product on the journey may hinder its subsequent ability to be discharged uniformly from the truck.

However, once the mud began to move, the mud flowed smoothly and evenly from the truck until it was empty. The resulting mud layer was around 50 to 70 mm thick on the ground.

The lower bulk density of the mud product (400 to 600 kg/m$^3$) from a centrifuge is an important consideration for the logistics of transporting the mud back to the cane field. Assuming 12 tonnes of mud is presently removed with each truck, and the bulk density is 665 kg/m$^3$, 18 m$^3$ of mud is transported with each truck. This represents about 1.63 tonnes of mud solids (assuming 13.6 mud solids%cake).

It was found that 18 m$^3$ of centrifuged mud product (assuming the mud has been reconstituted) contains only 1.51 tonnes of mud solids. However, the weight of 18 m$^3$ of centrifuged mud is only 8.15 tonnes.

Consequently, the volume of the truck filled with mud would need to be increased to remove the same quantity of mud solids with each truckload. A truck with an increased capacity to carry 12 tonnes of the drier cake would remove 2.22 tonnes of dry mud solids, about 35% more mud solids in each load.

**Conclusions**

Tests on the RVFs indicated that the moisture of the cake could only be reduced to 69–72%. This could only be achieved when no wash water was applied to the cake. As the cake dried, excessive air entered the filtrate pipes through cracks in the cake and caused significant loss in vacuum. There was also a 7 to 10 fold increase in the pol loss when the wash water was turned off.

The results from the SBC trials using typical filter feed can be summarised as follows:

- The final cake product was a powder of relatively low density;
- Final cake moistures approaching 50% are possible;
- The pol loss was high because there were no washing facilities in either of the SBC machines tested; and
- The use of flocculant and bagacillo was essential to maintain a high retention of the mud solids.

The results from the SBC trials using reconstituted mud are summarised as follows:

- A feed with a minimum of 85% water is required to produce a feed with sufficient fluidity to feed to the decanter centrifuge;
- A very low pol loss is possible;
- The final cake moisture was slightly higher, due in part to the higher bagacillo content and the need to use a high dosage of flocculant;
- High retention levels are possible only if the feed is conditioned with a suitable flocculant and sufficient bagacillo.
There appear to be no disadvantages associated with the distribution of dry mud product onto cane fields using conventional mud trucks or trucks that are designed to broadcast fertilisers.

Acknowledgments

Sincere thanks are due to the factory staff where the trials were conducted and to Alfa Laval for the loan of the pilot units for the trials. Funding for this project was provided by a syndicate of Australian mills and, via the Sugar Research and Development Corporation (SRDC), from the sugar industry and the Australian Government.

Résumé

L’HUMIDITÉ élevée des boues de moulins (généralement 75 à 80% pour les usines australiens) cause de forts frais de transport pour la redistribution de la boue sur les champs de canne à sucre. Les frais de transport élevés par rapport à la valeur nutritive des boues recènt la subvention des frais de ce recyclage par la sucrerie. Un moulin moyen génère environ 100 000 tonnes de boue (à 75% d'humidité) en une saison. Le développement d’installations qui produiraient une boue à faible
teneur en eau et facilement intégrée au sol serait favorable à la rentabilité; cela donnerait aussi une alternative économique aux engrais et réduirait le risque d'effets environnementaux négatifs. Une étude pour évaluer les centrifugeuses à bol solide pour réduire l'humidité et le pol de la boue a été entreprise et les résultats comparés a ceux de filtres rotatifs à vide existants dans les usines. Les centrifugeuses à bol solide ont traité la boue en parallèle avec les filtres rotatifs sous vide pour permettre des comparaisons de performances. Des échantillons de boue, de gâteau et de filtrat ont été analysés pour fournir des indicateurs de performance. La centrifugeuse à bol solide a produit des gâteaux avec des humidités et des pol très faibles. La dispersion des gâteaux dans les champs de canne à sucre a indiqué que le gâteau sec se propage facilement avec les camions standard et par des camions conçus pour répandre des engrais.

Resumen
El alto contenido de humedad de la cachaza (típicamente entre 75-80% en ingenios Australianos) da como resultado un alto costo de transporte durante su redistribución en las fincas cañeras. El alto costo de transporte relacionado con el valor nutritivo de la cachaza hace que muchas compañías azucareras subsidien este costo para asegurar la amplia distribución de la cachaza a lo ancho del área sembrada en caña. Un ingenio en promedio puede llegar a producir 100 000 t de cachaza con 75% de humedad durante la zafra. El desarrollo de un equipo que producirá cachaza de menor humedad que pueda ser incorporada adecuadamente a las tierras cañeras con los equipos existentes o con modificaciones en el equipo de dispersión incrementará la eficiencia en el costo de redistribución de la cachaza en las fincas cañeras y ofrecerá un fertilizante económicamente atractivo para la mayoría de las fincas en el área de suministro de caña, y reducirá el potencial impacto ambiental adverso desde las fincas. Se realizó una investigación para evaluar un decantador centrífugo sólido de canasta para producir cachaza con baja humedad y bajo pol residual los resultados fueron comparados con el desempeño obtenido en el existente filtro rotatorio al vacío en experimentos llevados a cabo en las fábricas. Los decantadores fueron operados sobre el filtro de alimentación de lodos en paralelo con el filtro rotatorio al vacío para permitir comparaciones sobre su desempeño. Los indicadores de desempeño fueron obtenidos a partir del análisis de muestras del alimento, los lodos, y el jugo filtrado. El decantador centrífugo podría producir una torta de cachaza con baja humedad y bajo pol residual. Los ensayos de dispersión en el campo indicaron que la cachaza seca podría ser esparcida fácilmente en los camiones de lodos típicamente usados o en camiones diseñados específicamente para esparcir fertilizantes.
MEMBRANE FILTRATION OF CLARIFIED JUICE

By

KEYWORDS: Membrane Filtration, Ceramic, Polymeric, Flux, Fouling.

Abstract

A MEMBRANE filtration plant using suitable micro or ultra-filtration membranes has the potential to significantly increase pan stage capacity and improve sugar quality. Previous investigations by SRI and others have shown that membranes will remove polysaccharides, turbidity and colloidal impurities and result in lower viscosity syrups and molasses. However, the conclusion from those investigations was that membrane filtration was not economically viable. A comprehensive assessment of current generation membrane technology was undertaken by SRI. With the aid of two pilot plants provided by Applexion and Koch Membrane Systems, extensive trials were conducted at an Australian factory using clarified juice at 80–98°C as feed to each pilot plant. Conditions were varied during the trials to examine the effect of a range of operating parameters on the filtering characteristics of each of the membranes. These parameters included feed temperature and pressure, flow velocity, soluble solids and impurity concentrations. The data were then combined to develop models to predict the filtration rate (or flux) that could be expected for nominated operating conditions. The models demonstrated very good agreement with the data collected during the trials. The trials also identified those membranes that provided the highest flux levels per unit area of membrane surface for a nominated set of conditions. Cleaning procedures were developed that ensured the water flux level was recovered following a clean-in-place process. Bulk samples of clarified juice and membrane filtered juice from each pilot were evaporated to syrup to quantify the gain in pan stage productivity that results from the removal of high molecular weight impurities by membrane filtration. The results are in general agreement with those published by other research groups.

Introduction

The sugar industry has long maintained an interest in the application of membrane filtration for both quality improvements and as a pre-treatment for processes to produce value-added products. Since the early work of Madsen (1973), sugar industry research organisations, commercial manufacturing and membrane supplying companies and sugar milling companies have been actively involved in the assessment of the benefits of membrane filtration systems and the installation and development of pilot plants into sugar factories.

Steindl (2001) provided a summary of available data from investigations undertaken at a number of sites around the world. Those investigations concluded that membranes would remove polysaccharides, turbidity and colloidal impurities and result in lower viscosity syrups and molasses, provide higher growth rates and improve exhaustion. The consensus from previous investigations undertaken in Australia was that membrane filtration was not economically viable due to high capital and operating costs. However, any economic analysis has to be based on the economic environment under which a particular factory is operating and the reasons why the installation of a membrane plant is being considered.
Despite the extensive investigations, the only two industrial installations of membrane technology in the cane sugar industry have occurred at Puunene Mill in Hawaii (Kwok et al., 1996) and at Felixton Mill, South Africa (Jensen et al., 2006).

This paper describes the recent assessment of current generation membranes undertaken by SRI.

Membrane trials

A comprehensive assessment of current generation membranes was undertaken by SRI using two pilot plants and ceramic tubular membranes provided by Applexion and spiral wound polymeric membranes provided by Applexion and Koch Membrane Systems (KMS). The assessment focused on the processing of clarified juice under a range of operating conditions to determine (a) the long-term sustainable flux levels and concentration factors that are possible for the different membrane configurations; and (b) improvements in juice quality and the derived downstream benefits. Suitable clean-in-place procedures were also examined using supplier recommended chemicals to maintain flux levels.

Bulk samples of clarified juice and membrane filtered juice were evaporated to syrup to assess the effects on pan stage productivity. The evaporated syrup was used in a laboratory vacuum pan to estimate changes in pan productivity and sugar quality improvements that could be achieved from membrane filtered juice.

Membrane pilot plants

Two pilot plants provided by Applexion and KMS were installed at an Australian mill for the trials. Schematics of the pilot plants are shown in Figures 1 and 2. Both plants contain (a) pre-filters fitted with 100 μm screens, (b) feed and recirculation pumps (c) feed buffer tank, (d) membrane modules (e) heat exchanger with thermostatically controlled valve and instrumentation.

Fig. 1—Schematic of the Applexion pilot plant (A - pre-filters; B - feed and recirculation pumps; C - feed buffer tank; D - membrane modules; and E - heat exchanger).

Both pilot plants were operated in a ‘feed and bleed’ mode. The Applexion unit operated by controlling the transverse membrane pressure (TMP) to maintain a relatively constant volumetric concentration factor (VCF) and permeate flux. TMP is defined as the force which drives liquid flow
through a cross flow membrane and equals the average of the feed and retentate pressures less the permeate pressure. The VCF is defined as the ratio of the volumetric flow rate of feed to the volumetric bleed rate of retentate in a continuous filtration system.

The retentate flow was adjusted using a pressure valve to control the VCF. The VCF was maintained by increasing the TMP (to a limit of 4 bar) to maintain the permeate rate as the membranes fouled. The KMS unit maintained a constant pressure drop between the feed inlet and the retentate outlet of the membrane modules for the duration of the run. This meant that, as the membranes fouled, the permeate flow slowly decreased.

Applexion provided several ceramic membranes to enable the investigation of the effects of the various flow channel configurations. KMS provided two spiral wound membranes including the sugar spiral (SS) and high yield sugar spiral (HYSS) that had never been applied to clarified juice applications previously. Both spiral membranes could be operated continuously on feed juice at 95°C. The polymeric membranes supplied by Applexion had lower operating temperature limits compared to the KMS membranes.

Details of the membranes investigated including the nominal molecular weight cut off (MWCO) or pore sizes and the filtration area of each membrane module are given in Table 1. Photographs of end views of some of the membranes are shown in Figures 3 and 4.

Trials were conducted using both pilots with clarified juice to assess membrane performance under a wide range of operating conditions including:

Temperature: 80 to 97°C
Recirculation flow velocity (Applexion): 3.9 to 5.2 m/s
Pressure drop (KMS - SS): 275 kPa
Pressure drop (KMS - HYSS): 415 kPa
VCF: 2 to 10X.

Analyses

Daily composited samples of clarified juice feed, permeates and retentate were collected for analysis of sucrose, brix, starch, dextran, total polysaccharides and colour using standard ICUMSA methods. Snap samples of feed and permeate were also collected every three hours for analysis of brix, pH and turbidity (absorbance at 900 nm). Bulk samples of clarified juice and membrane
filtered juice from each pilot were evaporated to syrup in the laboratory to assess the effects on pan stage productivity. Sugar was then produced using the SRI laboratory vacuum pan under defined conditions and procedures to provide predictions of overall growth rate changes and pan stage productivity changes. The sugar produced in the laboratory pan was analysed to determine the sugar quality improvements that could be achieved after membrane filtration of the clarified juice.

The crystal growth rates were measured using the method developed by Broadfoot and Steindl (1980). The procedure was designed to measure growth rates under constant conditions of supersaturation and temperature for each growth experiment. Variations in growth rate would then be a function of viscosity and impurities in the mother liquor. The solubility coefficient of the syrup was determined by analysing the saturated syrup used for the growth rate experiments and calculating the solubility coefficient from the sucrose/water ratio. Viscosities were measured with a Brookfield viscometer and a No. 2 spindle at 67°C.

**Cleaning procedures**

Water flux levels were measured before, during and after cleaning procedures. The pre-trial water flux was used as a reference to gauge the effectiveness of the cleaning procedure and the chemicals used.

The membranes were cleaned in place (CIP) during the factory trials using the CIP recommendation of the membrane suppliers. For the Applexion pilot plant a cleaning cycle was initiated when the maximum TMP was reached and the flux started to decline. A cleaning cycle was initiated for the KMS pilot when the permeate flux had declined below a pre-set limit (around 50–60 L/m².h).

The hottest clean water available (~85°C) was used to flush the chemicals and rinse the membranes.

**Results**

The results of the membrane trials are presented for each pilot plant separately because of the different operating conditions. The trials were conducted over two crushing seasons but only average data are presented for the more promising membrane configurations.

**Filtration rate**

The obtainable flux through a membrane is not only dependent on the liquid properties and the type of membrane system used but also on the operating parameters and conditions. Basically, there is pressure controlled and mass transfer controlled regions for filtration according to Cheryan (1986). Flux is dependent and can be improved by a number of factors influencing these regions such as:

- Increasing operating pressure, as this influences the permeability through the membrane. This will also be limited by physical limits of the membrane and the increased cost required to operate at higher pressures.
- Decreasing viscosity and density of the feed material which is generally characterised by turbidity, dry substance, pH, operating temperature and VCF. In many cases, the viscosity and density of the feed material will be set by other factors.
- Increasing diffusivity which is affected by the turbulence and velocity (determined by the recirculating flow rate) through the membrane. The flow channel arrangement will also contribute to the turbulence of the flow.

**Permeate flux model**

To accommodate the range of conditions investigated and the huge amount of data collected, models were developed to allow flux predictions to be made about expected flux levels for any nominated condition. The statistically significant variables included in the models were temperature, cross-flow velocity of the feed stream (Applexion), pressure drop (KMS), brix of the
feed, and the target VCF. Viscosity was not included in the regression analysis because of the very limited range of values. Separate equations were developed for each membrane type. Average analyses of the clarified juice are:

- **Brix**: 18.2 (15.9–21.3)
- **Turbidity**: 9 (absorbance at 900 nm)
  
  26 NTU
- **pH**: 7.0

Regression analysis was used on the data to determine model parameters. Forward stepwise multiple regression was applied to obtain a simplified model expression. Only significant regression coefficients were retained in this model. The remaining regression coefficients of the simplified equation were determined with higher precision (according to student t test). This methodology for determining model parameters is similar to that used by Dornier et al. (1994) to establish the optimal conditions of cross-flow filtration. The form of the regression equation is as follows:

$$J = \alpha_1 + \alpha_2 \log(VCF) + \alpha_3 T + \alpha_4 u + \alpha_5 Bx$$  

where

- **J** = Permeate flux, L/m².h
- \(\alpha_x\) = Coefficients determined by regression
- **T** = Temperature, °C
- **u** = Velocity, m/s
- **Bx** = Brix

Predictions from this regression model provided excellent agreement with the raw data with \(R^2\) values greater than 0.96 in all cases. The results showed that the VCF and feed flow velocity were the most important variables affecting flux through the ceramic membranes.

A similar form of the regression equation was developed for the KMS membranes with the pressure drop substituted for the feed velocity and an additional term added to account for the flux decline over time. An example of the quality of fit between the actual data and the model prediction is shown in Figure 5 for one trial with the HYSS membranes.

![Figure 5](image-url)

**Fig. 5**—Example of measured flux and the model prediction of flux for the conditions of the test.
**Applexion pilot**

The permeate flux predictions for the ceramic membranes are shown in Figure 6. The ceramic membranes, except the KB-W-07 (045), generally gave reproducible results over the two years of trials, were easy to clean and maintain 'clean' flux levels and could handle operation at high VCF (up to 50X). The KB-W-07 (045) membranes experienced fouling and cleaning problems that resulted in a much lower flux being obtained than expected. It was assumed that the larger pore size became blocked more easily and remained blocked during the cleaning cycles.

Interestingly, the flux obtained for the KB-W-07 (300), KB-W-07 (01) and KB-T were very similar. The diameter of the feed channel in the standard KB-W-07 (01 and 300) is 3.5 mm and the nominal diameter of the KB-T channel is 2.6 mm. There was a risk that the tight corners of the oval shaped channels would result in a thicker boundary layer in these regions. However, the measured flux indicated that there was no decline in performance.

The benefit with this profile is that single elements provide 42% extra filter area for the same overall element dimensions. This has implications for the initial plant cost, the replacement cost of membranes and the operating costs.

The spiral organic membranes supplied by Applexion had lower temperature limits and produced much lower fluxes. When compared with the performance of the KMS membranes, the membranes provided by Applexion were not competitive.

**KMS pilot**

For the KMS membranes, the model can also be used to predict the flux level after a period of operation which is important when determining the required membrane area for a nominated feed rate. Figure 7 illustrates the model predictions for the following typical conditions:
Temperature: 96°C  
VCF: 10X  
Brix: 18.0 Bx  
Pressure drop (KMS - SS): 485 kPa  
Pressure drop (KMS - HYSS): 415 kPa

The KMS data in Figure 7 show the predicted flux over 22 hours of operation for both the SS and HYSS types.

![Fig. 7—Predicted flux for spiral organic membranes.](image)

**Permeate analyses**

The average improvement in juice quality achieved from membrane filtration of clarified juice is shown in Table 2.

The results indicate that there is not a lot of difference in separation performance between the two membrane types. The level of removal appears to be almost independent of the nominal pore size of the various membranes (for the types of impurities of interest) and may be an indication that the dynamic foulant layer on the surface of the membrane influences the efficiency of removal.

If the data from all the Applexion plant trials are considered for each MWCO/ pore size range, there is a suggestion from Table 3 that more of the dextran passes through the membrane as the pore size increases. It is not so clear whether starch is similarly affected.

Pan stage productivity

The laboratory trials in the pilot pan determined that the increase in growth rate averaged 30% (from 221 μm/h to 287 μm/h). For a full pan cycle, the productivity improvement is about 15 to 23%. The improvement is similar to data presented from other investigations (Saska, 1997; Kwok, 1996). The improvement in pan productivity is due primarily to a reduction in viscosity of the syrup of 15 to 20%. This viscosity reduction was expected to flow through to the low grade C massecuite processing and provide an increase in sucrose recovery from final molasses.

The analytical results for the saturated syrup samples that were used to measure crystal growth rates indicate that the solubility coefficient of the feed syrup averaged 0.97 and it did not change following membrane filtration. The lower viscosity and higher growth rates of the syrups also resulted in the production of sugar with lower colour (~40%) reduced ash levels (~35%) and higher filterability (~17%).

Cleaning

Several cleaning procedures were assessed for their ability to recover to ‘near new’ flux levels. Initial CIP trials highlighted the importance of flushing and rinsing the membranes between cleaning cycles and indicated that high quality and hot temperature water improved the overall efficiency of the cleaning process. The detergent cleaning cycle was found to produce the most significant flux recovery.

During the trials, the water flux under standard operating conditions was monitored as an indication of the effectiveness of the CIP cycle and the condition of the membrane modules. After the usual decline in flux when the KMS membranes were first used, the water flux remained relatively constant over the period of the trials even when the membranes were stored for eight months between crushing seasons.

There was insufficient operating time with both the ceramics and the polymericas to determine the likely operating life of either type of membrane.

At the end of the trials, visual assessment and analysis of the water flux data for the KMS spirals were carried out which indicated no physical degradation of the membrane modules or blockages of the recirculating flow path.

Conclusions

A comprehensive assessment of the operation and performance of two membrane plants utilising a range of ultra and micro-filtration membranes was completed. The membrane types included spiral wound and tubular ceramic membranes covering a wide range of pore or MWCO sizes.
The 0.1 µm and the 300 kDa ceramic membrane elements provided the highest flux of the membranes tested. The factors that have a major influence on the flux rating are the feed properties including temperature, brix, and concentration of the impurities together with the feed velocity and pressure. The feed channel diameter and profile of the ceramic membranes only had a small influence on the achievable filtration rates. On the other hand, the width and the design of the spacer used to provide the feed channel in the KMS spiral membranes has a significant effect on the filtration rate.

Despite the larger pore sizes of the ceramic membranes, the separation efficiencies were similar to those achieved with the much tighter spiral membranes from KMS. It was assumed that the dynamic foulant layer played a major role in separating high molecular weight impurities from the juice stream.

The studies have shown that the ability to separate impurities from the juice was similar for both the ceramic and spiral membranes. The average reduction in impurity concentration is summarised as follows: colour 13%, turbidity 99%, polysaccharides 83%, starch 56%, and dextran 90%. As well, the membrane filtration of clarified juice led to improvements in downstream processes including an increase in crystal growth rate of 15 to 23% resulting from the reduction in viscosity of the syrup by 15 to 20%. The lower viscosity and higher growth rates of the syrups also result in the production of sugar of lower colour (~40%), reduced ash levels (~35%) and higher filterability (~17%).

A range of operating conditions was applied to each pilot. These data were then used to develop prediction models for each type of membrane. The fit to the experimental data was excellent. The models provide a useful tool to determine flux levels through each of the membrane types for a wide range of possible operating conditions.

Acknowledgements

The funding provided by the Sugar Research and Development Corporation and a syndicate of Australian sugar mills is acknowledged. The assistance provided by both Applexion and Koch Membrane Systems was extremely important to the success of the project.

Résumé
UNE UNITE de filtration sur membrane à l'aide de membranes micro- ou ultra-filtration a le potentiel d’augmenter la capacité des cuites et d’améliorer la qualité du sucre. Des travaux précédentes par le SRI et d'autres ont montrés que les membranes enleverent les polysaccharides, la turbidité et les impuretés colloïdales, et donnent des sirops et mélasses avec des viscosités plus faibles. Cependant, la conclusion de ces enquêtes a été que la filtration membranaire n’était pas économiquement viable. Une évaluation complète de la technologie des membranes de la génération actuelle a été entreprise par SRI. À l'aide de deux systemes pilotes provenant de Membrane Koch et d’Applexion, des essais ont été effectués dans une usine australienne avec du jus clarifie à 80–98 ° C alimentant chaque unite. Les conditions ont été variées durant les essais afin d'examiner l'effet d'une gamme de paramètres d'exploitation sur les caractéristiques de filtrage de chacune des membranes. Ces paramètres sont la température et pression de l’alimentation, la vitesse du jus, les solides solubles et la concentration des impuretés. Les données ont été ensuite combinées dans des modèles afin de prédire le taux de filtration (ou flux) pour les conditions d'exploitation désignées. Les modèles donnent un très bon accord avec les données recueillies durant les essais. Les essais ont également identifiés les membranes qui fournissent les plus hauts niveaux de flux par unité de surface de membrane pour des conditions spécifiques. Des procédures de nettoyage ont été mises au point et le flux d'eau a été retrouve après un processus de nettoyage en place. Des échantillons de jus de clarification et de jus filtré par les membranes de chaque pilote ont été évaporés pour produire du sirop, afin de quantifier le gain de productivité qui résulte aux cuites grace a l'élimination des impuretés de haut poids moléculaire par filtration sur membrane. Les résultats sont en accord avec ceux publiés par d'autres groupes de recherche.

PALABRAS CLAVES: Filtración con Membranas, Membranas Cerámicas, Membranas Poliméricas, Flux, Incrustaciones.

Resumen

El uso de micro o ultrafiltración con membranas tiene el potencial de incrementar significativamente la capacidad de los tachos y mejorar la calidad del azúcar. Investigaciones anteriores realizadas por el SRI y otros investigadores han mostrado que las membranas remueven polisacáridos, turbiedad e impurezas coloidales, disminuyendo la viscosidad de las meladuras y mieles. Sin embargo, estos estudios han concluido que el uso de membranas no es una alternativa económicamente viable. Una valoración comprensiva de la tecnología actual en membranas fue realizada por el SRI usando dos plantas piloto suministradas por Applexion y Koch Membrane Systems. Se realizaron una serie de ensayos en un ingenio australiano, alimentando a cada planta piloto jugo clarificado a una temperatura entre 80 y 98°C. Durante los ensayos se variaron algunas condiciones para evaluar efecto de variaciones en los parámetros de operación sobre las características filtrantes de cada una de las membranas. Estos parámetros incluyeron la temperatura y presión del alimento, la velocidad del flujo, y la concentración de sólidos solubles e insolubles. Los resultados obtenidos fueron usados en un modelo para predecir la velocidad de filtración que podría ser esperada para unas condiciones de operación determinadas. Los modelos mostraron una muy buena correlación con los datos recolectados en los ensayos. Se identificaron para unas condiciones de operación determinadas aquellas membranas que presentaron el mayor nivel de flujo por unidad de área de membrana (flux). Se desarrolló un proceso de limpieza para asegurar que el agua utilizada en la limpieza de la membrana fuera recuperada en el mismo lugar de su uso. Se concentraron hasta meladura muestras de jugo clarificado filtrado y sin filtrar de cada una de las dos plantas piloto para cuantificar la ganancia en la productividad en la etapa de tachos como resultado de la remoción de impurezas de alto peso molecular durante la filtración con membranas. Los resultados obtenidos coinciden en general con aquellos obtenidos por otros grupos de investigación.
THE IMPLEMENTATION OF A DRYER/COOLER CONVERSION AND SHORT RESIDENCE TIME CONDITIONING SYSTEM FOR REFINED SUGAR

KEYWORDS: Sugar, Dryer, Cooler, Conditioning.

Abstract

The rotary sugar dryer/cooler at Central Azucarera Don Pedro (CADP) refinery (Philippines) has been upgraded and a short residence time conditioning system has been installed through 2008–2009 to resolve hard caking issues being experienced in stored 50 kg sugar bags. This paper describes the modifications undertaken and the results achieved in resolving the caking issues. The reconfiguration and automation of the dryer/cooler and the installation of short residence time conditioning (eight hour conditioning period) provided a simple, low capital cost and low operating cost resolution to the caking issues previously encountered at the refinery, compared to alternatives. The reconfiguration and automation of the rotary dryer/cooler has reduced both power and steam consumption and allowed a significant increase in capacity, despite retaining the same rotary shell, fans, scrubber and air heater. The increased performance has eliminated the need for a fluidised bed cooler that was previously under consideration for purchase by the refinery. Since modification, the refinery has completely eliminated hard caking of refined sugar. There has been no need to remelt and recycle bags of sugar due to hard caking.

Introduction

Central Azucarera Don Pedro (CADP) refinery in the Philippines is a relatively new refinery (commissioned February 1994) and was initially rated at 550 tonnes refined sugar/day when built. After expanding twice, it is currently producing 900 tonnes/day (mostly in 50 kg bags).

Over recent years, problems were experienced with hard caking of some of the sugar produced (which is stored in 50 kg bags). This caking was severe around the edges of the bags with a thick, rock-hard crust forming only days after production of the sugar.

The refinery was considering the installation of a fluidised bed cooler for refined sugar, to be located downstream of the existing co-current hot air and counter-current cold air rotary dryer/cooler.

Options of conventional sugar conditioning were also investigated, though the capital involved was substantial and little comfort could be gained that the desired outcome would be achieved (based upon performance of recently installed conventional conditioning systems in the SE Asian region).

Sugar Technology International (STI) offered a solution to CADP which involved the uprating and upgrading of their rotary dryer/cooler and the installation of short residence time conditioning facilities.
Steps to conditioned sugar

To produce well conditioned sugar, it is believed that four key steps are involved:

1. Pan stage operations need to provide consistent grain size with low CV and few agglomerates,
2. The centrifuging step needs to achieve good purging and have no massecuite balls or wet lumps,
3. The drying step needs to be as slow as practical to minimise the quantity of sucrose in the amorphous state, and deliver sugar of appropriate moisture content and temperature, and finally,
4. The conditioning step needs to crystallise the excess sucrose held in the film around the crystal so the film is at equilibrium with its surroundings.

Of these steps, the first two relate purely to good refinery operating practice and will not be covered further. The CADP sugar refinery was already achieving good pan stage and centrifugal performance so these areas were not the cause of the hard caking that was observed.

This paper deals with the last two steps of achieving well conditioned sugar; drying and conditioning. The drying modifications at CADP are installed and commissioned and results are presented; however, at the time of writing, the conditioning system is under construction and not yet commissioned. It is the intention to discuss the conditioning system results at the ISSCT oral presentation.

Drying

The rotary dryer/cooler is an important part within the broader series of processing steps required to achieve well conditioned sugar that is free of caking problems.

The contribution of the drying step to potential caking issues is well established in the technical literature, but often over-looked within sugar refineries. It should be recognised that the drying step creates the problem of a supersaturated or amorphous sugar film around each crystal that the subsequent conditioning step must resolve.

In the drying step, the obvious goals are to consistently produce sugar of the desired moisture content and temperature. We contend that a more subtle goal is to prolong the drying step within the dryer to allow the greatest opportunity for crystallisation of sucrose within the film around each crystal.

While it is unrealistic to completely crystallise the sucrose within the film (such that the film leaves in a saturated state), to the extent that we can crystallise sucrose during drying, we minimise the quantity of sucrose in the amorphous film around each crystal and hence the task to be undertaken during downstream conditioning operations.

The major mechanism by which we moderate the rate at which drying occurs in the feed end of the dryer is to reduce the air flow rate and temperature. Reduced air flow leads to increased humidity in the exhaust from the dryer and thus a reduction in the driving force for evaporation.

It is interesting to contrast this approach with the earlier operations of this dryer when it used co-current hot air followed by counter-current cooling air flow. In that original configuration, co-current hot air (typically 90–100°C) was used in the sugar feed end of the dryer. Such air has an extraordinarily low relative humidity and sugar can be expected to lose moisture extremely rapidly under such conditions.

Other dryer types commonly used in various parts of the world similarly incorporate heated, extremely low RH air to perform drying (e.g. rotary louver, twin rotary drum and fluidised bed dryers). Of these, the speed with which moisture is removed is probably highest in the fluidised bed dryers.
Details of conversion of rotary dryer/cooler

Modifications to the rotary dryer/cooler involved a re-configuration to purely counter-current air flow, re-flighting of the drum to achieve a significant increase in capacity and the installation of instrumentation and controls to manipulate the dryer operating conditions over the entire sugar flow range (0%–100% capacity). The major modifications are shown in the schematic diagrams in Figure 1 (before conversion) and Figure 2 (post conversion).

Fig. 1—Sugar dryer before conversion.

Fig. 2—Sugar dryer after conversion.
The conversion retained the original dryer/cooler drum, though the central air exit holes were blocked when converting to purely counter-current flow. The original ID fan and cool air fan were retained, though variable frequency drives were fitted to reduce the air flows to the desired values. The original steam heated air heat exchanger was relocated, and (part way through the season) 67% of the heat exchange area blocked off, with a smaller steam control valve fitted.

**Results of modifications**

At the time of writing this paper, the dryer/cooler modifications are complete and have been operating throughout the 2008/2009 season. The conditioning silo modifications discussed in the next section are nearing completion but are not yet operational. The results presented here clearly show the benefit derived from the dryer conversions alone.

The sugar storage facilities at CADP are formidable as is clear from Figure 3. This photograph was taken in June 2009 and shows the CADP warehouse approaching full capacity with 900,000 x 50 kg bags of sugar in storage. Such tall stacks provide significant compressive loads and provide a real test of the caking propensity of the sugar.

Figure 4 shows the hard lumping of sugar in bags prior to the dryer conversion—such lumps were hardest towards the outside of the sugar bags.

Specialised machines to compressively deform the bags (known as ‘lump breakers’) were deployed in an attempt to resolve the issues. It is understood such machines are utilised in countries such as Brazil and Thailand. Since modification, only soft caking is observed even after three months storage in deep stacks (see Figure 5).

The lump breaker machines have not been in use for the entire 2009 season. The soft caking experienced after conversion readily breaks up in the normal handling of bags.

Fig. 3—CADP store with 900,000 bags, June 2009.
Fig. 4—Hard lumps of sugar prior to conversion, March 2008.

Fig. 5—Sugar nature after the dryer conversion and storage for three months, July 2009.

The quantities of sugar remelted due to caking over the past five years at CADP are given in Table 1. The statistics exclude bags remelted due to physical damage to bags in handling.
Figures 6 and 7 provide details of dryer temperatures before and after conversion. The air preheat temperature can be seen to be reduced during the year to the values recommended. This was achieved part-way through the season, when 67% of the air heater area was blocked off and a smaller steam control valve fitted to improve control. Note that, with the low counter-current air flow, hot air in the sugar discharge end of the dryer only has limited ability to heat the sugar, so the sugar outlet temperature after conversion is not increased.

The moisture content of the product sugar (by gravimetric determination) is seen to rise from the before modification period to after (though still within specification), yet the product sugar exhibits dramatically reduced caking propensity. This underlines the fact that moisture content in isolation is not a measure of the degree of conditioning or caking propensity (as discussed further in the conditioning section).

![Fig. 6—Inlet air and product sugar temperatures.](image)

![Fig. 7—Moisture content of sugar product.](image)
The elimination of hard caking of sugar through dryer modifications alone has been demonstrated. The sugar does still exhibit soft caking that breaks up readily in normal bag handling operations. This soft caking tendency will be addressed with the commissioning of the SRTC system.

The test through the 2008–09 season has been particularly good as many bags have been stored over several months in tall stockpiles without caking.

**Conditioning of refined sugar**

The means of assessing the ‘condition’ of sugar has been the subject of much debate over many years. Some refinery staff maintain that the moisture content of sugar can be used as a measurement of the degree of conditioning and that moisture removal is the primary aim of conditioning (Rein, 2007). While conditioning is often associated with a small reduction in moisture content, moisture content does not imply the state of conditioning, irrespective of how the moisture content has been measured.

In the conditioning of sugar, we maintain that the key goal is to crystallise sucrose that is held in a supersaturated state within the amorphous layer. By doing so, the later uncontrolled crystallisation of this sucrose is avoided. It is the crystallisation of sucrose at the contact points of sugar crystals leading to intercrystalline bridging that is caking.

Sugar moisture measurement is complicated by the known influence of supersaturated films on the moisture content as determined by conventional laboratory drying tests (Rein, 2007). Karl Fischer analysis of moisture is recognised as being a more accurate moisture determination than gravimetric techniques, but such equipment is not commonly available in refinery laboratories.

With highly supersaturated films, a significant proportion of the water is ‘bound’ and will not be detected during gravimetric analysis. With crystallisation of sucrose in the supersaturated film, bound water is converted to free water.

This is exemplified by the observation that the gravimetric moisture content of sugar can as much as double simply by storing the freshly dried sugar in a sealed container (Schmalz and Stroebel, 2004).

The observed ‘creation’ of moisture adds to the mystique of sugar conditioning but is quite easily explained in terms of the reduced activity of water in supersaturated films of unconditioned sugar.

In modelling of sugar dryers and sugar conditioning systems, the scientific means by which the ‘availability’ of water is expressed is by calculating the activity of water. The activity of water is simply the vapour pressure expressed by the water in a film divided by the vapour pressure that would be exerted by pure water at the same temperature.

If a supersaturated film has a water activity of 0.2, then it will be in equilibrium with air at the same temperature if the air RH is 20%. Water activity is useful because it can mathematically describe the varying ‘availability’ of water without resorting to a ‘bound water’ versus ‘free water’ classification.

The quantity of sucrose that is contained in a supersaturated film can be used to rank the caking potential of sugar as shown in Table 1.

The table below demonstrates that while the goal of a conditioned sugar is to achieve a nearly saturated film with low moisture content, knowing just the moisture content (however measured) is not sufficient to judge if conditioning has been completed.

In practice, no matter how well conditioned, it is always possible to induce caking by subjecting sugar to extreme treatment (e.g. gross wetting and partial dissolution followed by drying). In normal operations, however, having only thin films around crystals that are nearly saturated provides the least quantity of sucrose in solution that can form bridges.
Through the simulation of evaporation, heat transfer and crystallisation processes with a sugar dryer (Tait et al., 1994), it is possible to predict the partial pressure of water vapour exerted by the sugar as it progresses through the dryer. Figure 8 shows the predicted partial pressure of water exerted by the sugar in 30 equal increments as it moves through the rotary dryer (highest vapour pressure and temperature at the sugar feed end). Also presented in Figure 8 is the vapour pressure exerted by water of varying activities.

It can be seen that the calculated water activity at the sugar feed end is significantly less than that for pure sucrose at saturation (which is about 0.82–0.84). This is due to the rapid evaporation and concurrent crystallisation occurring near the feed end of the dryer. For about the first 6 elements (i.e. about 20% of the flighted length), the crystallisation rate is able to keep pace with the onset of supersaturation due to both the removal of water and the reduction in temperature. For the balance of the dryer, however, the activity of water rapidly reduces as the kinetics of crystallisation fall away. For this simulation of a refined sugar dryer, a water activity just under 0.4 is predicted. This prediction seems consistent with published measurements (Schmalz and Stroebel, 2004) who quote water activities of 0.45–0.55 for sugar of <0.05% moisture content. The results of these
simulations and plant measurements confirm that air of 10%–20% RH (as used in conventional conditioning) would remove further water from this sugar in the already supersaturated state it leaves the dryer. For a macro-scale comparison, to understand the nature of the films being dealt with, the water activity of ‘Hard Candy’ is 0.20 to 0.35.

Details of short residence time conditioning installation

The STI SRTC system at CADP is achieved by fitting radial internal divider partitions in two existing silos as shown diagrammatically in Figure 9. The silos are capable of receiving sugar of different grades from the refinery. The three compartments within each silo will consecutively fill, condition and empty on a cycle. The fill time is nominally six hours, conditioning time of eight hours and a further 5–8 hours in which to empty the compartment before the next charge is due.

By this means, an essentially continuous flow of sugar to downstream packaging equipment is maintained despite the conditioning operation being conducted as a batch. A specialised refrigeration and control package is used to supply air at the required conditions to each silo. Air is only directed to one compartment per silo simultaneously.

Comparison of SRTC and conventional conditioning

It is informative to reflect upon the combination of factors that lead to conventional conditioning systems requiring the long residence times they do.

In a tall silo, there will be an appreciable pressure drop as air is blown through it. Compressing refrigerated air raises the partial pressure of water vapour within that air. To avoid problems with moisture pick-up in sugar against the inlet or against the walls/floor of the silo, it is necessary to prepare quite low RH air. As this air expands (pressure reduces), the RH falls further. Thus, if you build a tall silo, there is not much choice other than to pass low RH air through it.

If sugar continually enters and leaves the conditioning silo (and perhaps is recirculated on occasion), this further complicates the issue because unconditioned sugar is more ‘moisture hungry’
than conditioned sugar of the same true moisture content. When comparing sugars of the same moisture content, the water in conditioned sugar has a higher water activity because its vapour pressure is not so suppressed by the supersaturated conditions in the film.

In conventional conditioning (Rein, 2007), air of typically 10% to 20% RH is supplied to silos of 24 to 48 hours residence time at a specific air rate of 3 m$^3$/h.t of sugar. For a refinery producing 50 t/h refined sugar, this translates to storage of 1200 to 2400 tonnes and air flows of 3600 to 7200 m$^3$/h. Such air flows have the capacity to aggressively strip moisture from the film surrounding each crystal resulting in a low water activity.

The rate of sucrose crystallisation in a supersaturated film is extremely slow under conditions of low water activity (Broadfoot, 1980) because, while the supersaturation driving force for crystallisation has been enhanced by removing moisture, the mobility of molecules within the film is severely reduced and therefore the kinetics of crystallisation are reduced.

If a silo operates under conditions of low RH, then the sugar within it is destined to undergo slow, conventional conditioning. Under these conditions, long residence times are required (e.g. 48 to 72 hours).

The STI short residence time conditioning system conducts conditioning in a batch of sugar over a much shorter residence time (hours) compared to conventional sugar conditioning (days). The obvious advantage of this is that the physical size of silos and associated equipment is dramatically reduced.

The underlying principle of short residence time conditioning is that conditioning can be performed relatively quickly if:

- the highly supersaturated sugar film is first given moisture to lessen the degree of supersaturation;
- crystallisation is allowed to proceed rapidly under the resulting higher mobility/ lower viscosity/ lower supersaturation film environment; and
- then, as the water activity rises in the film, moisture is removed (generally slightly more moisture is removed than was ‘loaned’ in the first place).

Central to the concept of short residence time conditioning is the establishment and propagation of a moisture wave through a batch of sugar. While supersaturated conditions are retained throughout the passage of the moisture wave, at the peak of the wave, the degree of supersaturation in the film is significantly reduced compared to the highly supersaturated film on sugar that enters the silo from the dryer.

In Table 2, the contrasting paths of conventional conditioning and short residence time conditioning are highlighted.

</tr>
</tbody>
</table>

Table 2—Caking potential highlighting alternate conditioning paths.
Conventional conditioning initially reduces moisture content flowed by slow crystallisation, while SRTC initially adds moisture before crystallising and drying under faster though moderate conditions. While the same net result is obtained, the kinetics of crystallisation along the SRTC path is dramatically faster.

It is fair to say that short residence time conditioning is considered somewhat controversial as it represents a radical departure from conventional conditioning operations. It is through the careful manipulation of moisture that the greatest gains in conditioning kinetics can be achieved. Ironically in sugar conditioning, it appears that when well handled, moisture can be your best friend, yet when poorly handled, it is your worst enemy.

MOTS-CLEFS: Sécheur, Refroidisseur, Conditionnement.

Résumé

LE SECHEUR/REFROIDISSEUR pour le sucre à la raffinerie de CADP (Centrale Azucarera Don Pedro, Philippines) a été revalorise et un système de conditionnement a court temps de séjour a été installé en 2008–2009 pour résoudre les problèmes de prise de masse rencontrées dans des sacs (50 kg) de sucre stocké. On décrit les modifications effectuées et les résultats obtenus pour résoudre le problème de prise de mass. La reconfiguration et l'automatisation du sécheur/refroidisseur et l'installation de conditionnement a court temps de séjour (période de conditionnement de huit heures) a été une solution simple et de coût faible pour résoudre les problèmes de prise de masse à la raffinerie, par rapport aux alternatives. La reconfiguration et l'automatisation du sécheur/refroidisseur ont réduit la consommation d'énergie et de vapeur et ont permis une augmentation en capacité, tout en conservant le même tambour rotatif, les ventilateurs, l’équipement pour le lavage des gaz et le réchauffeur d’air. L’amélioration des performances a éliminé le besoin d’un refroidisseur a lit fluidisé, qui avait été considéré précédemment par la raffinerie. Depuis la modification, la raffinerie a complètement éliminé la prise de masse du sucre raffiné et il n'a pas été nécessaire de refondre et de recycler les sacs de sucre.
IMPLEMENTACION DE LAS MODIFICACIONES EN LA SECADORA/ENFRIADORA Y DE UN SISTEMA DE ACONDICIONAMIENTO DE CORTO TIEMPO DE RESIDENCIA

Resumen
EN EL CENTRAL Azucarero Don Pedro (CADP) una refinería ubicada en Filipinas, se realizaron modificaciones a la secadora/enfriadora rotatoria y se implementó un sistema de acondicionamiento de corto tiempo de residencia durante la zafra 2008–2009. Estas modificaciones fueron hechas con el fin de resolver los problemas de aterronamiento observados en azúcar refinada empacada en bolsas de 50 Kg. Este artículo describe las modificaciones realizadas y los resultados alcanzados en la solución del aterronamiento. La reconfiguración y automatización de la secadora/enfriadora y la instalación de un sistema de acondicionamiento con un tiempo de residencia de 8 h fue una solución simple, de bajo costo de capital y operación, para resolver los problemas de aterronamiento comparada con otras alternativas. La reconfiguración/automatización de la secadora/enfriadora redujo la potencia y el consumo de vapor y permitió significativos incrementos en capacidad a pesar de que la secadora conservó tanto la misma carcaza, como los ventiladores, el scrubber y el calentador de aire. El incremento en el desempeño de la secadora eliminó la necesidad de un enfriamiento en lecho fluidizado alternativa que había sido considerada en la refinería. A partir de la modificación, la refinería eliminó completamente el aterronamiento del azúcar refinado. No ha sido necesario derretir o reciclar azúcar debido a aterronamiento.
GC-MS AS A TOOL FOR CARBOHYDRATE ANALYSIS
IN A RESEARCH ENVIRONMENT

By
S.N. WALFORD

Sugar Milling Research Institute, c/o University of KwaZulu-Natal, Durban, South Africa
swalford@smri.org

KEYWORDS: Gas Chromatography, Mass Spectrometry, Silylation, Carbohydrate.

Abstract

Gas chromatography, coupled with mass spectrometry (GC-MS) as a detection technique, is a powerful analysis tool in the hands of the research chemist. The fundamentals of the technique and its application to the analysis of carbohydrates using volatile derivatives such as trimethylsilyl ethers are described. Mass fragmentation spectra are shown to be useful in indicating carbohydrate ring structure (pyranoside vs furanoside), the reducing nature of the saccharide and the type of some glycoside linkages. The use of methylation and hydrolysis (typically called methanolysis), followed by silylation and GC-MS analysis, is shown to be a useful technique to characterise oligomer and polymeric carbohydrate material (gums and films). The use of these techniques using model compounds and use in one of the Sugar Milling Research Institute’s research programs will be discussed.

Introduction

The new Research Strategy of the Sugar Milling Research Institute (SMRI) has resulted in the creation of SMRI Strategic Research Thrust Areas and the move toward a medium-to-long term research focus (Dewar and Davis, 2007). To enable this shift in focus and achieve the required outcomes requires a commitment to both human and physical resources. As part of this resourcing, the SMRI has invested in new equipment including a gas chromatograph coupled to a mass spectrometer (GC-MS). This is an established analytical tool for obtaining both compound separation within a mixture and structural information on the separated organic compounds. It is used routinely in environmental analysis, forensics (profiling for drugs of abuse), arson analysis, food contamination and for identification and characterisation in the development of new pharmaceuticals.

The coupling of a mass spectrometer as a detector to a gas chromatograph was developed during the 1950s and 1960s (Gohlke and McLafferty, 1993). However, the type and size of the mass spectrometers available precluded their use in routine analysis. It was not until the 1980s, with the advent of the personal computer, that ‘benchtop’ instruments became available and the routine use of GC-MS became commonplace.

Since carbohydrates are thermally unstable, GC is an unsuitable method of analysis, unless the carbohydrate can be modified to make it volatile. The preparation of volatile derivatives such as methyl ethers, acetates and trimethylsilyl (TMSi) ethers was shown to be amenable to GC analysis (McInnes et al., 1958; Gunner et al, 1961; Sweeley et al, 1963).

This development was followed by the use of GC-MS in carbohydrate structural and identification research (DeJongh et al., 1969). Advances in GC-MS equipment and columns have resulted in the method becoming useful in compositional and structural analysis of monosaccharides, oligomers and polymers, especially in the environmental and life sciences fields.
Examples of the diverse use of the method include differentiation of strains of *Streptococcus pneumoniae* based on the capsular polysaccharide (Kim *et al.*, 2005), the identification and quantification of chitin in support of dating in the fossil record (Flannery *et al.*, 2001) and the analysis of plant gums used in works of art to check for forgeries (Bonaduce, 2007). This paper serves as an introduction to the technique and its use within a sugar research environment.

**Experimental**

Samples were prepared using the following methods.

**Permethylation**

Carbohydrate polymers were permethylated using the method of Laine *et al.* (2002). About 20 mg of ground sodium hydroxide and 0.1 mL of methyl iodide were added to 3–5 mg of the oligo- or polysaccharide sample in 0.5 mL dry dimethylsulfoxide. The sample was kept for 30 minutes in an ultrasonic bath at room temperature. Water was added and the mixture was extracted with dichloromethane (1 mL). The organic phase was separated, re-extracted with water, dried (anhydrous sodium sulfate) and evaporated to dryness with a stream of nitrogen at room temperature.

**Methanolysis**

Monosaccharides, permethylated carbohydrate polymers and carbohydrate polymers for compositional analysis were hydrolysed and methylated using the methanolysis method of Ciucanu and Caprita (2007). A solution of 2 M HCl/methanol was prepared by slow addition of 16 mL acetylchloride to dry methanol so that the final volume of the mixture was 100 mL. An aliquot of this solution (2 mL) was added to the sample (either from the previous step or 3–5 mg) in a Reacti-vial and sealed with a Teflon seal. The samples were heated in a ‘hot-block’ at 80°C for 16 h. After cooling, 5 μL of a sorbitol solution (100 mg / 100 mL in methanol) was added to the reaction mixture as an internal standard. The samples were evaporated to dryness using a stream of nitrogen at room temperature.

**Silylation**

The methylated sugars from the previous steps were silylated prior to analysis using a modification of the SMRI method (Anon, 2005a).

**GC-MS Conditions**

The derivatised sugars were separated on a Varian CP3800 GC equipped with a CP8400 autosampler. A Varian FactorFour VF-5ms (crosslinked 5% phenyl-methyl siloxane) column (30 m x 0.25 mm ID with DF=0.25 film thickness) was used. Column flow was set to 1.0 mL/min using helium as the carrier gas. The temperature program started with a temperature of 140°C held for 1 minute, a ramp of 2°C per minute to 218°C, followed by a ramp of 10°C per minute to 280°C. The final hold was two minutes. Injection temperature was 280°C with a splitless injection of 1 μL. The transfer line was held at 280°C and the mass spectrometer had a delay of five minutes. Data were collected over a range of m/z 40–650.

**Discussion**

**Basics of a GC-MS**

A GC-MS consists of four components (Figure 1). A sample containing a mixture of compounds of interest is separated in a GC column. As the separated volatile compounds elute from the column, they are bombarded with electrons within an ion-source in a process termed ionisation. These energetic electrons cause the compound to disintegrate and produce a mixture of positively charged ions in the gas phase. Provided the ionisation occurs under the same conditions, the disintegration will be reproducible. The resultant mixture of ions is accelerated into an analyser where they are separated and sorted from each other according to their mass-to-charge (m/z) ratio...
by manipulation of electrical fields. The sorted ions are collected by a detector and converted to a proportiona
tional electrical current. The data system records the magnitude of these electrical signals as a function of m/z and converts this information into a mass spectrum. The three MS components (ion source, analyser and detector) are housed within a vacuum system to minimise interaction with other molecules.

[Diagram of GC mass spectrometer]

A mass spectrum is a graph of ion intensity as a function of m/z ratio and is often depicted as a simple histogram (shown in Figure 2 for carbon dioxide). This record of ions and their intensities serve to establish the molecular weight and structure of the compound being analysed.

[Graph of mass spectrum of carbon dioxide]

As the CO$_2$ molecule enters the ion source, the electron beam ‘smashes’ some of the CO$_2$ molecules into ionised fragments; all of which are positively charged. The ionised CO$_2^+$ molecule (known as the molecular ion) appears at m/z 44 (the molecular mass of CO$_2$). The ionised fragments appear in the spectrum at m/z values less than the molecular ion.

Cleavage of a carbon-oxygen bond in the molecular ion to produce ionised carbon monoxide (CO$^+$) or ionised atomic oxygen (O$^+$) results in the fragment ions at m/z 28 and 16 respectively. The loss of two neutral oxygen atoms from the CO$_2$ results in an additional fragment at m/z 12 for carbon (C$^+)$.

There are different designs of mass spectrometer analysers, including quadrupoles, ion-traps, magnetic sectors and time-of-flight (TOF). They can not only be interfaced with GCs but can be
used as stand-alone instruments, connected to liquid chromatographs (LC-MS) or inductively coupled plasma spectrophotometers (ICP-MS).

**Analysis of sugars by GC**

A monosaccharide is classified as a triose, tetrose, pentose or hexose according to the number of carbon atoms in the molecule (three, four, five or six). The sugar may have an aldehyde or ketone group attached and these sugars are then termed aldoses or ketoses. Glucose is an example of an aldohexose while fructose is an example of a ketohexose. It can also be shown that monosaccharides can form a ring structure at the aldehyde or ketone. The formation of the ring produces an asymmetric carbon which gives rise to two isomeric forms of the sugar known as the α- and the β- anomers (Figure 3).

![Fig. 3—Anomeric forms of D-arabinose.](image)

A fundamental requirement for the separation and analysis of carbohydrates by GC is that they must be thermally stable and volatile. Carbohydrates must therefore be converted into stable, volatile compounds prior to chromatography. Suitable derivatives can be obtained in a reasonable time using silylation reagents such as hexamethyldisilazane. After silylation, the chromatogram will show multiple peaks of the α- and the β- anomers of the pyranose and furanose rings (Figure 4).

![Fig. 4—GC chromatogram showing separation of TMSi arabinose derivatives showing α- and β- anomers of the pyranoside and furanoside forms.](image)
Multiple mass spectra can be taken across each peak as it elutes from the column. The pertinent features of the mass spectra of the TMSi derivatised sugars are seen in Figure 5. No molecular ion at m/z 438 will be seen for the TMSi derivatised arabinose, as carbohydrate molecular ions are generally unstable. Very little difference can be seen between the \( \alpha \)- and \( \beta \)-furanoside spectra. These anomers have to be identified based on the difference in retention time on the GC column. However, there is a large difference between the pyranoside compared to the furanoside. The main peak at m/z 217 in the furanoside form is reduced in the pyranoside form, and the peaks at m/z 204 and 191 (not present in the furanoside spectrum) appear in the pyranoside form as seen in Figure 5. This characteristic difference in the mass spectrum can be used to distinguish between furanoside and pyranoside forms of a sugar – the presence of only m/z 217 indicates the presence of a furanoside form of the sugar. The peak at m/z 73 is due to the trimethylsilyl compound that replaced all the active hydrogens in the –OH groups in the sugar during derivatisation. Numerous GC and/or MS studies on TMSi carbohydrates have been reported and the mechanism of fragmentation elucidated (Kochetkov and Chizhov, 1966). Each peak in the mass spectrum can be assigned and used to help determine the structure of the sugar.

A direct silylation procedure produces multiple peaks (and thus mass spectra) for each sugar to be analysed. The number of glycoside peaks, their retention times and relative proportions are characteristic of each monosaccharide. If a mixture of sugars is analysed, a rather complex chromatogram results; however, the high efficiency provided by capillary GC columns generally permits satisfactory separations of the peaks to be achieved. Figure 6 shows a typical chromatogram for a mixture of TMSi sugars.
Compositional analysis of carbohydrate polymers

The analysis of carbohydrate polymers by GC is complicated by the reduced volatility of derivatised polymers.

The very high temperatures required to elute the compounds from the GC column simultaneously degrade and decompose the polymers.

Compositional analysis using GC-MS requires the polymer to be hydrolysed into its constituent sugars which can then be analysed as described.

Both chemical and enzymatic hydrolysis methods exist with the former being the ‘brute force’ method resulting in a mixture of monosaccharides, while the latter is very specific for a particular linkage and uses milder conditions.

The chemical method is ideal for compositional GC-MS preparation as all the sugars are released. A typical method would use an acidic solution of methanol with the sample being heated at 80°C for 16–20 hours—a method known as methanolysis (Bleton et al., 1996).

A methyl group attaches to the carbohydrate hydrolysed from the polymer. After complete hydrolysis, the sample is dried, silylated and analysed.

The resultant chromatogram will show most of the individual carbohydrates that made up the carbohydrate polymer. This process is shown for pullulan in Figure 7.

The mass spectrum of the two peaks shown in Figure 7 confirms that glucose is the only carbohydrate found in pullulan. Note also the presence of m/z fragments at 191, 204 and 217 indicating a pyranoside form of the ring.
Fig. 7—Methanalysis of pullulan showing hydrolysis and methylation at position 1 and resultant chromatogram after silylation showing only pyranoside glucose peaks.

If the carbohydrate were to contain sugars other than glucose, these would also be seen in the chromatogram and could be identified. An example would be xanthan gum (used to thicken sauces) which has a glucose backbone and a trisaccharide side chain consisting of mannose (with substituents) and glucuronic acid (Figure 8).

Fig. 8—Chromatogram from the methanalysis of xanthan gum showing the compositional sugars – glucose, mannose and glucuronic acid.
Structural analysis of carbohydrate polymers

The methanolysis method described above will only give the researcher compositional information about a carbohydrate polymer.

When studying the structure of an unknown polysaccharide, several questions arise: how many constituent monosaccharides does it contain, in what order are they linked; does it have a branched or linear structure; are the sugars in the pyranose or furanose form; and are the glycosidic linkages α- or β- or a mixture of the two?

There are many classical methods to determine the linkage between the sugars including methylation, the Barry degradation (Barry, 1943) and the Smith degradation (Smith and van Cleve, 1955) being the most common.

The aim of these techniques is to produce a series of derivatives which requires separation and can be used to identify the ring size and linkage position. These techniques are time consuming and require reasonable quantities of sample for analysis.

The resolving power and sensitivity of GC-MS techniques allows for very small quantities of these derivatives to be prepared and analysed.

The method adopted in our laboratories uses a methanolysis procedure based on the use of methyl iodide in dry dimethyl sulfoxide solution, extraction of the methylated polymer, followed by methanolysis and silylation (Laine et al., 2002).

Methylation adds a methyl group to all free hydroxyl groups on the sugar. Methanolysis will hydrolyse the sugar leaving a free hydroxyl group on the sugar which can then be silylated.

The position of the TMSi group will indicate where the sugar was joined to its neighbour. The structure of the sugar containing both methyl and TMSi groups can be determined by GC-MS and the position of the TMSi group will indicate the linkages on the particular sugar.

Dextran is a straight chain glucan consisting of α-1,6 glycosidic linkages between glucose molecules, with branches beginning from α-1,3 linkages (Figure 9, top).

Methylation of the dextran results in all the free hydrogens on the –OH groups being replaced by a methyl group (Step 1).

This is followed by methanolysis (Step 2) to yield the free methylated sugar with the methyl group on carbon 1 being in either the α- or the β- form (shown in the figure as –OMe horizontal on the page).

The other side of the bond now has a free –OH group which can be silylated (Step 3) to form the TMSi derivative.

Note that the glucose that had three other glucose units attached at the beginning of the branch now has two TMSi groups while the terminal glucose on the branch has no TMSi groups.

This results in three derivatised glucose units: 2,3,4-trimethyl-6-TMSi glucose, a lesser quantity of the terminal derivative 2,3,4,6-tetramethyl glucose and very small amounts of the linkage glucose, 2,4-dimethyl-3,6-TMSi derivative.
Fig. 9—Diagram showing the method of structural analysis using dextran as a model compound. The steps include methylation (Step 1), methanolysis (Step 2) and silylation (Step 3) to produce methylated, TMSi derivatives dependent on the position in the polymer.
The resultant chromatogram and two of the mass spectra from this scheme are shown in Figure 10. The mass spectra are quite different and the peaks easily identified.

![Chromatogram](image)

**Fig. 10**—Chromatogram resulting from the derivatization scheme shown in Figure 9 (top). Mass spectra of the 2,3,4,6-tetramethyl- and 2,3,4-trimethyl-6-TMSi glucose peaks (lower).
Based on the derivatives produced and the height of the peaks, it is possible to postulate that the dextran contains a small quantity of glucose that has linkages on the 3 and 6 position (based on the 2,4-dimethyl-3,6-TMSi derivative), a larger quantity of terminal glucose units (based on the 2,3,4,6-tetramethyl derivative) and most of the polymer consists of 1–6 linkages (based on the 2,3,4-trimethyl-6-TMSi derivative). Quantitation of the peaks is possible giving a ratio of each of the forms present.

In order to determine the retention time and mass spectra of each of the possible linkage combinations, a variety of di- and trisaccharides of known structure can be analysed by the method and a database of results accumulated. Table 1 is an abbreviated list of some of the compounds that can be used as examples for model linkages.

Table 1—Abbreviated list of compounds that can be used to illustrate model linkages for structural composition of carbohydrate polymers (coloured groups indicate different monosaccharides).

The practical use of the techniques in carbohydrate research

As part of the strategic research thrust, SMRI has been investigating the phenomenon of refractory (‘hard-to-boil’) massecuites.

Polysaccharides (gums) have been implicated as a possible contributing factor to this problem (Koster et al., 1992; Duffaut and Godshall, 2004; Eggleston and Cote, 2008) and, therefore, SMRI researchers wished to study the composition of the polysaccharides in the refractory materials.

The initial study included eight samples of refractory and normal B molasses collected from four South African mills. The massecuites were deemed normal or refractory by mill personnel based on low molasses exhaustions which subsequently resulted in high target purity differences and recovery losses.

Analyses on the samples included haze dextran, gums, starch, consistency, sulfated ash, sucrose, glucose, fructose and brix. The gums were isolated using the SASTA method for gum determination (Anon, 2005b) and the composition analysed using methanolysis and silylation as described.

Selected results are shown in Table 2 while a chromatographic comparison between one of the normal and abnormal massecuite pairs is shown in Figure 11.

The refractory samples showed both increased consistency and concentration of gums compared to the normal samples. GC-MS analysis of the gums showed that, while all gum samples contained arabinose, mannose, galactose, glucose and traces of gluconic acid, the amount of arabinose, xylose, and galactose decreased in the ‘hard-to-boil’ samples while glucose and mannose increased. Structural analysis of the gums is continuing in an effort to understand the causes of this phenomenon.

Fig. 11—Chromatograms comparing a normal (upper) and ‘hard-to-boil’ massecuite (lower).

Conclusion
Gas chromatography, coupled with mass spectrometry as a detection technique, has been shown to be a powerful analysis tool. Although the fundamentals of the technique are easily understood, it is only with modern PC-based equipment that the applications have become commonplace. The application of the chemical derivatisation methods (methylation and
methanolysis), combined with the sensitivity and selectivity of the GC-MS instrument, is allowing a new understanding in research problems of oligomer and polymeric carbohydrate compounds within the SMRI research program and is complementary to other analysis methods.

Resumen
LA CROMATOGRAFÍA de gases acoplada con espectrometría de masas (GC-MS) utilizada como una técnica de detección, es una poderosa herramienta de análisis para investigaciones químicas. Los fundamentos de esta técnica de análisis así como su aplicación son descritos para el análisis de carbohidratos usando derivados volátiles tales como el trimetil silil éteres. Se presenta el fragmento de un espectro de masas que puede ser usado como un indicador de la estructura del anillo (piranosá vs furanosá) de los carbohidratos, ó para establecer la naturaleza reductora de los sacáridos como también para establecer el tipo de algunos enlaces glicosídicos. El uso de la metilación y la hidrólisis (típicamente conocida como metanólisis) seguido por sililación y análisis GC-MS se presenta como una herramienta útil para caracterizar carbohidratos tales como polímeros y oligómeros (gomas y películas). Se presenta el uso de estas técnicas usando un compuestos típicos y su aplicación en uno de los programas de investigación del Sugar Milling Research Institute.
STUDIES OF LONG-TERM STORAGE OF HIGH QUALITY RAW SUGAR

By

V. KOCHERGIN

Audubon Sugar Institute, Louisiana State University AgCenter, St. Gabriel, LA, USA

vkochergin@agcenter.lsu.edu

KEYWORDS: VHP Sugar, Storage, VLC Sugar.

Abstract

AlTHOUGH existing contracts do not provide sufficient economic justification to increase raw sugar quality, the trend of manufacturing better quality raw sugar in the mills will likely continue. Relatively few studies have been conducted on storage of VHP (very high pol) and VLC (very low colour) sugars, especially when the storage period approaches 9–10 months. Monitoring of commercial sugar shipments indicated that, after an initial relatively safe period of storage, sugar colour might double or even triple in a short period of time. Large experimental piles of VHP and VLC sugar were monitored in two sugar mills with different crystallisation sequences (conventional and double magma) for two consecutive seasons. Temperature and relative humidity probes were placed up to 15 m inside the piles. Samples were taken periodically to evaluate the effects of storage conditions on colour, purity, invert content and other parameters. It was concluded that sugar of high quality stores better compared to conventional sugar. However, even VHP sugar can double its colour during long-term storage. Sampling near the surface of the sugar pile (up to 1.5 m inside the pile) is not representative of the bulk of sugar. It has been found that sugar temperature follows the ambient trend as deep as 3 m inside the pile. Sugar within 1.5 m of the surface that was not subjected to temperature increase stored well compared to sugar in the core of the pile. It is unclear what conditions trigger colour increase in storage. Changes in temperature profiles of raw sugar during storage in commercial warehouses indicate that some exothermic reactions take place in the core of the piles that result in colour increase and pol reduction. The reactions take place even when the initial sugar moisture and temperature meet the requirements accepted for safe storage (safety factor below 0.25 and temperature below 30°C). Lower sugar pH may be one of the reasons that makes sugar less stable in storage. Options of cooling sugar before or during the storage will be considered in future research.

Introduction

The increasing price of fossil fuels creates an impetus to manufacture better quality raw sugar in the mills that utilise renewable fuel (bagasse). In an analysis of impacts of high quality raw sugar on refinery parameters, Al Ghurair and Hikmat (2005) demonstrated that the transition from conventional raw sugar (98.4 pol and 3800 ICUMSA colour) to VHP sugar (99.4 pol and 800 ICUMSA colour) resulted in the elimination of the affination process, a reduction in low grade massecuite handling and consequent savings in energy and utilities. Various specifications of high quality raw sugar are used throughout the world resulting in different terminology. A detailed summary of the specifications and contracts can be found in Rein (2007).

Most Louisiana sugar mills use a conventional three boiling scheme and produce raw sugar within the range of specifications: pol 98.5–99.0 and colour 2000–3000 IU (pH 8.5). Several mills that use a ‘double magma’ boiling scheme have the capability of producing VHP and VLC sugar, but existing contracts do not provide sufficient motivation to do it. It is noteworthy that the values for colour measured at pH 8.5 are sometimes twice as high compared to values obtained at pH 7.
(following ICUMSA procedure). Louisiana millers produce sugar that is close to VLC specifications if the standard ICUMSA procedure is applied. The VHP and VLC sugar specifications for the purpose of the current paper are: colour 2000 IU (pH 8.5) and polarisation exceeding 99.2.

Because of the relatively short grinding season in Louisiana, raw sugar may be stored for 9–10 months. Historic data on conventional quality sugar indicate that colour increases significantly during storage with a relatively low decrease in pol (Kochergin and Saska, 2008). A typical curve illustrating colour increase in storage of conventional sugar is shown in Figure 1. It is generally accepted that a correlation exists between the colour and pol of the raw sugars. The expectation is, therefore, that production of VHP sugar automatically results in VLC sugar. This statement may be valid for freshly produced sugar, but does not necessarily apply for stored sugars.

![Figure 1](image-url)  
**Fig. 1**—Colour increase in storage typical for Louisiana sugar mills; shipment dates range from November through September of the following year.

Figure 2 presents the data collected from four Louisiana mills during production and storage seasons. Although the trend line follows the expectations, the low value of the correlation coefficient indicates that colour-pol relationships have to be treated with caution.

Consequently, production of low colour sugar does not guarantee colour preservation during storage.

The majority of the information on changes in sugar quality during long-term storage is related to refined sugar where sugar is stored in silos and bins without contact with ambient air (Mikuš and Budiček, 1986).

Limited data are available on storage of raw sugar, especially of high quality. Early investigations of quality change of raw sugars in long-term storage (Kopfler, 1933) demonstrated four to five-fold colour increase after 6–7 months of storage of sugar with 97 pol and 0.6–0.7% moisture.

Preferential destruction of glucose observed in the tests implied microbiological origin of sugar deterioration. The present analysis of degraded sugar syrup collected from the floor of a raw sugar warehouse showed a fructose/glucose ratio of 2, confirming rapid destruction of glucose. In a discussion on raw sugar storage, Honig (1963) attributed sucrose deterioration to bacterial activity, emphasising the importance of producing low moisture sugar for good storability.
Information on long-term storage effects on high quality raw sugar is scarce. Interpolating between two extreme cases of storage of white and conventional raw sugar, it is logical to assume that high quality sugar would store without significant colour increase. Investigating storage behaviour of VHP sugar, Kimmerling (1975) reported that ‘with the exception of moisture pick-up in the crust and a very slight colour deterioration therein, no deleterious effects were observed on VHP sugar stored in the silo for six months’. However, no quantitative data, besides sugar moisture and ambient relative humidity, were presented. South African technologists reference storage of 99.3 pol sugar for 6 months with a colour increase of 5–20% (Rein, 2007). Chen and Chou (1993) referenced a Hawaiian report that VLC sugar could be stored safely at low moisture. Data on accelerated storage of raw sugar in small closed containers indicate that colour of VHP sugar can be increased by simply holding it at elevated temperature, e.g. 70°C (Kochergin and Saska, 2008). Any colour changes at this temperature would most likely have chemical rather than bacterial origins. Most researchers agree that the colour changes happen within the thin film of molasses surrounding the sugar crystals. Payne (1987) insists that colour changes are happening within sugar crystals as well. The rate of such changes would be conceivably slower than that in the molasses film.

The main goal of the current study was to monitor storage of VHP and VLC sugar in factory warehouses. It was important to assess if sugar specifications could be kept constant throughout the grinding and storage seasons.

**Experimental procedures**

**Grinding season 2007–08**

Enhanced washing procedures were used at two Louisiana sugar mills to produce VHP and VLC sugar. Both mills started production of higher quality sugar in the beginning of November, 2007. Sugar was allowed to stay in the warehouse for the maximum practical storage time (about 300 days) before shipping. Five thousand tonnes of VHP/ VLC sugar were produced at Mill A with a conventional three-boiling configuration. Mill B with a ‘double magma’ boiling configuration produced two smaller piles next to each other in the same warehouse. Each pile contained about 300 tonnes of VHP/VLC and conventional quality sugar, respectively. All produced sugar satisfied the safety factor requirements for storage (safety factor below 0.25). Sugar samples were taken every 3–4 weeks at three different depths from each pile, namely, top crust (15–20 mm), immediately under the top crust (>20 mm) and at a depth of 0.3–0.4 m. Each sugar sample was prepared by blending 5–6 samples taken from positions around the pile about 3 m apart.
auger was used to take samples from 0.3–0.4 m deep in each pile. It was difficult to obtain samples from larger depths due to friction. After several months of storage, another sampling procedure was added at Mill A. Samples were collected about 1.5–2 m inside the pile at the bottom using a front end loader. The following parameters were measured for each sample: pol, moisture, ash, fructose, glucose and colour at pH 7 and pH 8.5.

HOBO data loggers (model U12-011, Onset Computers, Bourne, MA, USA) were installed right above the surface of the pile and at 1.5 metres depth, respectively, to record temperature and relative humidity (RH). The sensor submerged in sugar was placed inside a perforated pipe covered with a porous plastic screen to protect the sensor from immediate contact with sugar. Thus, air parameters at equilibrium with raw sugar were measured. Battery operated sensors recorded the RH and temperature every two hours throughout the whole storage period.

**Grinding season 2008–09**

The test program was continued during the 2008–09 grinding season. Mill B (double magma boiling configuration) produced 5000 tonnes of VHP and VLC sugar in the beginning of November 2008 and stored it until June 2009. From the results of the previous season, it was difficult to conclude whether the samples were truly representative of the entire bulk of sugar in the pile. Sampling procedures were modified to obtain samples deeper into the pile. A gas-powered auger model EA-400 (Echo Inc., Lake Zurich, IL, USA) was used to obtain composite samples from a 1.5 m depth. The auger was driven into the sugar pile through an opening in the bottom of a stainless steel bucket. When the auger was slowly removed without changing rotation, the bucket gradually filled with sugar representing a 1.5 metre cross-section of the pile. Two samples were collected from different spots to produce a composite sample for analysis. The samples were analysed for pol, purity, ash, glucose, fructose, colour and moisture.

To evaluate temperature and RH changes in the core of the pile, five RH-temperature sensors were installed inside a sectioned 10 cm diameter pipe positioned according to the diagram in Figure 3. Four sections of the pipe at various depths had cut-outs covered with plastic screens. The sensors were located at the depths of 0, 3, 7, 5, 10 and 15 m, respectively. The probe at 0 m was monitoring ambient conditions. Recorded data were periodically downloaded to a computer through connected USB cables.

**Analytical procedures**

Standard ICUMSA procedures were followed for measuring sucrose polarisation, brix and conductivity ash. Sugar colour was analysed according to the ICUMSA Method GS1/3-7(2002) at pH 7.0, and at pH 8.5; the latter measurement is required by contracts accepted in the USA. Glucose and fructose were analysed using Dionex DX-500 HPLC with Carbopac PA-100 columns and a
pulsed amperometric detector following ICUMSA Method GS1/2/3-4(1998) with lactose as the internal standard. All HPLC measurements were performed in duplicate.

Sugar moisture was determined by drying at 105°C under vacuum, for four hours. Initially, sugar pH was measured at about 16 brix, which was a convenient dilution for colour measurement. As a result, sugar pH values were not recorded at constant brix.

Separate dilutions were made for samples obtained later in the season, and the measurements were performed at 50 brix.

Results and discussion

Grinding season 2007–08

Colour changes in the samples collected 0.3–0.4 m below the top crust are shown in Figure 4. As expected, sugar colour in Mill A (using conventional three-boiling scheme) was almost twice as high as in Mill B with a ‘double magma’ configuration, and was very close in quality to conventional sugar produced in Mill B.

Rates of colour rise were similar in both cases. Since sugar colour was expected to be kept at or below 2000 ICUMSA units (pH 8.5), the results at Mill A were slightly higher than desired. Little change was noticeable in colour of sugar stored at Mill B throughout the season.

Data demonstrated that additional washing in a ‘double magma’ configuration allows production and maintenance of the sugar quality within the desired limits. However, wash water requirements and the associated sugar losses need to be evaluated.

![Fig. 4—Colour changes during 2007–08 grinding season at 0.3–0.4 m depth and at 1.5 m depth).](image)

Measurements at different depths in the pile are illustrated by curves in Figure 5. In all cases, the colour of the top crust changed significantly, with the most pronounced effect after 3–4 months of storage. The first several months corresponded to the time of storage when the ambient temperature was lower than that of the sugar.
Fig. 5—Colour changes at various depths in VHP sugar (Mill B).

Top crust (about 15–20 mm) has higher colour and moisture than the rest of the sugar. The crust is formed of fine dust particles that settled after sugar slinging.

Measurements showed that product sugar crystals (800 µm) have four times less colour than the fine fraction (less than 250 µm).

The results in Figure 4 show changes in colour at various sampling depths at Mill B. Colour of sugar directly under the crust is no different from sugar at a 0.3–0.4 m depth.

The same trend was observed in all sampled piles. The crust appears to work as a protective layer; this phenomenon was also mentioned by Kimmerling (1975).

Depending on ambient conditions, crust may be very hard (observed in January and February) or soft, but always different from the rest of sugar.

The changes in ambient conditions (temperature and RH during the trials) are reflected in Figures 12 and 13.

A reduction in both sugar polarisation and apparent purity was observed in all stored samples (Figures 6 and 7). The pol of conventional sugar in Mill B was slightly higher than that in Mill A, although the rate of deterioration was similar. Differences in degradation rates are difficult to discern due to the data dispersion. However, the pol and purity drop of 0.3–0.4 points should be considered significant.

Changes in concentration of reducing sugars (Figure 8) do not reveal if sucrose deterioration was caused by inversion or degradation reactions that have gone further.

Trends in Figure 9 represent the ratio of fructose to glucose (F/G) in stored samples at various depths.

While the F/G ratio fluctuated around unity (which was expected for sugar inversion), the crust samples showed drastically different F/G ratios, consistently below this level, reaching a value of 0.3.

This indicates that fructose was preferentially consumed in browning reactions.
Fig. 6—Changes in sugar polarisation (depth of 0.3–0.4 m and 1.5 m).

Fig. 7—Changes in sugar purity (depths of 0.3–0.4 m and 1.5 m).
Fig. 8—Change in the concentration of reducing sugars (depths 0.3–0.4 m and 1.5 m).

Fig. 9—Fructose/glucose ratio at Mill A.
Changes were observed in sugar pH (Figure 10). Sugar pH was not routinely measured at the beginning of the storage period. The pH trend showed a gradual decrease toward the end of storage, coinciding with observed pol decreases. The lowest pH was observed in the regular sugar at Mill B, followed by samples at Mill A. Mill B VHP sugar was the closest to neutral pH. These were also the samples that showed minimal deterioration. It is difficult to discern if low initial pH might
cause enhanced sugar degradation. It is conceivable that low pH in the molasses film could gradually invert sugar causing a further pH decrease. Sucrose inversion consumes water but further degradation reactions actually release water, which should result in increased sucrose moisture. Moisture changes observed during the study (Figure 11) do not provide reliable support to this hypothesis. Moisture content of the samples is also influenced by water migration in and out of the pile. Analysis of highly deteriorated sugar samples always shows increased moisture content. Moisture levels in the crust increased as high as 1–2% at the end of storage.

Fig. 12—Temperature change inside and outside the sugar pile.

Fig. 13—Change in RH during storage period.
Analysis of daily records of RH and temperature indicates that the top several metres of sugar act as an ‘insulation’ layer, protecting the bulk from sudden temperature or humidity swings.

The monthly temperature averages represented in Figure 12 show temperatures 1.5 m inside the pile follow the temperature trend outside the pile quite closely (sugar gradually cooled down from an initial 30 to 20°C). When the ambient temperature increased, sugar temperature started to rise as well. However, it never reached the initial sugar temperature. The graph in Figure 13 illustrates a continuous increase of RH both inside and outside the sugar pile (Mill A).

Moisture transfer is a function of vapour pressure, which is closely approximated by absolute humidity. Thus, the difference between absolute humidity of ambient air and the air inside the pile can give an indication of the direction of moisture transfer. The values for absolute humidity in Table 1 were determined from a psychrometric chart based on RH and temperature readings for several points during storage.

<table>

</tr>
</tbody>
</table>

Initially, absolute humidity of air in equilibrium with sugar was higher than that of ambient air, which meant that sugar tended to release some moisture to the atmosphere which will be migrating out of the pile. Later in the season, sugar was unlikely to lose moisture, because ambient humidity is higher. Sugar moisture levels (Figure 11) did not vary much toward the end of the storage season.

**Grinding season 2008–09**

Analytical results listed in Table 2 show that sugar colour in the composite samples remained virtually unchanged during storage. However, the samples collected from the bottom of the pile before shipping showed that colour almost doubled.

Samples taken during the loading/shipping of VHP pile 50 Bx
This may be explained by reviewing the temperature profiles presented in Figure 14. After an initial stable storage period, sugar temperatures started rising well above the initial values. The reading from 3 m inside the pile followed the ambient temperature trend (Figure 15). The greatest temperature rise was observed at the depths of 5 and 10 m. The probe located near the bottom of the pile floor measured a lower gradient due to heat transfer to a cooler floor surface.

Temperature rise in the pile and corresponding colour change imply that exothermic reactions take place even at low moisture and high pol. Relatively low pH was observed in all samples and no changes in pH were observed during the storage period. Fructose to glucose ratios were also different compared to results from the 2007–08 season. The fact that sugar as deep as 2 m inside the pile can store without deterioration implies that such conditions can be reproduced if mechanisms causing sugar degradation are better understood. The study will be continued with the emphasis on changes that need to be made to production to assure that high quality sugar can be stored reliably without deterioration.
Conclusions

- Sugar of high quality stores better compared to conventional sugar. However, even VHP sugar can double its colour during long-term storage.
- Sampling near the surface of the sugar pile (as deep as 1.5 m inside) is not representative of the bulk of sugar.
- It is unclear what conditions trigger colour increase in storage. Lower sugar pH may be one of the reasons that makes sugar less stable in storage.
- Sugar temperature follows the ambient trend as deep as 3 m inside the pile.
- Exothermic reactions take place inside the pile even when initial sugar moisture and temperature meet the requirements accepted for safe storage (safety factor below 0.25 and temperature below 30°C).
- Sugar within 1.5-m of the surface that was not subjected to temperature increase stored well compared to sugar in core of the pile. Options of cooling sugar before or during the storage will be considered in future research.

Acknowledgments

Author is grateful to the American Sugar Cane League (Thibodaux, LA) for providing funding for the project and to the personnel of Louisiana sugar mills for their continuous support of the test program. The contribution of Iryna Tishechkina, Dr. Lee Madsen and the analytical group of the Audubon Sugar Institute is greatly appreciated.

MOTS CLEFS: Sucre VHP, Emmagasinage, Sucre VLC

Résumé
BIEN QUE les contrats existants ne fournissent pas une justification économique suffisante pour améliorer la qualité du sucre brut, les usines continueront très probable à produire un sucre de bonne qualité. Relativement peu d'études ont été menées sur l’emmagasinage à long terme du VHP (pol très élevé) et des sucres VLC (couleur très faible), en particulier lorsque la période de stockage approche 9–10 mois. On a suivi les transports outre-mer de sucres commerciaux ; cela a indiqué que, après une période relativement stable, la couleur du sucre peut doubler ou même tripler en peu de temps. On a aussi suivi des sucres VHP et VLC stockes en vrac dans deux usines avec des systèmes de cristallisation différents (magma conventionnel et double) pendant deux saisons consécutives. Des sondes de tempéature et d’humidité relative ont été placées jusqu'à 15 m à l'intérieur des tas. Des échantillons ont été collectes régulièrement pour évaluer les effets des conditions de stockage sur la couleur, la pureté, la concentration de sucres invertis et d'autres paramètres. Il a été conclu que le sucre de haute qualité stocke mieux par rapport au sucre conventionnel. Toutefois, même le sucre VHP peut doubler sa couleur pendant le stockage à long terme. L’échantillonnage près de la surface du tas de sucre (jusqu'à 1,5 m à l'intérieur) n'est pas représentatif de la majeure partie de sucre. Il a été constaté que la température du sucre suit la tendance ambiante jusqu'à 3 m à l'intérieur du tas. Le sucre à 1,5 m de la surface qui n'était pas soumis à une hausse de température se conserve mieux que le sucre dans le coeur du tas. On ne sait pas quelles conditions déclenchent une augmentation de la couleur au stockage. Les changements de température du sucre brut au cours du stockage dans les entrepôts commerciaux indiquent que des réactions exothermiques se déroulent dans le cœur du tas ; cela donne une augmentation de la couleur et une réduction du pol. Les réactions ont lieu même lorsque la teneur initiale en eau dans le sucre et la température sont conformes aux exigences acceptées pour garantir la sécurité du stockage (facteur de sécurité < 0,25 et température inférieure à 30 °C). Un pH bas pour le sucre peut être une des raisons qui rend le sucre moins stable pendant le stockage. Le refroidissement du sucre avant ou pendant le stockage sera considéré dans le future.
ESTUDIOS DE ALMACENAMIENTO POR LARGO TIEMPO DE AZÚCAR CRUDO DE ALTA CALIDAD.

PALABRAS CLAVES: VHP (Azúcar de Alto Pol), Almacenamiento, VLC (Azúcar de Bajo Color).

Resumen

Los contratos actuales de compra de azúcar, no tienen suficiente justificación económica para incrementar la calidad del azúcar crudo, sin embargo la tendencia actual es la producción de azúcar crudo de mejor calidad. Pocos estudios se han llevado a cabo sobre el almacenamiento a granel de azúcar de alto pol (VHP) y azúcar de bajo color (VLC), especialmente cuando el período del almacenamiento está entre 9 y 10 meses. Monitoreos realizados a cargamentos comerciales de azúcar, indicaron que después de un relativo seguro periodo inicial de almacenamiento, el color del azúcar se puede duplicar o incluso triplicar en un corto tiempo. Grandes arrumes experimentales de azúcar grados VHP y VLC obtenidos a partir de dos esquemas de cristalización (convencional y doble magma) fueron monitoreados en dos ingenios azucareros durante dos zafra consecutivas. Medidores de humedad relativa y temperatura fueron colocados hasta 15 m al interior de las pilas. Muestras de azúcar fueron tomadas periódicamente para evaluar los efectos de las condiciones de almacenamiento sobre el color, la pureza, contenido de azúcares invertidos, y otros parámetros. Se concluyó que el azúcar de mejor calidad se almacena mejor que el azúcar convencional. Muestras de azúcar tomadas cerca de la superficie (hasta 1.5 m al interior de la pila) no son representativas del comportamiento del azúcar a granel. Se encontró que la temperatura del azúcar sigue la tendencia de la temperatura ambiente hasta una profundidad de 3 m al interior de la pila. Azúcar a 1.5 m de la superficie que no estuvo sujeta a incrementos de temperatura durante el almacenamiento se almacenó mejor que azúcar que estaba en el centro de la pila. No se identificaron las condiciones de almacenamiento que incrementan el color del azúcar. Los cambios en el perfil de temperatura del azúcar crudo durante el almacenamiento en bodegas comerciales, indican que algunas reacciones exotérmicas están ocurriendo en lo más profundo de la pila que ocasionan incrementos de color y reducción de pol. Estas reacciones toman lugar incluso cuando la humedad inicial y temperatura del azúcar cumplen con los requisitos aceptados para un almacenamiento seguro (valor de seguridad menor a 0.25 y temperatura menor de 30°C). Uno de los factores que hace menos estable el azúcar durante su almacenamiento es el pH bajo. Alternativas para enfriar el azúcar antes o durante el almacenamiento.
MODIFIED SINGLE SULFITATION PROCESS FOR PRODUCING BETTER QUALITY PLANTATION WHITE SUGAR

By

V.M. KULKARNI
V.M. Biotech, Pune, India
vmbio@vsnl.com

Abstract

The presence of sulfur in sugar, apart from making it potentially harmful for human consumption, causes the sugar to deteriorate at a faster rate during storage. These issues and the steep rise in sulfur prices, albeit temporary, have brought to the fore the need to reduce the sulfur dosage used in the production of plantation white sugar (PWS). The process generally used in the production of PWS (in addition to juice sulfitation) is syrup sulfitation, which reduces sugar colour by a further 6–15%. However, this reduction in sugar colour is short-lived and it also reduces the pH of the syrup, with the result that subsequent manufacturing processes are carried out under acidic conditions. Because of this, there could be significant sugar losses from sucrose inversion. The use of suitable biocides for cane and mill sanitation has been shown to reduce the acidity of the mixed juice, as also the quantum of the high molecular weight polymeric compounds in the sugar and the molasses. In view of these observations, a new process (the VMK process) was developed to produce PWS without resorting to syrup sulfitation, namely, a single sulfitation process using a polymer together with appropriate biocides that reduce impurities and colour by about 12–15%. This process was tried in a full season of about 100 days in a 2500 tcd factory where 25000 t of sugar was produced with colour below 80 IU. Further improvement in sugar quality was also achieved with the help of an on-line colour monitoring unit, WG Colormet 1.0, as well as through tight control on chemical consumption, especially that of lime and sulfur. The quality of the sugar, which was consistently achieved, showed colour to be <55 IU, conductivity ash <0.015%, calcium <30 ppm, pol >99.85, and dextran and sulfur below detectable limits. The colour transfer index was found to be 130:1 from clear juice to final sugar, as against the reported index of 100:1 from A massecuite to sugar. Based on these findings, a patent has been filed for the VMK process for the production of good quality PWS.

Introduction

Sulfur dioxide (SO$_2$) is a toxic gas. When it is used during the manufacture of any food product, residual traces of sulfur remaining in such food product may be hazardous to human health. Hence the use of SO$_2$ is always restricted. The food industry does not permit or recommend the use of any sulfur compounds for food preservation.

In the sulfitation process, the use of the sulfur burner is difficult as it causes the toxic SO$_2$ to be released into the atmosphere, leading to serious environmental pollution because of this potent greenhouse gas. It can also create health problems for the workers handling the sulfur burners.

Although the sugar manufactured through syrup sulfitation has low colour and good ‘lustre’ initially, it loses both the colour and the ‘lustre’ within a few months. Depending on storage conditions, the colour can increase from 60 IU to 100 IU or even 120 IU within 6 to 10 months. There are several reasons for this deterioration, but one of the main reasons is sulfur. When first
applied, SO₂ bleaches the syrup, reduces the iron present in the juice and makes it colourless, resulting in a low colour sugar. However, this is only a temporary effect. The colour returns with time, as the remaining iron compounds oxidise into dark-coloured compounds. In addition, the sugar retains high sulfur content.

Sulfur dioxide is first used to treat the juice, which helps in the clarification process. Then it is again used in syrup treatment. The latter treatment is known to reduce the viscosity of the syrup / massecuite and improve molasses exhaustion. It also reduces the pH to pH 5.5 or less depending on how much SO₂ is used. Hence, the crystallisation process is carried out in an acidic environment; this favours sucrose inversion, which, in turn, affects sugar recovery. The quantum of sulfur in the sugar produced in good sugar factories is about 15 ppm (the highest permissible level), but it can be over 25 ppm in the sugar produced by others.

The treatment of the syrup with SO₂ is known also to reduce sugar colour by just 6–15% (Keskar, 2009, pers. comm.; Londhe, 2009, pers. comm.). However, significant amounts of sulfur end up in the molasses which may be used for producing alcohol by yeast fermentation. Sulfur affects the fermentation of the molasses by inhibiting the growth of the yeast. Moreover, traces of the sulfur that get into the alcohol make it unsuitable for use as a fuel supplement, as also for use in the liquor and pharmaceutical industries, unless further refinements are carried out to remove these impurities.

Thus the use of SO₂ in syrup does not provide any significant benefit. Further, whatever benefit does result lasts only for a short period of time. This realisation prompted the development of an alternative technology that would avoid at least syrup sulfitation and help in producing good quality sugar.

The use of appropriate biocides in proper doses is known to limit the microbial degradation of mixed juice and hence limit any reduction in the acidity of the primary and mixed juice and prevent the formation of degradation products like polysaccharides (Kulkarni, 2004). Further, the need for additional lime is prevented and the level of residual calcium as soluble organic calcium salts in the clear juice is not increased. Similarly, there is some reduction in the rise in the colour of juices (Kulkarni and Warne, 2004).

Any reduction in polysaccharide content can play a significant role in molasses exhaustion, especially when syrup sulfitation is avoided. The use of appropriate biocides in the process can control the rise in this polysaccharide content; however, polysaccharides already present in the sugarcane and formed during the cut-to-crush delay will obviously get concentrated. The use of a mixture of crystal mobilisers, crystal developers and viscosity reducers can help to improve the pan output, as well as in better exhaustion. Such a formulation is also known to reduce sugar colour by about 12% (Kulkarni and Pallod, 2005). Thus, even when syrup sulfitation is avoided, its benefits can be more than matched by using appropriate biocides.

New single sulfitation process—VMK process

A new process has been developed, which requires only a slight modification to the existing process. It seeks to prevent the entry of impurities into the process. This is done by using appropriate chemicals in proper doses at the right stages of the process. Some of the currently used chemicals are replaced in the new process with more appropriate chemicals while others are new as identified in Table 1. Apart from the changes in the chemicals, the only modification needed in the process is the isolation and shutting down of the sulfur burner for the syrup.

Chemicals used in the VMK Process

Polmax Supreme is used for cane sanitation by spraying onto prepared cane at 2–5 ppm before the cane enters the fiberisor hammer. It consists of various salts of methyl and ethyl dithiocarbamates, organo-sulfur based activator and penetrating agents and has an active ingredient concentration of 40%. Up to 90% of the microbes are killed in just one minute of the spraying if Polmax Supreme is sprayed onto the cane at 10 ppm.
Polmax ESR is used for mill sanitation. It is added continuously at 10 ppm with the application split between all mills after the 2nd mill. It is a chemical formulation of various salts of methyl and ethyl dithio-carbamates and has an active ingredient concentration of 40%. At a dosage of 10 ppm, 90% of the microbes in the cane juice are killed in 10 minutes.

** Saving is more as sulfur consumption is less than 0.017%

Sucolor is used as an impurity-removing agent. It is added continuously at 10 ppm in the clear juice receiving tank. It is a special polymer of coco-di methyl amine, which reduces the affinity of various impurities to attach themselves to the sucrose crystal lattice during growth. Thus the colour transfer index is improved to produce lower coloured sugar.

Viscosity reducer is used to improve crystallisation and improve crystal washing efficiency. It is a formulation of various glycols, oleates, acetates with surfactants. It is added continuously at 2–5 ppm to the syrup.

Thus there would be some rise in the cost of process chemicals used for the VMK process as compared to the normal double sulfitation process for factories that do not use special agents like colour coagulants and/or colour precipitants. However, considering the benefits of lower inversion losses of sucrose, the VMK process offers economical advantages over the normal process.

Experiment 1
Initially, during the season 2006–2007, trials were successfully carried out for 15 days, which were repeated for 45 days, in a 3500 tcd factory, the Kisan Veer Statra S.S.K. Ltd., at Bhuinj, near Satara.

There was noticeable improvement in the process with respect to steam consumption, quality of bold grain sugar and bagasse savings. The viscosity reduction assisted to reduce the boiling time of A strikes by 10 minutes and B strikes by 20–30 minutes. About 135 000 bags of sugar were produced without syrup sulfitation.

This sugar was sent for analysis to Maarc Labs, Pune (an ISO 17025 lab accredited by NABL). Their report clearly states that the quality of the sugar produced by this process was very good. The SO₂ content and dextran content were below detectable levels and it had a microbial count of less than 120 cfu per 10 g. The conductivity was only 0.014%, and the moisture and calcium levels were lower. This substantial reduction in most of the impurities as compared to those found in the normal PWS has also improved the sucrose content to 99.85% pol.
Sugar of such quality has been produced for the first time in India without the use of any additional equipment or any modification to the process for clarifying the juice and syrup. It is also noticed that the pH of the sugar was more than 6.6. Table 2 gives the requirements for PWS as per IS specifications, EU II specifications and the results obtained by using the VMK process.

**Experiment 2**

The same factory, Kisanveer Satara SSK Ltd., produced raw sugar during the season 2007-2008 and similar trials were conducted for a week to produce raw sugar without the use of sulfur. The sugar looked good and also had ‘lustre’, with a colour of 170 IU. Although the colour was higher than the IS specifications for PWS, the raw sugar looked better than one year old PWS from some factories. The raw sugar was sent for analysis at Savola Sugars, KSA, which revealed that it was better than the best raw sugar developed in Brazil (Table 3), especially with respect to conductivity ash and some other impurities. This sugar is now called pre-refined (PR) sugar. It is best suited as raw material for sugar refineries for producing refined sugar, with minimal difficulties and at low cost.

**Experiment 3**

The VMK process with single sulfitation was also tested at a 2500 tcd private factory, Cane Agro Energy Ltd., Dongari near Karad for the entire 2007–2008 season. A WG Colormet 1.0 instrument was used to display online the colour level of the clear juice every 10 seconds. This helped in the optimisation of chemicals used for the clarification.

The optimisation of the process resulted in production of sugar with colour less than 60 IU for about a month. Sometimes, a colour of 50 IU was also recorded. During this optimisation of the clarifier it was observed that, depending upon cane quality; the lime quantity could be reduced and therefore sulfur quantity in achieving better colour removal. Hot liming was used with simultaneous sulfitation, whereby the quantity of lime was reduced, with a concomitant reduction in sulfur, to maintain pH 6.9 in the clear juice. This adjustment was based on the observation of clear juice colour on the WG Colormet 1.0.
These observations were then used to reduce the lime quantity and thus sulfur quantity, in order to maintain the colour of the clear juice at around 8000 IU. The lime and sulfur quantities used were the lowest for the final three weeks of the season (days 65 to 80 in Figures 1 and 2).

The colour of the clear juice was around 7500–8500 IU and the sugar colour was often below 60 IU, especially in the final three weeks.

Figure 1 shows that the colour transfer index increased from a typical 100:1 to more than 130:1 during the last three weeks of the season. This could be due to the better clarification, as well as the better process control assisted by the online monitoring of the clear juice colour. This resulted in the reduction in sulfur consumption to less than 0.017% on cane, yet sugar with less than 60 IU colour was produced.

Figure 2 shows the daily average sugar colour for the season. Figure 3 shows the daily average sugar colour (×100) and clear juice colour during experiment 3.
Conclusion

Good quality sugar can be produced by avoiding syrup sulfitation without entailing any additional capital expenditure on equipment etc or any alterations or modifications in the process. Sulfur consumption can be reduced still further by using the WG Colormet 1.0 to monitor online the colour of the clear juice. Depending on the cane quality, sulfur consumption on cane can be reduced to less than 0.02%. In short, the VMK process can be adopted for producing both PWS and raw sugar. For PWS, the VMK process uses single sulfitation while, for raw sugar, it dispenses with the use of sulfur altogether.

The quality of the PWS as well as the raw sugar produced by the VMK Process is superior to that of the normal PWS and raw sugar respectively. The lower sulfur consumption and, consequently, the lower residual sulfur content in the sugar means that the keeping quality of the sugar is superior to the PWS sugar.

Acknowledgements

The author wishes to acknowledge the support given by Mr Madan Bhosale, MLA, Chairman, Kisanveer Satara SSK Ltd., without which the experiment could not have initiated and by Mr Chandrashekhar Ogale, MD, Cane Agro Energy Ltd., for giving permission to use the process at his factory for trials during a full season. Dr Vishwas Udpikar, Dr Ramesh Natu and Dr Mrs. Dhamankar are thanked for their support and work on WG Colormet 1.0.

SULFITAGE SIMPLE MODIFIÉ POUR LA PRODUCTION DE SUCRE BLANC PLANTATION AVEC UNE MEILLEURE QUALITÉ

Par

V.M. KULKARNI
V.M.Biotech, Pune, Inde.
vmbio@vsnl.com

MOTS-CLES: Sulfitage, Soufre, Sucre Blanc de Plantation, Impuretés, Processus VMK.

Résumé

La présence du soufre dans le sucre le rend potentiellement nuisible à la consommation humaine et entraîne le sucre à se détériorer plus rapidement au cours du stockage. Ces questions et la forte hausse des prix du soufre, quoique temporaire, demandent la réduction de la dose de soufre utilisée pour la production de sucre blanc plantation (PWS). Le processus généralement utilisé dans la production du PWS (en plus du sulfitage du jus) est le sulfitage du sirop, ce qui augmente la décoloration du sucre par 6–15%. Toutefois, cette réduction en couleur de sucre est de courte durée; elle réduit également le pH du sirop, de sorte que les procédés de fabrications ultérieures sont effectués en milieu acide. De ce fait, il pourrait y avoir des pertes de sucre significatives grâce à l'inversion du saccharose. L'utilisation de biocides appropriés pour l'assainissement des cannes et des moulins réduit l'acidité du jus, comme aussi le quantum des composés polymères de haut poids moléculaire dans le sucre et la mélasse. Compte tenu de ces observations, un nouveau processus (le processus VMK) a été développé afin de produire le PWS sans avoir recours au sulfitage du sirop, à savoir, un processus de sulfitage simple à l'aide d'un polymère avec biocides appropriés qui réduisent les impuretés et les couleurs d'environ 12 à 15%. Ce processus a été utilisé pendant une saison complète d'environ 100 jours dans une usine broyant 2500 tonnes de canne par jour; on a produit 25 000 tonnes de sucre avec une couleur inférieure à 80 UI. On a également obtenu une amélioration de la qualité du sucre à l'aide d'un appareil WG Colormet 1.0 surveillant la couleur en ligne, ainsi que par le contrôle strict sur la consommation de produits chimiques, en particulier celui de la chaux et du soufre. La qualité du sucre, qui a été constamment obtenue, a montré une couleur à 55 UI, une conductivité (basée sur les cendres) de 0.015 %, un calcium de 30 ppm, un poI > 99.85; le dextran et le soufre n’ont pas été détectés. L’indice de transfert de couleur a été 130:1 à partir du jus clair au sucre final, par rapport à l'index signalé de 100:1 d'une massecuite au sucre. Selon ces conclusions, un brevet a été déposé pour le processus de VMK pour la production de PWS d’une bonne qualité.
PROCESO MODIFICADO DE SULFITACIÓN SIMPLE PARA PRODUCIR AZÚCAR BLANCO DE MEJOR CALIDAD

Por

V.M. KULKARNI
V.M. Biotech, Pune, India
vmbio@vsnl.com

PALABRAS CLAVE: Sulfitación Simple, Bajo Azufre, Azúcar Blanco, Impurezas Proceso VMK.

Resumen

LA PRESENCIA de azufre en el azúcar, además de hacerlo potencialmente nocivo para consumo humano, causa que el azúcar se deteriore a una tasa más alta durante el almacenamiento. Estos aspectos junto con el incremento en los precios del azufre, han resaltado la necesidad de reducir las dosis de azufre usadas en la producción de azúcar blanco. El proceso generalmente seguido, además de la sulfitación de jugo, es la sulfitación de meladura, la cual reduce el color un 6–15% adicional. Sin embargo, esta reducción es de corta vida y también reduce el pH de la meladura con el inconveniente que las etapas posteriores de proceso se realizan bajo condiciones ácidas. Debido a esto pueden existir pérdidas importantes por inversión de sacarosa. El uso de biocidas adecuados y sanitización de molinos han mostrado reducciones en la acidez del jugo diluido así como de la cantidad de compuestos poliméricos de alto peso molecular en azúcar y mieles. Un nuevo proceso (proceso VMK) fue desarrollado para producir azúcar blanco sin recurrir a la sulfitación de meladura, es decir, un proceso de una sola etapa, usando un polímero junto con biocidas apropiados que reducen impurezas y color en cerca de 12–15%. Este proceso fue ensayado en una zafra de cerca de 100 días en una fábrica de 2500 tcd, donde se produjeron 25 000 t de azúcar con color por debajo de 80 IU. Un mejoramiento adicional de la calidad del azúcar se obtuvo con la ayuda de una unidad de monitoreo continuo de color, WG Colormet 1.0, así como con cuidadoso control del consumo de químicos, especialmente de cal y azufre. La calidad del azúcar, lograda en forma sostenida, <55 IU, conductividad de cenizas <0.015%, calcio <30 ppm, pol >99.85, y dextranas y azufre por debajo de los límites detectables. El índice de transferencia de color se encontró como 130:1 desde jugo claro hasta azúcar final, frente al índice reportado de 100:1 desde masa A hasta azúcar. Con base en estos hallazgos se ha solicitado patente para el proceso VMK para la producción de azúcar blanco de buena calidad.
IMPLEMENTATION PLANS FOR SUPERVISORY CONTROL OF PAN STAGE OPERATIONS

By

Abstract

PAN STAGE operations have a major influence on the quality of shipment sugar production, the processing efficiency of the centrifugal and dryer stations, the sugar recovery from final molasses and the steam consumption of raw sugar factories. As well, for many factories, the production capacity of the pan stage is often the rate limiting station of the factory. Several Australian factories now operate with only one pan stage operator and a management tool such as a smart supervisory control system (SSCS) would assist the operator in making better decisions for managing the stage. The SSCS integrates the projected boil-on rates for syrup and molasses to each pan on the stage with the forecast production of syrup based on cane receival data and molasses from the centrifugals. By using the phase of each pan into an operational model the levels of syrup, A molasses and B molasses in the respective stock tanks are forecast and the information used to forewarn of potential problems or inefficiencies if current operating strategies are maintained. A hybrid fuzzy logic based expert system is employed to advise corrective procedures. While the system is not yet adopted commercially each phase of the development plan has been undertaken. Forecast tank levels have been found to compare favourably with actual tank levels. The SSCS should result in improved use of the installed equipment on the pan stage to achieve increased sugar recovery, improved sugar quality and reduced steam consumption while fulfilling the production rate requirements. One of the important benefits of the control system should be reduced variability in the steam consumption on the pan stage, leading to improved steam economy for the factory.

Introduction

Australian sugar factories face two major costs, viz. high unit labour costs and high capital costs for equipment. As a consequence, each factory employs only a few operators/supervisors and capital items are generally large (and few in number) in order to capture the benefits of economies of scale. For example, for the pan stage, several factories have only one operator to manage the whole stage (typically 8 pans) and batch pans of 200 t dropping capacity are common through the industry.

Most Australian factories employ only one supervisor to oversee all operations from the cane weighbridge, milling and boiler stations, through to the sugar bin and outloading. The number of operators on shift for the whole plant is about 11.

For several years, the benefit of a supervisory/advisory support tool for pan stage operations in sugar factories has been recognised (Frew and Wright, 1977; Merensky, 1985; Watson, 1989; Verwater-Lukszo et al., 2003), but it appears no system is currently operating to the extent considered necessary for strongly beneficial results.
Supervisors and operators currently rely on their knowledge and experience of the process, and the operational plan nominated by the production manager, to manage the operations of the shift. However, the complexity of the task in operating the pan and fugal stations in an optimal way has increased and at the same time the financial implications of those outcomes have increased. To achieve a truly optimal result, management decisions for the pan and centrifugal stations must be undertaken in relatively short time frames e.g. during each hour, and compliance with a rigid operational plan set by the production manager may not be appropriate. Ideally the production manager will set the production objectives for the shift and the supervisor/operators will make real time optimal decisions to meet those objectives.

A smart supervisory control system (SSCS) was developed as a management tool to assist the operator in making better decisions for managing the stage.

**Pan stage operations in Australian sugar factories**

Figure 1 shows the typical flowscheme adopted by Australian mills to produce raw sugar with polarisation between 98 and 99.4, depending on the customer requirements. The syrup from the evaporators is usually at 88 to 92.5 purity. The flowscheme incorporates three grades of massecuite (A, B and C) with the mixture of the A and B sugar production being combined and dried to produce the shipment sugar of mean size 0.8 to 1.0 mm. The C sugar provides the crystal seed material to produce a high grade seed (after boiling on syrup) for the A and B massecuite production. The flowscheme incorporates a complex combination of feedforward (e.g. some syrup fed onto the B strikes; A molasses (or syrup) onto the grainings for the C strikes) and feedback (e.g. A molasses onto the A strikes). Both batch and continuous pans are used and batch and continuous centrifugals are used for processing the A and B massecuites. Only continuous centrifugals are used for processing the C massecuite.

The high interdependency of operations on the pan stage and the centrifugal station requires that optimal supervision of the two stations is considered collectively and not in isolation. The management of the centrifugals/dryer station is undertaken by a different operator from the pan stage.

**Operational objectives for managing the pan and centrifugal stations**

The operational objectives for the pan and centrifugal stations are a combination of the following:
• Throughput rate. The A, B and C massecuite production rates per tonne of cane crushed changes as the sucrose and soluble impurity content of the cane supply changes. A farmer’s supply of cane to the factory (known as a rake of cane) may vary from four minutes to 30 minutes of cane crushed by the milling train and the composition will vary from rake to rake and to a lesser extent within the rake. In addition to this variation is the more significant variation in the cane composition through the season. The cane supply has a lower sucrose content and higher soluble impurity content in the early and late periods of the crushing season and a higher sucrose content and lower soluble impurity content in the mid-season period. The typical effect of the seasonal change in cane composition on the A, B and C massecuite production rates is shown in Table 1 (Broadfoot and Pennisi, 2001).

<table>

</tr>
</tbody>
</table>

• Sugar quality. The main sugar quality parameter that is influenced directly by pan stage operations is the mean size (and uniformity) of the A and B sugars. The centrifugal station impacts directly on the polarisation of the shipment sugar. Variations in the wash water addition in the A and B fugals to meet the pol specification directly affect the extent of sugar dissolution during fugalling and consequently affect the A and B massecuite production quantities. Sugar of premium quality receives a bonus payment so revenue for sugar production is directly affected by the quality.

• Sugar recovery. Improved exhaustion of the C massecuites, yielding final molasses of lower purity directly results in increased sugar production from the sucrose in the syrup supply to the pan stage. For the three-massecuite boiling scheme used in Australian factories, a critical operational target for the pan stage is to ensure that the B molasses is at an appropriately low purity, otherwise the production of a higher purity C massecuite will result in increased sucrose loss to final molasses. Reduced sugar recovery occurs when the soluble impurity content of the cane supply is high, resulting in increased production of B and C massecuites, and final molasses.

• Steam/vapour consumption for the pan stage. As a consequence of the large batch pans that are used in Australian factories, the steam/vapour consumption on the pan stage commonly varies through the pan stage cycle by +/-25% about the mean. These fluctuations impact negatively on the steady operation of the evaporators (where bleed vapour is used on the pan stage) or increase the make up of high pressure steam to the exhaust steam mains and venting of steam to atmosphere. The fluctuations in steam/vapour consumption on the pan stage usually result in inefficient use of steam and reduced revenue from attached cogeneration plants. Smoothing of the steam/vapour usage on the pan stage is highly beneficial.

The optimal operational plan set by the production manager for a shift (or perhaps 24 h period) is a weighted consideration of all four criteria with the weighting (importance) placed on the individual criterion varying in the short and long term. For example, during mid season when the
sucrose content in the cane supply is at its peak, stronger emphasis will be given to throughput rate; if the cane crop is reduced, greater emphasis will be placed on sucrose recovery and quality; if there is a mechanical breakdown in a section of plant and crushing rate is reduced, greater emphasis will be given to sugar recovery, sugar quality and perhaps steam consumption.

It is possible to produce a single weighted objective function for the pan and fugal stations for the shift and use the supervisory/advisory control system to manage the operations to best meet the requirements of that objective function. The supervisory system uses real time data and input from the supervisor and operators to take into account the operational circumstances for the shift. For example, if a particular pan experiences a vacuum leak and its boil-on rate is affected, then this needs to be included in the supervisory plan.

**Overview of the framework for the smart supervisory control system**

Figure 2(a) shows the information transfer between the operator, the pan stage control system and the pan stage plant that is currently used in most Australian factories. The smart supervisory control scheme (SSCS) works in tandem with the pan stage operator and the current pan stage control systems to make projections of performance against the nominated objective and to provide advice. Figure 2(b) shows the information transfer for the pan stage incorporating the SSCS.

![Diagram showing information flow between operator, pan stage control system, and pan stage plant with current and smart supervisory control systems](image-url)

The SSCS takes operator input along with information from the existing sugar mill control system and factory databases (such as cane receipt information) and provides recommendations and expert advice. The operators use the advice/recommendations from the SSCS to influence their management of the pan stage and fugal station operations e.g. through the values they input to the pan stage and fugal station control systems, allocation of pans to A or B massecuite boiling etc.
There are four primary outputs provided by the SSCS, viz.
1. Pan duties management;
2. Pan control strategies;
3. Pan scheduling management; and
4. Stock tank management.

In addition the SSCS provides support information to the operators in two categories, viz.
1. Prediction of future pan stage operating conditions; and
2. Explanatory and justification capabilities.

The SSCS is a hybrid fuzzy logic based expert system design incorporating rule based decision making, explanatory capabilities and process models (Dodd et al., 2005a; Dodd et al., 2009). The knowledge base is composed of human expert knowledge coupled with mathematical models simulating the pan stage and centrifugal station processes.

This arrangement maintains significant human interaction with the SSCS as part of the process, which is considered to be highly desirable.

Framework of the supervisory control system

The framework of the SSCS is based upon conventional expert systems (Leung and Wong, 1990; Gisolfi and Balzano, 1993) and conventional If-Then fuzzy rule based systems design (Goel et al., 1995; Berkan and Trubatch, 1997). Dodd (2009) provides a detailed description of the framework and core operations of the SSCS.

As depicted in Figure 3 the SSCS incorporates several modules performing multiple tasks. This modular structure aids in maintenance, upgradeability and flexibility. A brief description of each of the modules follows.

Input module

The input module draws real time information directly from the sugar mill control system through relevant databases including information on cane receival (rate, juice analyses), juice processing station, laboratory analyses (syrup purity), the pan stage and centrifugal station.

Pan stage operators provide information such as equipment performance ratings, operational problems, plus characteristics of the syrup, molasses and sugar process streams.

Editor module

The editor module provides the capabilities to modify the functional parameters for the process model input parameters and output data to match the local operating conditions. As well, this module can assign or modify the explanations tagged to each of the rules.

Data module

The data module contains several databases for information storage including the fuzzy If-Then rule knowledge base, the parameters specific to the pan stage models, databases storing text based information for presentation to the operators, a blackboard system for storing the predicted values of the process variables (from the process models) and from the rule based decision making block, information from the sugar mill control system (including information from cane receival, the juice processing station, laboratory, pan stage and the centrifugal station).

Input data from the operators on the pan and centrifugal stations are also captured in this module. The information flows in Figure 3 show the important role of the blackboard system, as the working memory for results from the pan stage process models, and the rule based decision making block. Output data are obtained from the blackboard data system.
System module

The system module carries out data processing of the two major sources of input information and transforms these to six system outputs. The system module is the most complex and essentially comprises the majority of the system software operations. The system module contains three subsystems as shown in Figure 3 viz.:

- Process models of the pan stage;
- Rule based decision module adjusting process models for local conditions; and
- Explanatory communications.

In total six process models are used for the predictions of pan stage and fugal station conditions and these are described in Table 2.

Fig. 3—Framework of the SSCS.
Table 2—Descriptions of the models used in the SSCS.

<table>
<thead>
<tr>
<th>Model name</th>
<th>Model description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pan and fugal phase determination models</td>
<td>Determines the current status and phase within the pan stage schedule for each vacuum pan and the status of the centrifugal station. For the pans, a simple classification procedure based upon steam usage, level and change in level as presented by Frew and Wright (1976) is used. Receiver levels and change in receiver levels allow fugal station status to be inferred. Once this determination is made, this model is coupled with the pan stage schedule and the other process models for prediction of future pan stage operating conditions.</td>
</tr>
<tr>
<td>Syrup prediction model</td>
<td>Determines the future flow of syrup to the pan stage based on cane receive data at the weighbridge and laboratory. The prediction of the quantities of sucrose and impurities in the syrup stream allows a forward forecasting of the stocks of syrup. The forward predictions of syrup rate and composition are key inputs to predicting the massecuite production loadings.</td>
</tr>
<tr>
<td>A, B, C massecuite model</td>
<td>Calculates the average production rates of A, B and C massecuites, C sugar remelt, molasses and sugar streams given the syrup purity and flow rate to the pan stage. Crystal sizing determinations assist in calculating the necessary quantities of C sugar needed for the A and B pans to ensure final product sugar is of the required size. Typical parameters for crystal content, sugar size, coefficient of size variation and purity rise at the fugals are assumed in this model.</td>
</tr>
<tr>
<td>Empirical pan models</td>
<td>The rate at which each pan takes feed material (syrup, A molasses or B molasses) during the different phases of the pan's operation is determined by experimentation and modelling. This boil-on rate for feed materials is a function of the massecuite level and phase of the pan, steam rate, head space pressure (vacuum), brix and purity of the feed syrup/molasses.</td>
</tr>
<tr>
<td>Stock tank prediction models</td>
<td>By using the empirical pan models, the boil-on rates for each feed stream at the different stages of the pan stage schedule can be determined by summing the syrup, A molasses and B molasses feed rates for all the pans at that point in the schedule. Given the expected syrup production rate and C sugar remelt production rate, the predicted tank levels can be determined for the syrup tank for a series of intervals. Similarly, the predicted tank levels for the A and B molasses can be calculated from the production rates of the molasses at the centrifugal station and the sum of the consumption rates on the individual pans at the specific point in the pan stage schedule.</td>
</tr>
</tbody>
</table>
| Schedule optimisation model                          | Manages the schedule e.g. determines when pans should start and complete strikes to avoid pan idling, while minimising and smoothing steam usage on the overall pan stage and adhering to sugar production productivity, recovery and quality requirements. This model optimises the objective function. The information from this model is used in conjunction with information gathered through the input module, the rule based decision making process and from the other process models to provide information on:  
  • Recommended steam rates for the specific phases of the individual vacuum pans;  
  • Choice of A/B massecuite duties for the ‘swing’ vacuum pans;  
  • Forecasting of stock tank levels and future disturbances e.g. tank overflow;  
  • Footing quantities to the vacuum pans; and  
  • Scheduling when pans should start and complete strikes. |

The SSCS uses default parameters for the process models from the pre-defined knowledge base. However, to customise the SSCS for the current or defined operating circumstances, the fuzzy logic rule block uses the input data from the operator/supervisor to pre-process the pan stage models input parameters and, likewise, to post-process the output results from the models to align with the current and defined operating conditions. The post-processing results take precedence over the pan stage model output values and these are stored on the blackboard system for subsequent use by the models.
Examples of pre-processing and post-processing adjustments to match local operating conditions are:

- If cane is fresh and A massecuite purity is greater than 88 and the target pol of A sugar at the fugals is between 99.0 and 99.1, then A fugal purity rise = 1.75 units;
- If a vacuum leak exists on a particular pan, then set the boil-on rate characteristic for the pan to 0.92. It would be 1.0 at typical vacuum;

For a particular factory, the refinements that are undertaken through the fuzzy logic rule block customise the SSCS to suit the specific equipment and operational circumstances for the factory.

**Output and support modules**

The four control strategy recommendations are passed from the blackboard data system to the output module. The supporting results, including justifications for the presented advice and predictions for future pan stage operations, are provided in the support module.

**Application of the SSCS**

While the SSCS system is not yet adopted commercially, each phase of the development plan has been undertaken. Dodd (2009) provides the detailed specification for the framework, the incorporation of the process models, the software for implementing the fuzzy logic block and the procedures for communicating data among the modules.

Factory data were obtained from the databases at Racecourse Mill to assess the suitability of the prediction models for use in the SSCS. Information on these assessments is provided in the sections to follow.

**Syrup rate prediction**

Dodd et al. (2005a) outlined the procedure using cane receival data (cane rate and pol % cane) to forward predict the quantity of sucrose in syrup to the pan stage from cane and subsequently, using laboratory analysis of the purity of syrup, to determine the quantity of impurities in syrup. The model uses rolling average error corrections to accommodate the analytical errors in syrup and cane analyses and the variations in impurity/sucrose losses between cane receival and the pan stage (i.e. to allow for losses in mud, bagasse, degradation and analytical anomalies). Dodd et al. (2005a) demonstrated a high level of agreement of the predictions with syrup rates measured by magnetic flowmeters for a whole season at two factories.

**Empirical pan models**

For each phase in each pan at Racecourse Mill, the syrup or molasses boil-on rate was determined from the change in level in the pan (as measured by a differential pressure transducer), the brix of the feed material and the brix of massecuite at the start and finish of the phase (Dodd et al., 2005b).

The measured boil-on rate was assigned to the current operating status for the pan using the classification procedure based on steam rate, level and change in level according to the procedure of Frew and Wright (1976). An iterative computer simulation for a batch pan was used to determine the change in syrup or molasses boil-on rate with change in steam rate to the pan.

Thus, within practical operational constraints, the steam rate during a phase of a pan, and collectively for all pans, can be adjusted to provide an improved outcome for the total pan cycle by avoiding idling time, increasing productivity, smoothing steam demand etc.

**A, B and C massecuite model**

This model develops steady state mass balances for all streams (massecuite, sugar, molasses, remelt, magma) on the pan stage and is well tested against factory data (Broadfoot and Pennisi, 2001).
Stock tank models

These models determine the stock tank levels for the syrup, A molasses and B molasses by utilising the above models plus the pan and fugal phase determination model and the schedule optimisation model. Figure 4 shows a comparison between the actual quantity of syrup in the stock tank and the predicted quantity for an 8 h period at Racecourse Mill. Similarly, Figure 5 shows the comparison of the predicted and actual levels for A molasses over the same 8 h period.

![Figure 4](image1.png)

**Fig. 4—Comparison of forward prediction of syrup stock tank levels with actual data.**

![Figure 5](image2.png)

**Fig. 1—Comparison of forward prediction of A molasses stock tank levels with actual data.**

The data provided in Figures 4 and 5 are snap-shot data from an on-going forecast. In practice, when the SSCS is implemented, the projection for a specific time period will use the actual tank level as the starting position, resulting in closer alignment.

Conclusions

The SSCS is a hybrid fuzzy logic based expert system incorporating rule based decision making, explanatory capabilities and industrial process models of the pan stage and fugal stations. While the SSCS has not yet been commercially adopted, all components have been developed and its forecasting capability appears to be satisfactory.

The next step is to implement the system into a factory. The objective of the SSCS is to provide advice to supervisors and operators so that early decisions, such as changes to steam rates or allocation of pans to different duties, result in improved outcomes with respect to avoiding production rate difficulties, and maintaining good operational performance with respect to sugar quality, sugar recovery and minimisation of steam consumption on the pan stage.
Acknowledgments

The cooperation and support provided by the staff at Racecourse Mill, Mackay, Australia are acknowledged. The funding assistance provided by an Australian Research Council linkage grant (Project No: LP0230710) and by the Sugar Research Institute, Brisbane, Australia are also acknowledged and appreciated.

MOTS CLEFS: Control, Logique Fuzzy, Logiciels, Models pour les Cuites.

Résumé

Les opérations aux cuites ont une influence majeure sur la qualité du sucre, l'efficacité des centrifuges et du sécheur, le recouvrement du sucre dans la mélasse finale et sur la consommation de vapeur des usines de sucre roux. Pour beaucoup d'usines, la production est limitée par la capacité de la station des cuites. Plusieurs usines australiennes fonctionnent maintenant avec un seul opérateur aux cuites; un outil de gestion, comme un système de contrôle intelligent (SSCS), pourrait aider l'opérateur à prendre de meilleures décisions. Le SSCS intègre les taux d'ébullition projetés pour sirop et mélasses à la production de sirop basée sur le tonnage de canne et à la production de mélasses des centrifuges. En utilisant la phase de chaque cuite dans un modèle opérationnel, on prédit les niveaux de sirop, de mélasse-A et de mélasse-B dans les réservoirs; ces informations évitent d'éventuels problèmes. Un logiciel est employé pour donner des procédures correctives. Quoique le système ne soit pas encore adopté commercialement, chaque phase du plan de développement a été entreprise; les niveaux calculés dans les réservoirs se comparent favorablement avec les niveaux mesures. Le SSCS doit aboutir à une meilleure utilisation de l'équipement installé, il devrait aussi donner une augmentation du sucre produit, une meilleure qualité de sucre et une consommation de vapeur réduite. L'un des avantages importants du système de contrôle est une réduction de la variabilité de la consommation de vapeur, et donc une économie de vapeur pour l'usine.
PLANES DE IMPLEMENTACIÓN PARA UN CONTROL SUPERVISORIO DE LAS OPERACIONES EN LA ESTACIÓN DE TACHOS

PALABRAS CLAVE: Control Supervisorio, Lógica Fuzzy, Sistemas Expertos, Modelos De Cocimiento.

Resumen

LAS OPERACIONES en tachos tienen una influencia clave en la calidad del azúcar final, la eficiencia de las estaciones de centrífugas y secado, las pérdidas en miel final y el consumo de vapor de las fábricas de azúcar crudo. También, para muchas fábricas, la capacidad de la estación de tachos es a menudo la estación que limita la tasa de molienda. Actualmente varios ingenios australianos tienen un único operador de la estación de tachos y una herramienta de gestión como el Sistema de control supervisorio inteligente, (SSCS) asiste al operador en la toma de las mejores decisiones. El SSCS integra las tasas proyectadas para meladura y mieles para cada tacho con la producción prevista de meladura basada en la recepción de caña y las mieles de las centrífugas. Usando la fase de cada tacho en un modelo operacional, se predicen los niveles de meladura, mieles A y B en los respectivos tanques y la información es usada para anticipar problemas o ineficiencias potenciales, de mantenerse las estrategias de operación vigentes. Un sistema experto basado en lógica fuzzy híbrida se emplea para recomendar procedimientos correctivos. Aunque el sistema no ha sido adoptado todavía comercialmente, cada fase del plan de desarrollo ha sido considerada. Los niveles de tanques emitidos por el sistema se comparan favorablemente con los niveles reales. El SSCS debe resultar en un mejor uso del equipo instalado en tachos para lograr incrementos en recuperación, mejor calidad de azúcar y menor consumo de vapor, manteniendo los requerimientos en cuanto a las tasas de producción. Un beneficio importante del sistema de control debe ser la reducción de la variabilidad en el consumo de vapor en tachos, lo que conduce a economías de vapor en la fábrica.
DEVELOPMENT OF DESCRIPTOR TOOLS FOR THE CHARACTERISATION OF AUSTRALIAN SUGAR MILL EVAPORATOR SCALE

By

KEYWORDS: Evaporator, Scale Composition, Chemical Cleaning.

Abstract
CLEANING of sugar mill evaporators is an expensive exercise. Identifying the scale components assists in determining which chemical cleaning agents would result in effective evaporator cleaning. The current methods (based on x-ray diffraction techniques, ion exchange/high performance liquid chromatography and thermogravimetry/differential thermal analysis) used for scale characterisation are difficult, time consuming and expensive, and cannot be performed in a conventional analytical laboratory or by mill staff. The present study has examined the use of simple descriptor tests for the characterisation of Australian sugar mill evaporator scales. Scale samples were obtained from seven Australian sugar mill evaporators by mechanical means. The appearance, texture and colour of the scale were noted before the samples were characterised using x-ray fluorescence and x-ray powder diffraction to determine the compounds present. A number of commercial analytical test kits were used to determine the phosphate and calcium contents of scale samples. Dissolution experiments were carried out on the scale samples with selected cleaning agents to provide relevant information about the effect the cleaning agents have on different evaporator scales. Results have shown that by simply identifying the colour and the appearance of the scale, the elemental composition and knowing from which effect the scale originates, a prediction of the scale composition can be made. These descriptors and dissolution experiments on scale samples can be used to provide factory staff with an on-site rapid process to predict the most effective chemicals for chemical cleaning of the evaporators.

Introduction
The sugar industry experiences scaling of evaporators; the extent of scaling varies from mill to mill, within a season and from season to season for individual evaporators. These encrustations are formed from the combined effects of several processes involving inorganic and organic molecules or ions.

The type of the scale formed depends on a number of parameters, including the concentrations of scale-forming ions, the amount of dissolved and suspended solids, the pH and flow properties of the solution, the rate of evaporation, and the operating temperature (and pressure) of the system.

Impurities in juice deposit onto heating surface areas because heating surface areas have a higher temperature at their surface than the surrounding juice and provide nucleation sites for scale growth. Scale facilitates the corrosion of surfaces, restricts fluid flow and, because it has low thermal conductivity, its accumulation on metal surfaces impairs heat transfer across the metal-fluid interface.
One of the most important characteristics of any evaporator set is to ensure that it can evaporate water from the juice at an adequate rate to ensure that the set does not become the rate-limiting step in the factory.

After a clean, evaporator sets typically have sufficiently high average heat transfer coefficients to meet the rate of production. However, as the heating surfaces become covered with scale, the heat transfer coefficients (HTC) decline, and if the set is heavily fouled it will not always meet production rates.

This is particularly so in Australian sugar factories where spare evaporators are not available and fouled effects cannot be taken off-line for cleaning without interrupting factory operation. In these circumstances, some limited options are available to reduce the impact on the factory. Options such as the reduction of maceration water on the milling train, lowering of the syrup brix set point and the reduction of filter wash water help to maintain the required evaporator rate. However, these techniques can only sustain the evaporator set for a certain period and ultimately the only option is to stop the factory so that the evaporators can be cleaned.

Cleaning of evaporators is an expensive exercise. The estimated cost associated with scale formation and scale removal for a typical Australian mill is $400,000 per season. This estimate comprises the costs of: (a) labour due to extended season; (b) factory shutdown causing loss of production, and (c) cleaning chemicals.

The factory stoppage time for cleaning of the evaporator set and the operating time between cleans depends on various factors such as the nature of the scale, type of cleaning chemical and the cleaning procedure adopted (Doherty, 2000). Identifying the compounds present in scale helps in determining which cleaning agents would result in effective cleaning of evaporators and which scale inhibitors will significantly reduce scaling rates (Crees et al., 1993).

Scale consists of many components and its composition can best be determined using a combination of techniques. Applicable techniques include atomic absorption spectrophotometry, x-ray powder diffraction (XRD), x-ray fluorescence (XRF), ion exchange/high performance chromatography, thermogravimetry/differential thermal analysis and electron microscopy (Crees et al., 1992 and 1993). This project aims to characterise scale samples with some of these techniques with the ultimate aim to describe the type of scale in each evaporator by visual and tactile descriptors, simple elemental analysis and dissolution experiments with cleaning chemicals currently used in Australian sugar mills.

Scale formation

Figure 1 illustrates typical distributions of the components in scale (as mass percent), relative to the position in the evaporator set and brix concentration of the juice. The data are based on scale analyses conducted by Sugar Research Institute in Australian sugar mills over the last 15 years.

The distribution trends are similar to those reported by Honig (1963). A large portion of scale formed has calcium as an elemental constituent due to an excess of calcium that is introduced into the process via liming prior to clarification. Any residual calcium that remains in the juice after clarification has the potential to contribute to scale formation in the evaporators, pans and fugals.

In general, in any evaporator set, the calcium phosphate and hydroxyapatite (a phosphate compound) content in scale decreases from the first to the last vessel, while the amorphous silica, calcium oxalate, calcium sulfate and aconitate content increase from the first to the last vessel. Solubility of amorphous silica and calcium oxalate are known to decrease with increasing sucrose concentration and reducing temperature leading to prevalence of these scales in the latter effects (Crees et al., 1992; Walthew and Turner, 1995; Doherty, 2000). Organic matter is present in all scales, but in decreasing proportions towards the end of the evaporator set.
Experimental

Scale collection

Samples of scale from calandria tubes were obtained by mechanical means from seven Australian sugar mills during the 2001 crushing season. The samples are further classified with mills A, B and C from the northern growing region, mills D and E from the central growing region and mills F and G from the southern growing region.

These samples were obtained both before and after the calandria tubes had been chemically cleaned, depending on the flexibility of the factory. In most cases though, scale samples were collected with a mechanical device (scale sampler) which allowed samples to be collected prior to cleaning or during maintenance stops without the need for the vessels to cool down considerably. The scale samples were collected from quintuple sets.

Scale characterisation

XRF and XRD analysis

The scale samples were thoroughly washed with distilled water to remove residual sugar and then dried to constant weight under vacuum prior to analysis. They were characterised using XRF and XRD. The elements were analysed using an x-ray fluorescence spectrometer equipped with a Radium tube. The x-ray studies were carried out using a Riagaku camera and a x-ray generator with CuKα radiation of wavelength 1.5418 Å. X-ray powder diffraction techniques were used as they are the standard methods for the identification of scale components.

Visual and tactile descriptors

The scale samples that were analysed by XRF and XRD were also characterised based on their visual and tactile appearance. The appearances of the scale samples were detailed as powder, granular or flakes. The texture of the scale samples was assessed by rubbing them between the fingers and was described as smooth, coarse, rough or gritty. A visual assessment of the colour of the scale was also made. To obtain the original colour of the scales present in the evaporators, it was
necessary to treat the collected scale samples with water since dehydration during storage might affect their colour.

**Scale dissolution**

Dissolution experiments using a proprietary Sugar Research Institute procedure were conducted in the laboratory on scale samples with the following chemicals:

- 10% (w/v) caustic soda solution.
- 3% (w/v) sulphamic acid.
- 10% (w/v) ethylene diamine tetra-acetic acid tetra-sodium salt (EDTA).

The dissolution experiments enabled generalised deductions to be made on the effect the cleaning agents have on individual scale components.

**Scale characterisation by simple chemical means**

The aim of scale characterisation by simple chemical means is to enable factory staff to quickly and cheaply determine the elemental composition of scale samples. The two main inorganic elements (apart from silicon) present in scale are calcium and phosphorus. Standard test kits used for the determination of phosphorus and calcium in boiler feedwater are available in the market and can be used by persons with little background chemistry knowledge. Preliminary assessments were conducted on four analytical test kits. The Hach test strips and the Nalco orthophosphate octet colour comparator were assessed for phosphate determination, while the Merck calcium analytical test strips and the Nalco hardness test kit for total hardness and calcium hardness (drop titration method) were assessed for calcium determination.

Scale (0.1 g), HCl (5 mL of 10% solution) and distilled water (15 mL) were placed in a 250 mL conical flask and heated to boiling. The solution was further boiled for 30 min with 5 mL water aliquots added from time to time. The solution was filtered through a Whatman No. 91 paper and transferred to a 1 L volumetric flask and made to the mark with distilled water. The scale solution was diluted with distilled water by a factor of five prior to phosphorus and calcium analysis.

**Results**

**Scale characterisation**

*XRF and XRD analysis*

The XRF results gave the elemental composition of the scale samples based on their metal oxides (SiO$_2$, Al$_2$O$_3$, Fe$_2$O$_3$, MgO, CaO, Na$_2$O, P$_2$O$_5$, and SO$_3$). The XRF data also gives a loss on ignition value due to the volatilisation of organic acids, lipids, proteins, polysaccharides, chemically bound –OH and H$_2$O as well as adsorbed water. The results from the XRF showed:

- CaO, P$_2$O$_5$ and SiO$_2$ were the main oxides identified in the scale samples.
- The highest proportion of P$_2$O$_5$ was present in the earlier effects (i.e. Nos. 1, 2 and 3).
- There was a reasonable amount of Fe$_2$O$_3$ in the scale samples. The presence of large amounts of Fe$_2$O$_3$ in some of the scale samples is probably due to corrosion of the tube plates.
- Each scale sample contains a large amount of organic matter as deduced from the loss on ignition.

Interpretation of the XRD patterns of the scale samples identified the following compounds: amorphous silica, hydroxyapatite, iron oxide, calcium carbonate, calcium oxalate (mono- and di-hydrate). Table 1 shows data for the seven factories on the approximate proportion of the scale
components determined by simple mass balance calculations and the XRD and XRF data for Nos. 1, 4 and 5 effects.

The results are summarised as follows:

- When SiO₂, P₂O₅, Fe₂O₃ and SO₃ are present in the scale, it has been established that SiO₂ is present as amorphous silica; P₂O₅ is present as hydroxyapatite, Fe₂O₃ is present as iron oxide and SO₃ is present as calcium sulfate di-hydrate.
- High CaO levels in Nos. 4 and 5 effects suggest the presence of calcium oxalate.
- Amorphous silica, hydroxyapatite and organic matter are the main scale components deposited in the No. 1 effect with hydroxyapatite as the largest scale component.
- Amorphous silica, calcium oxalate and organic matter are the main scale components deposited in the later effects with calcium oxalate and silica the largest scale components.

* The scales were collected after caustic clean.

The results are in agreement with the data in Figure 1. The results also show some variation across the various cane growing regions. Provided similar farming practices are used and similar cane varieties are grown, the scale composition should be reasonably similar over subsequent seasons but the concentrations of the scale components may vary due to changes in phosphate, calcium and organic acid content of the juice.
Visual and tactile descriptors

Some general trends were determined for the visual and tactile descriptors of the scale samples as follows:

- The colour of the scale samples is usually darker in the earlier effects than the later effects of an evaporator set.
- Dark coloured (chocolate brown/black) scale contains mainly hydroxyapatite and organic matter, while creamy coloured scale contains mainly calcium oxalate or is a mixture of calcium oxalate and amorphous silica.
- There was no marked change in colour between the ‘dry’ and wet scales, although the wet scale was darker in some samples.
- Flakes tended to be present in the last effects and were mixtures of calcium oxalate and amorphous silica.
- There was no discernible pattern on the texture of the scales across an evaporator set, other than at some factories the scales in the earlier effects were softer than those in the later effects.

Scale dissolution

The dissolution experiments showed that when the scale contained two main compounds with different chemical properties (e.g. hydroxyapatite and organic matter) a two-step cleaning process was required to completely dissolve the scale sample. The results are presented in Table 2 and confirm the earlier work of Doherty (2000).

Elemental analysis

Descriptions of the analytical test kits and preliminary testing results are given in Table 3. The kits were first tested on a series of standard solutions (made from sodium orthophosphate and calcium chloride) containing varying amounts of phosphate and calcium ions to determine the ease of use and any practical issues involved with the analytical procedure.

</table>
The results in Table 3 showed that the Nalco colour comparator can be used to determine the concentration of phosphate in scale, while the Nalco hardness drop titration method can be used to determine the concentration of calcium in scale. Table 4 shows the comparison of the phosphate (expressed as $P_2O_5$) and calcium (expressed as $CaO$) results obtained with the Nalco test kits with those obtained from XRF for a number of scale samples.

**Table 4—Scale analysis with Nalco test kits.**

</tbody>
</table>

The results show differences between the Nalco test methods and the XRF method. The differences of the $P_2O_5$ results between the Nalco colour method and the XRF method were not very large. As such, the Nalco colour method for phosphate may be used to determine the $P_2O_5$ content of scale. Marked differences were obtained in the calcium results. These differences may be due to certain components in the scale interfering with the Nalco hardness test method. Also, the colour change (from reddish-purple to bluish purple) for the Nalco hardness test method was broad and hence the end-point was difficult to detect. As a result, the Nalco hardness test, though suitable to analyse calcium in simple solutions, is not recommended for calcium determination in scale.

**Development of scale and cleaning tools**

The data obtained from the various scale analysis characterisation methods (XRF and XRD analyses, visual and tactile descriptors, scale dissolution and elemental analysis) allow the development of scale descriptor information data sheets for typical scale types present in Australian sugar mill evaporators.

The conclusions from the tactile studies were that it was not an effective method to identify different scale types since the textures of most of the scale types were similar. Nonetheless, the tactile data were included in the data sheets. These data sheets are summarised in Figures 2 to 4 for the scale samples obtained from the Nos. 1, 4 and 5 evaporators.

As chemical analyses of scale samples are expensive and can not be completed in a timely manner, the aim was for the portfolio of data to serve as a reference for factory staff to qualitatively assess the scale composition based on the colour and appearance of the scale. This will assist in the prediction of appropriate and effective chemical cleaning agents to be used in the different effects to remove scale.

The following steps should be undertaken to characterise an unknown scale sample and to propose a cleaning procedure:

**Step 1.** Identify sample source e.g., No. 1 effect.

**Step 2.** Identify the colour of the sample (note whether the sample is wet or dry).

**Step 3.** Identify the appearance of the sample.

**Step 4.** Based on the results of steps 1, 2 and 3 refer to scale descriptor data sheets containing No.1 scale.

**Step 5.** Based on the results of step 4 propose a cleaning procedure by referring back to the scale descriptor data sheets.

**Step 6** The proportions of the mail scale components may be different from those represented in the data sheets. Therefore, it may be necessary to determine the calcium and phosphorus contents.
It should be noted that the data sheets are not comprehensive as only one set of scale samples was obtained from each mill at varying times through the 2001 crushing season and the composition of scale is known to vary as the crushing season progresses (Doherty, 2000). Certain types of scale may also look the same but have different compositions that will impact on the efficacy of cleaning agents. For example the scale obtained from No. 1 effect at mill G is similar in appearance and texture to the scale obtained from No. 4 effect at mill D; however, one scale is readily attacked by acids and the other by EDTA. Knowing from which effect the scale originates provides an extra parameter that can be used with generalised trends shown in Figure 1 that may allow a more accurate prediction of the scale composition.

Discussion

The procedures adopted by different mills to control scale in their evaporators vary in the choice and concentration of chemicals, the length of cleaning time and the degree of cleaning obtained. If the evaporator has sufficient monitoring of operating and process parameters, then the HTC can be calculated and used to determine the degree of cleaning obtained and the effectiveness of cleaning chemicals used (Broadfoot and Dunn, 2007).

Alternatively, visual inspection of the heating surfaces enables a similar indication of cleaning effectiveness but requires adequate sight glasses and lighting to observe the evaporator heating surfaces following a clean or that the evaporator is opened for access which takes time and labour. Simple probes could also be developed to allow on-line sampling of scale to overcome these issues.

The cleaning protocol recommended from the present study involves the use of one cleaning chemical at a time. In certain situations, it has been found that this cleaning procedure has yielded unsatisfactory results. This occurs when the composite scale is made up of different layers/regions with different compositions. This has recently been illustrated from scanning electron microscopy and energy dispersive spectroscopy studies on scale in an evaporator tube which showed two different types of morphologies in a composite (East and Doherty, pers. comm., 2009).

Figure 5 shows poorly formed bi-pyramidal calcium oxalate di-hydrate crystals covered by a silica layer with smaller silica ball particles dispersed in the composite matrix. Such a scale matrix can only be effectively removed by the use of a formulation made up of caustic soda and EDTA. EDTA on its own will not dissolve or dislodge calcium oxalate scale that is covered by a layer of silica. However, caustic soda will readily attack the silica layer exposing the oxalate layer to EDTA attack.

Conclusions

Results have shown that, by identifying the chemical elements of scale and knowing from which evaporator vessel the scale originated, a prediction of the scale composition can be made. If the elements silicon, phosphorus, iron and sulfur are detected, then their associated chemical compounds can be predicted. It is not as straightforward with calcium. This is because calcium is
present in a number of chemical compounds and so the use of x-ray powder diffraction becomes necessary. However, in many situations, high calcium levels in Nos. 4 and 5 effects of a quintuple evaporator set suggest the presence of calcium oxalate.

![Fig. 5—Scanning electron micrograph of silica/calcium oxalate dihydrate composite in an evaporator tube.](image)

The visual descriptor studies have shown that if the origin of the scale is known, the colour and the appearance of scale can be used to qualitatively assess the scale composition. Dark coloured scale usually contains hydroxyapatite and organic matter, while creamy coloured scale contains calcium oxalate or is a mixture of calcium oxalate and amorphous silica.

When the scale is flake-like in appearance, it is likely to be a mixture of calcium oxalate and amorphous silica. The conclusions from the tactile studies were that it was not an effective method to identify different scale types since the texture of most of the scale types was coarse.

The paper presents a methodology for developing reference information on the scale types present in evaporators for factory staff based on various scale characterisation techniques. The database of information can add to the experience of factory staff that may enable a useful reference to determine effective and appropriate chemicals for cleaning purposes.

**Acknowledgements**

The funding provided by the Sugar Research and Development Corporation and a syndicate of Australian sugar mills is acknowledged. The assistance provided by a number of mills in collecting scale samples is also appreciated.

**Résumé**

Le nettoyage des évaporateurs de sucreries est un exercice onéreux. L’identification des composants des incrustations aide à déterminer les meilleurs produits chimiques pour le nettoyage. Les méthodes actuelles (diffraction des rayons x, chromatographie liquide à échange d'ions/haute performance et l'analyse thermique thermogravimétrie/différentielle) utilisées pour la caractérisation des incrustations sont difficiles, onéreuses et ne peuvent pas être effectuées dans un laboratoire d'analyse conventionnel ou par le personnel du moulin. Cette étude a examiné des descripteurs simples pour la caractérisation des incrustations dans des évaporateurs australiens. Des échantillons d’incrustations provenant de sept évaporateurs australiens ont été obtenus par des moyens mécaniques. L'apparence, la texture et la couleur des incrustations ont été notées; les échantillons ont été caractérisés à l'aide de fluorescence de rayons x et diffraction de poudre de rayons x, pour déterminer les composés présents. Un certain nombre de kits de test analytique commerciaux ont été utilisé pour déterminer le contenu de calcium et phosphate des échantillons. Des expériences pour étudier la dissolution ont été effectuées sur les échantillons avec les agents de nettoyage sélectionnés, pour fournir des informations pertinentes sur l'effet des agents de nettoyage. Les résultats montrent que, en identifiant tout simplement la couleur et l'apparence des incrustations, leur composition élémentaire et de savoir de quel effet l’incrustation est issue, une prévision de la composition de l'incrustation peut être faite. Ces descripteurs et les résultats des expériences de dissolution donnent au personnel d’usine un processus rapide, sur place, pour prédire les substances chimiques les plus efficaces pour le nettoyage chimique des évaporateurs.
DESARROLLO DE HERRAMIENTAS DE DESCRIPTOR PARA LA CARACTERIZACIÓN DE INCRUSTACIONES EN EVAPORADORES EN AUSTRALIA

PALABRAS CLAVE: Evaporador, Incrustación, Limpieza Química.

Resumen
LA LIMPIEZA de evaporadores en un ingenio es una operación costosa. La identificación de los componentes de la incrustación ayuda en la determinación de los agentes químicos eficaces para la limpieza. Los métodos actuales (basados en técnicas de difracción de Rayos X, intercambio iónico/HPLC y termogravimetría/análisis térmico diferencial) usados para la caracterización de incrustaciones, son difíciles, costosos, consumen tiempo y no pueden ser ejecutados en un laboratorio de análisis convencional o por el personal de planta. Este trabajo ha examinado el uso de pruebas simples de descriptor para la caracterización de las incrustaciones en evaporadores australianos. Se obtuvieron muestras de incrustación por medios mecánicos de siete evaporadores. La apariencia, textura y color se registraron antes de caracterizar las muestras usando fluorescencia de Rayos X y difracción de polvos en Rayos X para determinar los compuestos presentes. Se utilizaron varios kits de pruebas analíticos y comerciales para la determinación de fosfatos y calcio en las muestras. Se hicieron experimentos de disolución con agentes de limpieza química para determinar sus efectos sobre diferente tipo de incrustación. Se demostró que simplemente identificando el color y la apariencia de la incrustación, la composición elemental y cual efecto se analizaba, podía hacerse una predicción de la composición de la incrustación. Estos descriptores y experimentos de disolución pueden ser utilizados para suministrar información rápida y formular los químicos para la limpieza de los evaporadores.
IRON MEDIATED CLARIFICATION AND DECOLOURISATION OF SUGARCANE JUICE

KEYWORDS: Colour, Removal, Clarification, Iron.

Abstract

IN ORDER TO operate most profitably, the sugar producers in Louisiana wish to engage in a cooperative arrangement with the sugar refineries. Because the sugar refinery is an industrial scale decolouriser that operates using natural gas as fuel, it makes sense that sugar with less colour, produced using bagasse-power, would likely have greater profit margins. The removal of phenolic colorants from raw juice using native cane protein as a vehicle and Fe$^{3+}$ as an oxidative catalyst was studied. Colour was removed as phenol-protein conjugates which rapidly precipitated with the addition of a cationic flocculant. The decanted juice was clarified via cold-liming. The treatment yielded clarified juice with up to 70% lower colour than hot-liming juice. It appears that the phenolics were oxidised by Fe$^{3+}$ which engaged a REDOX cycle yielding quinoid species. The free N-$\varepsilon$-amino groups of lysine in the albuminoid proteins appeared to add to the quinones. Stoichiometry indicated a degree of polymerisation of eight. Oligomer formation ceased at this length which appeared sufficient to facilitate irreversible cross-linking and/or capping of the protein. The aggregates of iron, lignol(s) and protein were insoluble and precipitated. The process was tested in a 150 L settling clarifier which was operated in both pulsed and continuous modes. The method scaled well and the product juice exhibited 50–60% less colour than a cold-limed control when Fe$^{3+}$ was applied in quantities ranging from 100–200 mg/L.

Introduction

Commercial cane sugar in the U.S. is refined from a raw sugar (~800–2500 IU) to yield a product with a colour of 15–50 IU. This arrangement is currently in a state of flux as global competition is encouraging vertical integration of the industry (Brady, 2005). Refineries use natural gas to power their operations. The white sugar premium is approximately 6.6 cents (Todd, 1997) per kg but the cost of natural gas can offset as much as 39% of this premium. The cost of the fuel used to process raw sugar is integrated with the price of cane. This price differential is pushing refiners to demand lower colour raw sugar to reduce their cost of refining.

The prohibitive expense associated with the implementation of affination in the raw sugar mill makes alternative options attractive. A wide variety of techniques and additives have been tested to either improve clarification and/or reduce the colour of raw sugar. A comprehensive review has been presented elsewhere (Madsen, 2006). There are no industrial-scale decolourising processes operating at raw sugar mills in the United States. The base technology is in the form of the carbon and resins that are used in refinery facilities.

It has been noted that the phenolic materials present in sugar originate in the cane. Removal of these materials from the juice will prevent them from propagating through the process. The colour load of the clarified juice rapidly saturates decolourising carbon which necessitates frequent regeneration via kilning (thermal desorption). This can be surmounted by a chemical regeneration process (Bento, 2006; Rein and Bento, 2006).
Additives can be used to bleach or inhibit colour formation in processing streams or on sugar. For example, hydrogen peroxide has been considered as a pre-treatment method for resin/carbon decolourisation (Bento, 2004) or as a bleach for sugar when applied directly (Saska, 2006). Iron salts can be used to effect clarification and decolourisation when used in tandem with ultrafiltration (UF), peroxide, sulfitation and/or conventional liming procedures. A hybrid decolourisation/clarification method similar to the work presented here was reported by Zerban (1921) who applied 20 ppm of Fe$^{3+}$ and observed little effect. A patent (Madsen et al., 1984) describes the use of ferric chloride as a chelant/oxidant. The agent served to create floc which was removed via ultrafiltration and the resulting liquor was hot-limed.

Iron is present in cane, and some 30–40% (Seip, 1947) of it is extracted into the juice during milling. Additional iron enters the juice as soluble salts (Subbarao, 1935) via the action of acidity upon mild steel piping and equipment. The total amount is about 10–20 mg Fe per L (van der Poel et al., 1998) of juice. This iron is implicated in the formation of colour in cane juice, presumably via formation of both coloured complexes and oxidation products (quinones and polymer) with intrinsic phenolic compounds (Riffer, 1986). This mechanism can be exploited to effect coagulation of the phenolic colorants which could facilitate removal via UF.

Described in this work is a process where ferric iron is used, in conjunction with a cationic flocculant and conventional cold-liming to reduce juice colour without the use of carbon, resin or ultrafiltration.

Materials and methods

**Iron clarification: Settling rate of flocs from raw juice**

Raw juice was treated with an aqueous solution of Fe$^{3+}$ as FeCl$_3$ (Mallinckrodt, hexahydrate, 99.8%). The material was standardised against a five-point curve (EM, IX0230-2, 1000 mg/kg Fe$^{3+}$ in HCl, $R^2 = 0.9999$), as the Fe$^{3+}$ tris(o-phenanthroline) complex via absorbance (Beckmann Coulter DU-800) at 510 nm. The determination was made both with and without hydroxylamine as a reductor. By difference, it was determined that the working solution, made with 18 MΩ de-ionised water, contained 49 232 mg/kg of iron, 1.71% of which was Fe$^{2+}$. This solution was used in all subsequent tests.

Directly following the addition of Fe$^{3+}$ to raw juice, the mixture was stirred and cationic polyamine (Ecolab PCS-3106) was added at 10 mg solid/kg juice. The polyamine content of the liquid preparation was determined via gravimetry to be ~60 g/100 g.

Immediately following the addition of the cationic flocculant, the juice was stirred and poured into an Imhoff cone and the settling rates were determined using a stopwatch. The time was marked onto the cone and the supernatant juice was collected via syringe. The supernatant was weighed and expressed as the mass percent of juice recovered/time. Mud was defined as the difference.

The mud was filtered through a coarse paper and the filtrate was mixed with the decantate. The mixed juice was brought to a pH of 7.1 with slaked lime (Ca(OH)$_2$ 5g/100g) and then rapidly brought to boil using a microwave oven. To the boiling mixture was added anionic polyacrylamide (Magnafloc LT-340), 5 mg/kg as polymer). This mixture was settled as before to yield a clarified juice. The juice was adjusted to pH = 7±0.1, filtered through 0.45 μm membrane filter and colour was measured by absorbance at 420 nm. This process was repeated for the samples containing 50–600 mg/kg Fe$^{3+}$, in 50 μg/g increments.

**Pilot Test**

Briefly, the ‘dual clarification’ method involved:

1. Treatment of raw juice, at ambient temperature, with approximately 150 mg/L Fe$^{3+}$ and 10–15 mg/L of cationic flocculant.
2. Settling of this mixture to yield ‘stage-1’ juice.
3. Stage-1 juice was limed ‘cold’ to pH 7.1 and rapidly boiled.
4. To this was added up to 5 mg/L anionic flocculant. The mixture was settled to provide a decolourised, ‘stage-2’ juice.

A pilot-scale settling clarifier was constructed to hold approximately 150 L of juice and was designed to operate continuously at approximately 7.7 L/min. The clarifier was used to test the efficacy of the iron mediated clarification and decolourisation (FeMCaD) process. The equipment used for this work can be seen in Figure 1.

The goal was to evaluate the colour removal both in batch (single-tank of juice dosed at once) and continuous modes of operation (steady-state with in-line addition of chemicals).

In the batch tests, the iron was added in increments from 0 to 50, 100, 150 and 200 mg/L in 150 L of raw juice. In continuous mode, the clarifier was brought to steady-state. The 150 L vessel was fed raw juice at 7.7 L/min. Iron and cationic flocculant were dosed to supply 150 and 15 mg/L, respectively. The stage-1 juice was taken off at a rate of 6.7 L/min and mud was removed via a progressive cavity pump at a rate of 1.0 L/min.

![Fig. 1—Pilot clarification module tested at Raceland (2007 campaign).](image)

**Irreversible coagulation and a covalent mechanism**

Protein, fraction V bovine serum albumin (BSA, Cohn fraction V), was used to make a solution that delivered 9.04E-8 mMol/μL (5853 μg/g) in de-ionised water. Acetate buffer (1 M) was prepared from de-ionised water and sodium acetate and was adjusted to pH 5.00±0.05 (Oakton 11 series with Ag/AgCl probe) using glacial acetic acid (Mallinkrodt, AR).

A model phenolic compound, 3,4-dihydroxycinnamic acid (caffeic acid, CFA), was used to make a solution of 4.95E-5 mMol/μL (8825 μg/g) in a degassed matrix consisting of absolute ethanol and water, 1:1.
A solution was prepared from analytical grade sucrose (Fisher, ACS, 99.8% $\left[\alpha\right]_D^{25}=+66.5^\circ$) and 18 MΩ de-ionised water.

This solution contained 40 g/100 g (brix) and was standardised by refractometry (Bellingham and Stanley RFM340). With dilution, this solution was used as the base for the model solutions.

A 0.2 M phosphate buffer solution (PBS) was prepared by dissolving 9.36 g NaH$_2$PO$_4$, and 32.73 g Na$_2$HPO$_4$ into 1 L of de-ionised water. Eluent for gel permeation chromatography (GPC) was prepared using 250 mL of this solution and 17.53 g NaCl diluted to 1 L.

The eluent contains 50 mMol PBS and 0.3 M NaCl, at pH= 7.0±0.1. This solution was degassed under vacuum (24’ Hg) with sonication prior to use.

In order to establish the stoichiometry that exists between BSA, CFA and Fe$^{3+}$, the aforementioned materials were used to prepare a series of samples according to the matrix given in Table 1. The amount of BSA applied to each sample equates to 9.04E-5 mMol of protein or 5.42E-3 mMol of N-ε-NH$_2$-lysine. Fe$^{3+}$ was added at 5.65E-3 mMol, a slight excess over the BSA amino equivalent.

The samples CFA 3 and 7 (bold text), represent one and two equivalents of CFA, respectively. To 15 mL polyethylene centrifuge tubes was added, in this order: water, sucrose solution, BSA solution, CFA solution, AcONa buffer and, finally, FeCl$_3$ solution.

The samples were sealed and swirled (vortex mixer) to mix and allowed to stand at room temperature (24°C) for 10 minutes. The samples were centrifuged at 3600 r/min for 10 min. The tubes were sampled and analysed via GPC.

The operational parameters for the GPC are given in Table 2. The instrument was standardised for molecular weight using apro tinin (6.5 kDa), carbonic anhydrase (29 kDA) and BSA (66.4 kDa) via absorbance at 280 nm.

A quantitative calibration was made using a mixed standard containing BSA and CFA. Since only one wavelength is available at a time, 330 nm was chosen because it is an absorbance maxima for caffeic acid ($R^2=0.997$). BSA has a very small absorbance at this wavelength, so quantitation could be made using the DRI ($R^2=0.995$).

The samples were analysed via GPC. The plots acquired using the DRI were not used because the BSA rapidly fell below the limit of quantitation. Under the conditions specified in Table 2, caffeic acid had a retention time of 14.68±0.04 minutes.

A response factor (amount/area) of 6.022E-05±4.7% was used for quantification. The points at 200, 390, 568, 780, 992, and 1204 µg/mL represent 1.0, 2.0, 3.0, 4.0, 5.1 and 6.2 BSA (60 * LYS) equivalents, respectively.

Results and discussion

Decolourisation, given in Figure 2, reconstructed using equation 1, was dependent upon the dose of Fe³⁺. The limitation imposed upon the decolourisation process is the mud pack volume.

This is illustrated in Figure 3, which describes the behaviour of the mud-pack relative to the Fe³⁺ dose. Decolourisation reached a maximum of 60% using decantation for mud removal. The mud-pack volume was 20% greater than that observed with the standard clarification process.

![Graph](image-url)
The colour reduction, the colour removed relative to the control, was dependent on the amount of iron applied. This relationship appears to follow the following empirical equation, where Fe\(^{3+}\) is the amount of iron added in mg/kg.

\[ \text{Colour removed,\%} = \left( \frac{\text{control colour} - 35289 \times Fe^{3+}{-0.32}}{\text{control colour}} \right) \times 100 \tag{1} \]

It was noted during the bench scale trials that, although the decolourisation continues to improve as iron levels are increased (up to a point), the settling rates decrease (and mud-pack volume increases). This can be seen in Figure 3 for juice settled for 20 minutes.

![Graph showing the relationship between Fe\(^{3+}\) and juice recovery](image)

\[ y = -9E-05x^2 + 0.0211x + 60.464 \]
\[ R^2 = 0.974 \]

Fig. 3—Juice recovered in 20 minutes when increasing iron dosages beyond 200 mg/L.

In the laboratory, the juice can be filtered or centrifuged to provide a sample for analysis. Because this would be uneconomical to do in the mill, it was decided that dosing to 150–200 mg/L to provide a decolourisation of up to 50% was a practical limit.

While type/brand of anionic flocculant demonstrated little variation, the cationic materials were not equivalent. For example, products such as the Cytec Superflocs (regardless of charge density) performed marginally, while the PCS-3106 was exemplary.

A chart displaying the removal of juice colour, relative to a cold-limed control is given in Figure 4. The decolourisation % for each bar is calculated relative to a control taken at the same time from a tap preceding the dosing points on the clarifier module.

The behaviour of the pilot scale process is similar to that observed at bench scale and decolourisation behaves in a manner similar to that described by equation 1.
The two step process yielded a low colour juice similar to what can be seen in Figure 2. After 45 minutes, the mud had a settled volume of 26 mL/100 mL. This volume of mud contained approximately 1.2 g of dry solids which was similar to that recovered during the bench-scale trials plotted in Figure 3.

The overall colour reduction, in pulsed tests, versus raw juice clarified by cold-liming (control) was approximately 50% when the iron was applied at 150–200 mg/L. When the iron dose exceeded this amount, the settling rate decreased. Thus, a dosage of 150 mg/L of iron was selected for tests where the clarifier would be operated continuously. The results were consistent with those achievable in the lab, in terms of dose-response and an equivalent nominal colour removal of ~50%.

The clarifier operated without incident for approximately six hours. During this time, the juice was collected, along with a concomitant control, limed, brought to boil using a microwave, flocculated (5 mg/L anionic flocculant) and settled to yield stage-2 juice which was assayed for colour.

This juice exhibited a level of decolourisation which was comparable to that observed in the batch test at equivalent dosage. It was concluded that the two-stage method scales well and can provide a clarified juice with 50% less colour than that achievable with normal hot or cold-liming procedures.

It was found that if cane juice is treated with iron, cationic flocculant and cold-limed, up to 50% of the colour in the juice can be removed at the clarifier. The liming step must take place before the juice is heated. If this order is reversed, the sucrose inverts and the juice will form colour on contact with air. The treated juice can then be limed and clarified normally.

The samples in Figure 5A appear to be identical. Upon the addition of the iron, it was immediately noted that samples containing two BSA equivalents (1.1E-2 mMol) of CFA precipitated immediately. The samples in Figure 5B were centrifuged. The precipitation of coloured material in Figure 5C is striking and increases with the amount of added CFA. Upon standing sealed for three days, all samples containing at least 1 BSA equivalent (5.4E-3 mMol) precipitated completely. The precipitate pellets in Figure 5D appear smaller because the mixtures were re-centrifuged to settle the flocs that had formed.
Fig. 5—Addition of iron and centrifugation of model samples. 148 and 375 μg/mL CFA correspond to CFA 3 and 7.

The amount of CFA consumed, expressed in Figure 6 in mg/L, inset, reached a maximum at 200 and was resolved at 500 μg/mL CFA. This is equal to 0.005 mMol and is very close to 1 N-ε-lysine BSA equivalent (0.0054 mMol).

Fig. 6—Amount of CFA consumed. Note the plateau (steady state) and point of saturation (inset).
From this it appeared that at least two, simultaneous reactions were occurring. The first suggests a saturation effect and the second suggests polymerisation. Between 7.971 and 8.333 BSA equivalents of CFA are needed before the rate of consumption stabilises. Approximately 14.5 equivalents are needed before the amount of CFA detected equals the amount that was applied.

The plot in Figure 6 suggests that there is a fast initial consumption of CFA which ended when ~1 lys-BSA equivalent, or 0.05 mMol of CFA was added. This suggests that the free sites are reacting/binding until saturation. Following this, there is a short induction period, possibly the accumulation of an undetectable intermediate, followed by a linear increase in consumption. This implies that either the residues added in the prior step are reacting with further CFA and removing it from the bulk solution or the CFA is homopolymerising.

It appears that first, the free N-ε-amino-lysine groups are reacting with the phenolic species, probably in the quinone form. Then, the quinone end-groups are reacting further to extend phenolic chains outward. This continues until either the CFA reservoir is exhausted and/or the chains extending from two separate proteins meet and couple.

From the stoichiometry given in Figure 6, where the maximum CFA consumed amounts to 0.0343 mMol, it can be derived that the equivalence to BSA is approximately 380:1. On free amino-groups this amounts to a ratio of 6:1. There appears to be, depending upon the cross-linker used, of the 60 lysine residues in BSA, approximately 8–12 are able to crosslink with the N-ε-NH₂ lysine(s) of other protein molecules in the bulk solution (Huang et al., 2004).

If the number of chains per protein is, on average, 10, the CFA to amino group ratio then becomes 38:1. Dividing this figure by two, for two interacting protein molecules gives a bridge length or degree of polymerisation of approximately 8.

Upon examination of the stage-1 (acidic Fe³⁺) process under a microscope, it was found that the application of 6 M urea failed to disrupt the floc, and the addition of EDTA caused only a marginal disassociation. Addition of o-phenanthroline caused the flocs to become larger and more robust. This is demonstrated in Figure 7. GC-MS analyses of mixtures of juice and phenanthroline with and without iron indicated that the ligand was either removed from solution or otherwise destroyed.

The failure of 6 M urea to disrupt the floc argues that little in the way of hydrogen bonding is responsible for the stability of the BSA:CFA aggregates. The very slight disruption observed when the aggregate was treated with EDTA indicates that some, but not all of the structure is likely dependent upon chelation of iron. The effect of added o-phenanthroline was unexpected.

Rather than causing the material to disintegrate (at least partially) due to sequestration of any bound iron that might be structural, the addition of o-phenanthroline caused the flocs to become larger (Figure 7). Unsure of this result, the juice was treated with “excess” o-phenanthroline with
and without added FeCl₃. These samples were analysed via GC-MS and revealed a marked (>90%) removal of the ligand. In order to explain this, it was found that Cavalieri et al. (2002) had reported on the electrophilic addition of o-quinone species to purine bases in DNA. The reaction involves the radical semiquinone and is functional over a relatively wide range of pH, including physiological. An adapted scheme is given in Figure 8.

![Fig. 8—Synthesis and reaction of a o-quinone with a purine base.](image)

This scheme (Figure 8) is in line with observations. Instead of using cyp (cytochrome P) 450, Fe³⁺ serves as the initial oxidant to yield the semiquinone which is subsequently subject to autooxidation via O₂. The resulting quinone then reacts with the purine base to yield the adduct.

We were unable to confirm that the o-phenanthroline was behaving in a similar way. It was suspected that the compound, being difunctional, might be serving a crosslinking species. Because the aggregates appear to be covalent in nature, they are irreversibly formed. This irreversible nature indicates that the flocs once made, may be stable through liming, removing the need for the second stage of the process. With cold liming, it might be possible to do both steps, sequentially, in one reactor.

**Conclusions**

Ferric chloride can be used to remove phenolic compounds from cane juice via coagulation. As iron dosage is increased, the amount of floc increases as the settling rate decreases. Addition of cationic polyacrylamide improves the settling rates allowing for higher iron dosages to be used. Under the best conditions, it appears that a removal of approximately 50% (55±4%) of the colour can be practically achieved while maintaining a satisfactory degree of clarification within 20 minutes of settling.

The method scaled well and performed as predicted by the bench-scale experiments. It was found that the 50% reduction of colour (relative to a cold-limed control) was achieved with the application of 150–200 µg/mL Fe³⁺ and then liming to pH 7.1.

The mechanism appears to be a mixture of classical charge-neutralisation, complexation and covalent linkages between the phenolic compounds and native albuminoid protein found in the juice. The aggregates made via charge-neutralisation can be disrupted via addition of further coagulant while the complexes are labile to changes of pH, treatment with o-phenanthroline and/or application of urea. The flocs made here were especially resistant to the action of urea, were insensitive to pH and were demonstrated to aggregate with and remove o-phenanthroline.

This action was tested on BSA using varied amounts of the phenolic surrogate compound caffeic acid. It was found that the rate of consumption increases until flocs are no longer observed to form. At this point, steady consumption dropped to zero and the process was considered complete.

The observed consumption revealed an initial saturation of the protein which occurred at 200 µg/mL CFA. This corresponded to the number of free N-ε-amino groups from BSA. Following this, the rate of consumption increased until 1500 µg/mL of CFA had been consumed. At 2250 µg/mL, the rate of consumption drops to zero and the reaction is complete. Based on the number of N-ε-amino groups present, it was elucidated that crosslinks formed between the proteins which were between 6 and 10 phenolic residues in length.

Résumé
POUR AMÉLIORER la rentabilité, les producteurs de sucre en Louisiane souhaitent coopérer avec les raffineries de sucre. Étant donné que l’opération principale de la raffinerie est de réduire la couleur et que la raffinerie fonctionne à l'aide de gaz naturel comme combustible, il est logique que le sucre avec moins de couleur, produit à partir de bagasse, donnerait de meilleurs gains financiers. L'élimination des matières colorantes phénoliques du jus brut à l'aide de protéines présentes dans la canne et du Fe$^{3+}$ comme un catalyseur oxydatif, a été étudiée. La couleur a été supprimée grâce à la précipitation de composés phénol/protéine cause par l’addition d'un floculant cationique. Le jus décanté a été clarifié par le chaulage à froid. Le traitement a donné un jus clarifié avec une couleur réduite par 70% comparée au jus provenant d'un chaulage à ébullition. Il semble que les phénoliques ont été oxydés par le Fe$^{3+}$ à travers une réaction RÉDOX produisant des quinoides. Les groupes N-ε-amino libres de lysine dans les protéines albuminoïdes s’ajoutent aux quinones. La stoichiométrie a indiqué un degré de polymérisation de huit. La formation d’oligomères cesse à ce point ce qui facilite la réification irréversible de la protéine. Les agrégats du fer, lignol(s) et protéines étaient insolubles et sont précipités. Le processus a été testé dans un décanteur de 150 litres qui a été exploité en mode pulsé et continu. La méthode à bien fonctionnée et le jus produit présentaient 50–60% moins de couleur compare à un contrôle chaulé à froid, avec 100-200 mg/l Fe$^{3+}$ ajoute au jus.
CLARIFICACIÓN CON HIERRO Y DECOLORACIÓN
DE JUGO DE CAÑA

Abstract
PARA OPERAR en un modo más rentable, los productores de azúcar en Louisiana desean emprender un arreglo cooperativo con las refinerías de azúcar. Debido a que una refinería es una estación reductora de color a escala industrial que opera usando gas natural como combustible, tiene sentido que un azúcar de menos color, producido usando energía del bagazo, pueda dar mejores márgenes de ganancia. Se estudió la remoción de colorantes fenólicos del jugo crudo usando proteína de la caña como un vehículo y Fe³⁺ como un catalizador oxidante. El color fue removido como conjugados de fenol-proteína que precipitaron rápidamente con la adición de un floculan te catiónico. El jugo decantado fue clarificado vía encalado en frío. El tratamiento dio jugo claro con hasta 70% menos color que el jugo encalado en caliente, Parece que los fenólicos fueron oxidados por Fe³⁺ el cual entró en un ciclo REDOX produciendo especies quinoides. Los grupos libres N-ε-amino de lisina en las proteínas albuminoides parecieron sumarse a los quinoides. La estequiometría indicó un grado de polimerización de ocho. La formación de oligómeros cesó en esta longitud que parece suficiente para facilitar ligado cruzado irreversible y/o capping de la proteína. Los agregados de hierro, lignoles y proteína resultaron insolubles y precipitaron. El proceso se probó en un clarificador sedimentador de 150 L que operó en modo pulsante o en modo continuo. La escalabilidad del método fue buena y el jugo mostró 50–60% menos color que uno encalado en frío cuando se aplicó Fe³⁺ en cantidades entre 100–200 mg/L.
PROCESS SYNTHESIS AND MANAGEMENT IN THE BOILING HOUSE OF SUGAR FACTORIES

KEYWORDS: Sugar, Boiling, Modelling, Scheduling, Synthesis.

Abstract

IN THE BOILING house of sugar factories, the process manager may conduct the process through different ways due to the batch mode of operation of vacuum pans, the need for cutting over materials among pans to achieve the required crystal sizes, and the different types of materials that must be handled, some of which are recycled. The process manager addresses most of his efforts to this area since he must try to reach the required standards of quality in end-products and the expected yields, but meanwhile he must also keep a stable steam demand and accumulation of intermediate materials in adequate quantities to maintain a steady operation. A new approach for synthesis and management (material and energy balances, scheduling) of the processes on the pan stage for sugar production from cane is presented and its advantages demonstrated in this paper. Detailed models and approaches for process synthesis and operations management on the pan stage of sugar factories are described. These models are the basis of the software tool PLANAZUCAR® dedicated to the scheduling of complex production systems in the sugar industry. Approaches include the use of HAZOP techniques and other software tools. Through actual case studies, the feasibility of using the software tool PLANAZUCAR for scheduling analysis in the sugar industry was demonstrated. Use of the software has allowed a thorough study of the utilisation rates of the equipment in a factory as well as an analysis of the influence of the production planning on the steam consumption profile, looking for stability in demand.

Introduction

From the process operation point of view, the pan stage differs from other areas of the factory. Whereas most stations operate in a continuous way, most pans do not. The main task of the production manager is to ensure that this batch-wise part of the process operates as steadily as possible, since the efficiency of sugar recovery and maximum processing of raw materials depend on the co-ordination of operations, use of recycled materials, use of equipment, etc. A very important aspect for pan stage operation is the stabilisation of steam demand.

For years these management tasks have been accomplished by process managers using tools which they developed themselves through practice and heuristically. Modern approaches for process synthesis and management in this area have been studied.

Aguado (1973) published a paper proposing a discrete programming model for scheduling of operations in vacuum pans. De Armas and Rostgaard (1983) proposed another approach: that of representing this problem as an activity network with limited resources and the use of linear programming (LP) for solving the materials balances.

The Monte Carlo method was used to predict duration times of activities during simulation runs to establish the more probable way of conducting operations in the boiling house. Since then,
simulation languages and dynamic programming methods have been used. All these jobs had limitations in representing the whole process.

In this paper, three case studies introducing new models for process synthesis in both raw and refined sugar production from cane are presented. Two of them are used for operations scheduling and another, at operations level, is proposed for material balances linked to the operations schedule.

**Case study 1: The EON approach**

This approach is based on the definition of recipes describing tasks being done for sugar production on the pan stage. These recipes include information about operations that should be carried out and resources (materials, utilities) used by them. Operations are then assigned to equipment to represent a strategy to be simulated. The structure of the activities to be performed within each process is represented through a general activity network called Event Operations Network or EON (Graells et al., 1998). The rigorous modelling of the operation timing involved in the recipe is achieved by means of EON elements: events, operations and links.

Events designate time instants in which a change may occur. They are represented by nodes in EON graphs and should be linked also with other events. Each event is associated with a time value and a lower bound. The time values for each event will be the variables of the timing problem that must be solved. The lower bound can be used to force delays in a given solution or force a new solution fulfilling special constraints.

Operations designate those time intervals to be observed between the starting event (initial node) and the ending event (final node). Operations are expressed as equality links between nodes in terms of the operation time and the waiting time. The operation time is a pre-determined value as a function of the amount being processed, unit assigned, etc. The waiting time is a value below the maximum time a material could be stored in the vessel before discharge.

Finally, links designate event-event precedence constraints.

Thus the linear programming problem formulation may be defined by:

- Ending time of operation $i$ in stage $j$ in unit $k$ is equal to operation starting time plus operation duration time, plus waiting time.
- Starting time of operation $i+1$ in stage $j$ in unit $k$ is greater than or equal to the ending time of operation $i$ in the same stage and unit.
- If any two operations $i$ and $i^*$ corresponding to tasks $j$ and $j^*$ are done simultaneously in two $k$ and $k^*$ units and one depends on the other (such as transfer of material from one pan to another), then waiting time of operation $i$ in stage $j$ in unit $k$ is less than or equal to the maximum waiting time defined for that operation in that stage and unit.
- Duration time of operation $i$ in stage $j$ in unit $k$ is defined as a function of unit $k$ volume occupation during operation $i$ of task $j$.
- Consumption of material $l$ for each operation $i$ in every stage $j$ and unit $k$ is defined in the same way as the duration time.
- Lower and upper bounds for unit operating capacities.

An objective is needed to discriminate a good solution among the infinitely feasible solutions. A simple and practical one is minimising the total duration of the process which allows compressing the resulting schedules and improving capacity utilisation. This function takes into account durations of all operations done in the process.

The factory being studied produces 2000 tonnes per day of refined sugar, using a four massecuite processing system with double seed magma preparation in raw sugar production, producing ‘A’ sugar for the refinery and raw sugar for sales. In the refinery, a three massecuite processing system is used for the production of three qualities of refined sugar, while final molasses from the refinery is recycled to the raw sugar factory. In the raw sugar section of the factory, there
are 23 vacuum pans, 14 vessels for intermediate and final materials, 52 crystallisers and 35 batch centrifugals. In the refined sugar section, there are eight vacuum pans, six vessels for intermediate materials, 11 crystallisers and 17 batch centrifugals. Seventeen different materials are processed. All the mentioned equipment, materials and areas were included in the analysis, so the dimensions of both the models for material balances and scheduling were large.

The material and energy balance calculations were done using the SIMFAD software package (Sabadi et al., 1991). The mathematical model describing the process includes constraints for:

- Solids, total flows and pool balances;
- Mass fraction of sugar crystals contained in massecuite;
- Growth of sugar crystals from seed to commercial size;
- Steam and power demand in operations; and
- Other technological constraints based on operators’ experience.

The main purpose was to study the best co-ordination between vacuum pans, crystallisers and centrifugals to achieve an optimal equipment utilisation and to avoid any instantaneous high steam demand. The objective function used was to minimise steam consumption, both for raw and refined sugar production. All results, including those for purities of intermediate materials are in close agreement to the actual values in the plant.

Different boiling strategies were defined and 10 basic recipes were developed for raw sugar and six for refined sugar production strategies. Data regarding resource information and recipe definitions were used to perform the calculations that end up into a desired production plan.

In sugar boiling, the duration of the operation depends on the crystal growth which is not a fixed value. A closer representation to reality is reached using the Monte Carlo simulation method based on the historical average values of task duration and their variance. These values are used in PLANAZUCAR© 2.0 for randomly generating values for duration in order to select the most probable makespan of the process.

Manual modifications in the proposed schedule were done to evaluate the consequences of the changes performed. Timing of operations, predicted evolution of the level profiles of intermediate storage, prediction of the use of resources such as steam, etc., were considered. The Gantt chart in Figure 1 shows operations done in six of the pans in the factory, as a prediction over 32 hours.

![Gantt chart](image)

Fig. 1—Gantt chart for six pans showing materials generation and consumption.
It also includes the production consumption profiles for the final massecuites (MCC) as well as for the required and/or produced intermediate materials (first growth of seed crystals (SPC), syrup (MCOMP), A molasses (MAP), 1st purge, B molasses (MB1) and 2nd purge B molasses (MB2)) and vapour bleed from the evaporators (VVFC, also called ‘vegetal’ steam). These charts compare well with actual operations in the plant. The predicted number of batches is similar to those produced in the factory in the selected equipment for guaranteeing the final products demand.

The profiles of steam consumption for every stage of operation were determined. A highly variable steam demand was shown to exist, thus affecting the boilers and evaporator station in a negative way (Figure 2).

Fig. 2—Steam consumption profiles.

Despite this positive experience (Sabadi et al., 2005), some further improvements in the software were identified and introduced in PLANAZUCAR© 3.0:

- Equations used for consumption of utilities such as steam were improved by using second or third degree polynomial expressions.
- Objective function is optional and flexible; in each case study, the user can select the criterion to be satisfied.

Case study 2: The STN approach

The objective of this case is to evaluate the state task network (STN) approach (Kondili et al., 1993), which is a mixed integer linear programming model (MILP), in boiling schemes synthesis, through the software tools gBSS (Pantelides et al., 1993) and PLANAZUCAR© 3.0 (Hurtado and Sabadi, 2005). Although it is an actual case, its representation is not so detailed because it is oriented to evaluate the new approach and software instead of supporting actual decisions in the factory. The fundamental constraints to be satisfied include:

1. The resolution of conflicts when pans are allocated to tasks. At any given time $t$, a pan can only start at most one task. Of course, if a pan starts performing a given task, then it cannot start any other task until the current one is finished.

2. Limitations on the capacities of pans and storage vessels:
   - The amount of material $B$ that starts undergoing task $i$ in unit $j$ at time $t$ is bounded by the maximum and minimum capacities of that unit.
– The amount of material stored $S$ must not at any time exceed the maximum storage capacity $C_s$ for this material.

(3) Material balances. This constraint simply states that the net increase in the amount of a material stored at time $t$ is given by the difference of the amount produced and that used. The initial amount of each material is assumed to be known. All material inventories (including intermediate and final products) have to be specified for adjusting the model to the actual situation in the factory.

In a similar way, some other constraints may be included, extending the model:
1. Temporary unavailability of equipment.
2. Limited availability of utilities and materials.
3. Cleaning of equipment items.
4. Use of equipment items for storing task feeds.
5. Continuous feeds addition and products withdrawal.

As an objective function, the model is capable of accommodating a variety of either economic or system performance measures. The criterion mainly used in the present study is the maximisation of processed syrup.

Figure 3 represents the operation strategies in the production of massecuites. The circles represent the pans, identified by their number, and the other equipment (crystallisers and intermediate storage tanks for example) is represented by rectangles and other symbols. The arrows indicate the feeding and discharge of material. The high grade massecuites are boiled in seven pans while low grade massecuites are boiled in two pans.

Note that there is not a previous assignment of a particular equipment item to a task. Only the information on which tasks can be done in each equipment item is supplied. The solution includes the assignment of tasks to equipment items along horizon time.

Figures 4 and 5 show the results of the process synthesis for a 24 hours time horizon. In the Gantt chart, operations carried on in each equipment (pans, blender, centrifugals) are represented by blocks of different lengths according to their duration. Each operation is identified by a colour. Numbers inside the blocks identify batches and tasks.

Profiles of production and consumption of materials are shown in Figure 5. Massecuites are denoted by MCA, MCB and MCC, and molasses by MA, MB and MC. Intermediate materials in high grade massecuites are identified with an initial S and, in low grade massecuites, by an initial G. AA and AB are commercial raw sugars. Green colour in the profiles indicates no violation of
volume constraints and enough material for operations. A red colour profile indicates an unfulfilled condition.

Although all details of operations corresponding to each task were not defined, it is demonstrated that the model determines the definition and use of each task in the analysis for an optimal solution. Such a solution allows a more effective use of installed capacities due to the fact that an initial feasible solution is not required. Any solution reached must take into account real equipment connectivity in the factory to avoid mathematically feasible, but practically infeasible, solutions. This condition could be included in the mathematical model which can also accommodate equations for defining new piping and pumping installations for a solution. These options were not tested in the actual case study.

Using discrete variables in time representation (MILP) causes a bigger size of the problem, even for analysis of small cases. This case generated 593 equations for an 8 hour time span and 1905 equations for a 24 hour analysis. With gBSS and PLANAZUCAR 3.0, it is now possible to find solutions to these models.

**Case study 3: Balances at operations level**

The development of a non-linear mathematical model for material balance calculations in cane sugar production has been described (Ribas et al., 2002) as well as the software CALIFA©
(Hurtado et al., 2002), supported over such a model. The use of a LP model for the calculation of the material balance in sugar boiling for a specific configuration of pans has been described by De Armas and Sabadi (1993). That approach was used in a scheduling case study for a flow sheet of a three massecuite processing system for a sugar factory which also produced refined sugars based on an EON approach (Sabadí et al., 2001). A similar case study is used to allow comparison. In order to use the results in operations scheduling at the operator’s level, it is necessary to extend the balances to equipment at operations level.

In Figure 6, a non-detailed flow sheet corresponding to the operations level is shown. Nodes (geometric figures) represent the boiling operations, centrifugation, seed preparation and materials distribution; arrows represent flows among nodes and evaporated water. This representation is useful for balances in equipment at the operations level.

![Fig. 6—Flow sheet at operations level.](image-url)
Recipes at operational level were built for high and low grade massecuite production. These recipes describe the way in which operators conduct the operations in the selected equipment. All relevant tasks for producing the output material are included. Each task is described through its operations. The material balance for each recipe was usually introduced through coefficients related to one of the flows coming in or out of the recipe. In former exercises, those coefficients were calculated from an overall material balance for the process flow sheet and adjusted to the number of ‘trees’ required for a specified level of production of a certain material in a certain time interval (Sabadí et al., 2001). In this approach the material balance is done considering every individual operation, so the results are actually fitted to the equipment configuration and production strategy.

In this case, only values for eight variables need to be fixed, including the syrup flow, brix and purity to be processed. The rest of the values for the brix and purity of each flow are lower and upper bounded, based on actual experience and describe the characteristics of final products.

The model includes:
- total flow, solids and purities balances in each node;
- lower and upper bounds corresponding to limiting operating capacities in pans; and
- lower and upper bounds for intermediate storage vessels.

For this exercise, the maximisation of commercial ‘A’ sugar production was used as the objective function.

The results of the material balance for the strategy of production of ‘A’ massecuites, when compared with actual values, show no significant differences. The maximum value for commercial sugar production was 871.5 tonnes, and the value reported by the factory is 864.0. While the calculated ‘A’ massecuites is 2022.4, the value reported by the factory is 2013.0.

Similar comparisons can be done with results for the balances in ‘B’ and ‘C’ massecuites. The main benefit of this methodology is that these results are now easily, and more realistically, associated with the operations when facing a scheduling problem.

It is now possible to know the values for each stream going in and out of the pans and other vessels in each operation. So it is possible to conduct the process provided that the balances include the technological constraints which must be followed during operation for guaranteeing production and quality.

These material balance results can be compared to the corresponding Gantt chart representation of the process obtained with PLANAZUCAR® software tool and shown in Figure 7.
The operations for the ‘A’ massecuites are those in the first five lines of the chart (corresponding to pans 1, 2, 3 and 4 and the ‘A’ crystalliser called CRA). Operations for ‘B’ massecuites are done in pans 5, 6, 7 and 8, using crystalliser CRB. Operations for ‘C’ massecuites are done in pans 9, 10, 11, 12 and 13, using crystalliser CRC. Red colour in the blocks represents waiting time in operations.

With both results, the operator has a proposed schedule for the operations, including the values of the flows. He can guide the process knowing the time in which every operation must begin and the materials he should use to reach the expected results. In practice, it is very difficult to exactly follow the proposed schedule because of the possible occurrence of abnormal situations. So, operators must be well trained to face these problems. A hazard and operability (HAZOP) analysis would be a good basis for such training.

To represent the whole flow sheet of the process with this approach, a medium or large scale model must be built. Experiences with the SQP algorithm demonstrated that it is feasible to do it (Sabadí et al., 2003). To improve user exploitation of the software, it is recommended to include the automatic generation of the initial solution. The Powell algorithm for simultaneous solution of non-linear equation sets can be used for this aim (Sabadí et al., 1991). The lower and upper bounds for all streams could also be generated from this initial solution and improved, if necessary, based on estimates recommended by actual experience. Bounds such as lower and upper operating capacities of vessels and pans should always be provided by the user as well as the selected calculation basis.

Conclusions

Two new approaches have been studied for process synthesis and management of the boiling house of sugar mills: the event oriented and the state task networks, based on LP and MILP models. Both of these models have proven to be useful and included in PLANAZUCAR® 3.0 software. The usefulness of doing material balances at operations level when undertaking scheduling studies has been demonstrated. A model for such an analysis has been included in CALIFA® software. The next step in our work will be the creation of a software suite including the above mentioned tools and another one for hazard and operability analysis (HAZOP) in the boiling house.

Resumen
EN LA CASA de cocimientos de un ingenio azucarero, el jefe de elaboración puede conducir el proceso de diferentes formas debido al modo de operación de los tachos, la necesidad de repartir el material entre los tachos para obtener los tamaños de cristal requeridos, y los diferentes tipos de materiales que se deben manejar, algunos de ellos recirculados. El jefe de elaboración orienta la mayoría de sus esfuerzos en esta área dado que debe obtener las especificaciones requeridas de calidad en los productos finales y los rendimientos esperados, pero debe mantener una demanda estable de vapor y acumulación de materiales intermedios en cantidades adecuadas para mantener operación estable. Un nuevo enfoque para síntesis y gestión (balances de masa y energía, secuenciación) de procesos en la estación de tachos, se presenta en este trabajo junto con las ventajas de su adopción. Se describen modelos detallados y enfoques para síntesis de procesos y gestión de operaciones en la estación de tachos. Los modelos se basan en el programa PLANAZUCAR® dedicado a la programación de sistemas complejos de producción en la industria azucarera. Las aproximaciones incluyen el uso de técnicas HAZOP y otras herramientas informáticas. Se demuestra la aplicabilidad del programa PLANAZUCAR para análisis de programación en la industria azucarera usando el análisis de casos reales. Su uso ha permitido un completo estudio de las tasas de utilización del equipo en un ingenio así como un análisis de la influencia de la planeación de producción en el perfil de consumo de vapor, buscando estabilidad en la demanda.
COLOUR BEHAVIOUR IN CANE JUICE CLARIFICATION
BY DEFECATION, SULFITATION AND CARBONATION

KEYWORDS: Sugarcane, Colour, Clarification,
Sulfitation, Carbonation.

Abstract

COLOUR is sugar’s most important commercial attribute but, in juice clarification, its
removal is usually not considered among primary objectives. However, based on results
presented, all standard clarification procedures have the potential for significantly
higher removal of colour than is realised in the industrial practice. Four principal juice
clarification procedures, viz. defecation by hot liming, sulfitation, carbonation and
double-carbonation were tested and various aspects of colour behaviour investigated.
Carbonation is not widely used in the cane sugar industry, but periodic spikes in sulfur
prices, sugar quality issues and environmental concerns have stimulated efforts to
consider replacing or supplementing sulfur dioxide with carbon dioxide that may be
available cost-free from the fermentation plant. The colour removal, viz. the relative
difference between colour of raw and clarified juice, obtained in our tests was on
average 35, 47, 44 and 74% for defecation, sulfitation, single-carbonation and modified
double-carbonation, respectively. Several factors affecting clarified juice colour in hot
liming were tested, viz. the time and temperature during settling; bagacillo and soil
content, and phosphate and protein addition. At low lime dose, below about 1 kg
CaO/tonne cane (defecation, sulfitation and carbonation), most colour removal results
from adsorption on the heat-coagulated cane protein, rather than on the nascent calcium
precipitate. However, the adsorptive capacity of the precipitate for cane colorants
appears only partially exhausted in the normal procedure. Lowering the clarifier
temperature by 11°C was found to limit the juice colour increase in the clarifiers to
nearly zero. Although the decolourisation effects of sulfitation and carbonation were
found to be about equal, the apparently lower thermal stability of clarified juice and
syrup produced by carbonation may require further study.

Introduction

The colour of sugar, be it raw, direct mill white or refined is its most important commercial
attribute, and much resource is spent by the millers and refiners to comply with the market
requirements on the colour of their product. Crystallisation itself, apart from producing a stable,
marketable product is also 95–99% effective in partitioning colour and is, in the production of low
colour sugar, supplemented by a number of carbon and ion-exchange resin-based adsorption
processes and, to a lesser degree, by methods based on chemical reactions that render colourless the
colorant molecules.

The main objectives of juice clarification are to raise its pH and eliminate suspended solids.
Colour removal is at best considered a secondary objective, rarely monitored by the mill laboratory
and to our knowledge never used as a criterion to assess, let alone control, the process. The use of
SO₂ is widespread in clarifying juice in production of plantation white sugar, however periodic spikes in sulfur prices and sugar quality issues have stimulated efforts to reduce or even eliminate its use. With that in mind, a carbonation process has been tested and compared with standard sulfitation and defecation. Besides eliminating the use of sulfur, carbonation would also provide a means to utilise and sequester some of the excess CO₂ that may be available cost-free in some sugar factories from molasses or juice fermentation. The traditional double-carbonation process was used initially in cane juice clarification in Java (Honig, 1959), later practised for many years in South Africa (Rault, 1960), and is still used nowadays in some cane factories in China, Taiwan (Sheen et al., 2003) and elsewhere. Although it is reported to provide excellent, low colour clarified juice, the very high lime consumption of 11–15 kg CaO per tonne cane is making the economics increasingly un-sustainable. In this program, some modifications were tested to reduce lime consumption and replace the filtration of all first carbonation juice by settling and filtration of the concentrated mud.

**Materials and methods**

In most cases, raw juice was prepared by milling samples of cane brought to Audubon from the Sugar Research Station. Usually, 0.6 to 0.8 L of pressed juice was diluted to 1 L volume to bring the brix closer to that of factory mixed juice, and clarified by four methods: defecation by hot liming, sulfitation, single carbonation or double carbonation.

For defecation, the diluted juice was brought to and kept boiling for about one minute in a microwave oven, then quickly limed while stirring with Ca(OH)₂ slurry to a pH between 7 and 8.2. Then 2.5 ppm of Ciba Magnafloc LT340 flocculant was added while stirring, the whole volume of limed juice transferred to a covered 1 L glass beaker and allowed to settle in a 96°C water bath, usually for 60 minutes, before sampling the supernatant for analysis.

Sulfitation was done in a 6 L stirred jacketed glass reactor provided with lime slurry and gas inlets, and pH and temperature readouts; usually by first liming 1 L of diluted juice at about 50°C to a pH of 8–9 and then gassing with SO₂ to a pH of about 7. Alternatively, gassing was done first to pH 3–4 followed by liming to pH 7. The clarification performance was about equal, but the former was preferred as it was considered to be more closely comparable with the carbonation tests where gassing with CO₂ must be done at alkaline pH (Figure 1) because of the negligible rate of absorption of carbon dioxide below pH 6. In either case, the sulfited and limed juice was heated and kept boiling for one minute, flocculant added and settling done as in defecation.

![Fig. 1—Absorption rate of carbon dioxide and sulfur dioxide in limed juice.](image-url)
Carbonation was done by liming the diluted juice in the 6 L stirred reactor kept at 50 to 60°C, to pH 8–9, kept at the high pH for 2 to 5 minutes and then gassed with CO₂ to pH 7–8, over about 5 minutes. The heating, flocculating and settling followed as before. The quantity of lime was maintained about the same in both sulfitation and carbonation to allow direct comparison between the two methods, and at levels comparable with those used in plantation mill white factories throughout South and Central America. In the following text, the pH measured at room temperature (about 25°C) is denoted as pH₂₅.

Double carbonation was done by preheating 1 L of diluted raw juice in the 6 L reactor to 50°C and liming with 3–5 g CaO to a pH 10.5–11. The pH was then reduced with CO₂ to about 10, temperature raised to 60°C, flocculent applied, and the mud settled for about 60 minutes to 25–30% of the initial volume. No precautions were taken to remove dissolved air from the juice. The supernatant from settling and filtrate from vacuum filtration of the thickened mud were combined and pH of the combined clear juice then reduced with CO₂ to pH 6.5–7. The carbonated juice was brought to boil and the small amount of the second carbonation precipitate removed by filtration under vacuum. The filterability of the first carbonation mud was measured with the same apparatus and mostly following the same procedure as before (Saska, 2005) in measuring filterability of clarifier mud. A temperature of 60°C was chosen, at 0.7, 1.4 and 2.1 x 10⁵ Pa pressure, a filtration area of 3.1 cm² with the support formed by a 20 µm stainless steel mesh and pre-coated with HyfloSuper Cel filter aid.

It is sometimes recommended that lime suspension be ‘aged’ before its use in juice clarification but, in these tests, the analytical grade Ca(OH)₂ that was used was mixed with water at about 1:10 ratio and used immediately. No adverse effects on settling or turbidity removal were noted.

All tests reported in this paper were done during the 2008–2009 season at ASI with juice extracted from the main varieties of cane nowadays grown in Louisiana (i.e. L 97-128, HoCP 96-540, LCP 85-384, etc.). However, other tests at EEAOC in Argentina (Zossi and Cardenas, 2009) have confirmed the validity of the present conclusions regarding the colour behaviour in clarification of juice produced from the two main cane varieties grown in Tucuman.

Results

Colour removal in clarification

The colour of raw juice ranged from 10 000 to 20 000 IU (Table A1 in the Appendix) with the variations reflecting effects of different cane varieties, cane conditions and the varied quantities of tops and green leaves crushed with the clean billets. The relative decolourisation, defined as 100 × (Colour of raw juice – Colour of clarified juice) / Colour of raw juice for defecation by hot liming, averaged 32%; sulfitation and carbonation were nearly equally efficient in terms of colour removal, with decolourisation of 45% and 42%, respectively (Table A2) with lime (CaO) consumption of about 0.7 and 0.9 g/L respectively versus the 0.5 g/L used in normal defecation (Table A1).

Although the colours of clarified and in particular of mixed juice are rarely measured in the factories, the limited available data (Eggleston, 2002; Sahadeo et al., 2002) indicate that the factory performance in terms of colour removal is substantially lower than the laboratory test results reported in Table 1 and in the Appendix Table A2.

Among the reasons for the difference between factory performance and laboratory decolourisation may be localised overheating or overliming in the industrial process, excessive residence times of juice or mud in the industrial heaters, clarifiers or filters, or other factors.

No systematic measurements were done of the mud settling characteristics. However, all three procedures produced well-settling mud with no apparent differences in settling rates among the three methods. Clarified juice turbidity varied mostly within the 50–150 NTU range, similar to
the range of industrial clarified juice and, as with mud settling rates, no systematic differences among the three clarification methods were observed. The large standard deviation of the CaO dose comes from the intentional variations introduced in the procedure to test the robustness and response of the process.

Table 1—Average colour before and after juice clarification, the lime dose used and relative decolourisation achieved.

Changes of juice pH and colour during settling

The composition of clarified juice and consequently the clarification method may have an impact on the rate of colour increase later in settling, during evaporation and in the vacuum pans. Thus thermal stability of the juice needs to be considered when evaluating clarification. To that effect, the residence time was varied from ½ to 4 hours for the three types of clarified juices (Table 2), at 96°C i.e. close to the average temperature in the industrial clarifiers, and at 85°C for clarified juice from hot liming, and its effect on juice colour and pH.

Table 2—Colour increase and pH drop during settling at 96°C and 85°C, for different clarification conditions.

<sup>* Different superscript letters (a or b) indicate a significant difference (p ≤ 0.05) between two data sets; while same letters indicate a statistically insignificant difference</sup>

At 95°C, the colour increase in defecation and carbonation juices was found to be about equal, approximately 600 IU/h, but lower for juice produced by sulfitation. The pH drop during settling of defecation juices was found significantly higher than in sulfitation and carbonation.

Reducing the temperature from 96°C to 85°C during settling of defecation juice had a dramatic effect on colour formation rate and pH drop. Colour increase was reduced six-fold to less than 100 IU/h and the pH drop about two-fold.

Although not studied here, it is probable that comparable improvements would ensue in sulfitation and carbonation. It was suggested (Zossi et al., 2009) that this could be accomplished in the industrial process at a low cost by re-routing the vacuum filtrate that is now usually sent back to the mixed juice tank.

The limed juice would be heated and flashed as usual, but its temperature would then be reduced downstream of the flash tank by the cooler filtrate. This would be expected to reduce juice
colour and reduce the sucrose inversion loss, similar to the benefits derived from the short residence time clarifiers. Additional benefits are expected from avoiding recycling through the juice heaters the considerable amount of mud and flocculant contained in the generally poor quality filtrate.

**Thermal stability of syrup**

The rates of Maillard and other mechanisms responsible for colour formation are known to increase at lower water concentrations. Therefore, a series of ‘thermal storage’ tests at 70°C were also done with syrup following the same methodology as in the recent raw sugar storage tests (Saska and Kochergin, 2009). Syrup from each clarified juice was prepared in a glass laboratory ‘rotovap’ evaporator, under vacuum at 50–55°C. Colour increased in storage in each case (Figure 2); with the approximate slopes of 15, 9, 29 and 13 IU/h for defecation, sulfitation, carbonation and double carbonation, respectively.

![Graph showing colour increase of 60 – 70 brix syrup produced from the four different clarification procedures and stored at 70°C.](image1)

**Fig. 2**—Colour increase of 60 – 70 brix syrup produced from the four different clarification procedures and stored at 70°C.

![Graph showing pH drop during storage of syrup produced by the four different clarification procedures.](image2)

**Fig. 3**—pH drop during storage of syrup produced by the four different clarification procedures.
Because of the lower temperature, the rate of colour formation is much slower than in settling (Table 2), but the sulfitation syrup again exhibits the slowest colour increase of all. The pH drop (Figure 3) is about equal in all four cases, and apparently independent of the initial pH.

**Mechanism of colour removal**

It is usually assumed that, in juice clarification, any colour removal is due to adsorption of colorants on the nascent crystals of calcium phosphates and other sparingly soluble anions, in analogy to the more frequently studied colorant behaviour in sugar refining by phosphatation or carbonation. However, the few experiments that are summarised in Figures 4 and 5 indicate that adsorption on heat-coagulated cane protein may be the prevalent mechanism for colour removal in juice clarification. In the experiments in Figure 4, bringing the raw juice to boiling without any lime addition removed nearly 7000 IU or 39% of the initial colour. The full hot-liming and clarification done on the same juice only added another 6% to the total 45% decolourisation. When 100 mg/L aliquots of phosphoric acid were added to the mixed juice prior to liming, the colour removal by hot-liming increased by about 600 IU per aliquot.

![Fig. 4—Colour of raw juice, raw juice after boiling and clarified juice by hot liming after addition of phosphoric acid.](image)

In the experiment in Figure 5, cane protein was supplemented by sequential additions of bovine serum albumin (BSA), a structurally similar protein.

An addition to diluted raw juice of 1.5 g/L of protein increased the colour removal by hot liming by an additional 1500 IU. Another 3 g/L of BSA was added (for a total of 4.5 g/L) to the clear juice from this experiment, and the spiked juice was briefly boiled again; however, no additional lime was added.

The colour decreased by another 1300 IU. This was repeated one more time, for a total of 7.5 g/L of protein, with an additional 600 IU removed. It is therefore clear that both BSA and cane protein when heat-coagulated or during heat-coagulation have strong affinity for cane colorants.

The decolourisation effect, however, decreases with increasing dose of the protein; perhaps because the affinity of the protein is specific for only certain fractions among the wide variety of cane juice colorants. Unlike BSA, egg-white albumin was found ineffective in juice colour removal. Bagacillo or soil particles in only coarsely screened industrial cane juice have a substantial effect on the mud behaviour in clarifiers, most notably the former providing the bulk of the mud volume.
FIG. 5—Colour of raw juice, clarified juice by hot liming (control), and clarified juice after sequential additions of bovine serum albumin.

Whether they affect colour of clarified juice as has been sometimes alleged is less certain. The experiments summarised in Figure 6 indicate that neither has any detectable influence above the normal experimental variations. The added amounts indicated in Figure 6 are given in g dry matter/100 mL raw juice.

FIG. 6—Colour of raw juice (13 200 IU), juice clarified by hot liming (control), and juice clarified by hot liming after additions of bagacillo or dry mud to the raw juice.

The clarifier underflow is made up of 90–95% clarified juice with colour that one could assume identical to that of the clarifier overflow provided the residence times were comparable. However, some previous observations in factory tests (Saska, pers. comm., 2009) indicated that the colour of the ‘mud juice’, that is the juice entrained in, and recovered from the mud in vacuum filters, was on occasions actually lower than that of the overflow from the clarifiers. This prompted tests to determine the state of saturation of the adsorptive capacity of mud particles for colorants. In
the experiments reported in Table 4, cane juice was clarified by hot liming and its colour determined as usual (CJ colour and Decolourisation 1 in Table 4). The settled mud was then blended for a few seconds in a standard kitchen blender, solids separated by centrifugation, and the colour of the supernatant juice again determined by the standard method. In all, twenty experiments were done and are reported in Table 4; the colour of the supernatant from the blended mud (Mud colour and Decolourisation 2 of Table 4) always decreased, sometimes by up to 2700 IU. This is evidence that the adsorptive power of the hot-liming precipitate is not exhausted in the standard process.

Table 4—Colour of raw juice, juice after hot liming and of the ‘mud juice’ after blending the mud.

Blending the mud may expose internal surfaces of the precipitate, rendering them available to adsorb more colorant. It would seem, therefore, that potential exists for further improvements in decolourisation above the levels reported in Table 1.

Double-carbonation

In the modified double-carbonation procedure, the CaO dose was reduced on average to 3.1 g/L (Table 5), or about four-times greater than the present industrial process. Decolourisation at these conditions was 74% on average, with some values exceeding 80%. Clarified juice turbidity was less than 10 NTU, and Ca and Mg ions determined by ion-chromatography were about 500 and 200 mg/L, respectively.

The filterability of the thickened first carbonated mud may be the critical parameter for the scale-up of the modified process. Therefore, the effects of various parameters, e.g. the quantity of lime used were measured. The filterability of the juice, thickened by settling to about 30% of the original volume, was found unaffected (Figure 7), and comparable with filterability of the standard hot liming defecation mud determined under identical conditions (Saska, 2005). The volume to be
handled by the filter station is greatly reduced, and its capacity in terms of tonnes of cane per day increased.

![Graph showing filterability of thickened mud from the modified process and the industrial double carbonation process.]

**Fig. 7**—Filterability of thickened mud from the modified process (solid lines) with 3 and 5 g/L of CaO, and that of the industrial double carbonation process with 12 g/L CaO (dotted line).

**Conclusions**

The average decolourisation that was achieved in juice clarification by defecation, sulfitation, single carbonation and modified double carbonation was 35, 47, 44 and 74%, respectively. However, available data indicate that decolourisation that is routinely achieved in defecation (Eggleston, 2002; Sahadeo *et al.*, 2002) and sulfitation factories (Zossi and Cardenas, 2008) is considerably less.

Replacement of SO₂ by CO₂ (carbonation) is feasible, achieving comparable decolourisation and mud settling characteristics, but the apparently lower thermal stability of clarified juice and syrup from carbonation requires more study.

The colour increase at conditions typical in industrial clarifiers was found to be about 600 IU/h for defecation and carbonation, and about 350 IU/h for sulfitation clarified juice. By reducing the settling temperature by 11°C, the colour increase could be reduced to less than 100 IU/h.

An indication was obtained that, in juice clarification, most decolourisation comes from adsorption of cane colorants onto heat-coagulated cane protein rather than onto the nascent calcium precipitate, and that some of the adsorption capacity remains unused in the standard process.

No significant effect was observed from either bagacillo or soil on colour removal in clarification.

Significant reductions of CaO consumption in the commercial double carbonation process to about 3 kg CaO/tonne cane are possible, in conjunction with thickening of the first carbonation mud by settling and polishing filtration after the second carbonation.

MOTS CLEFS: Canne a Sucre, Couleur, Clarification, Sulfitage, Carbonatation.

Résumé

LA COULEUR est le plus important attribut commercial du sucre mais, à la clarification, sa réduction n'est pas considérée parmi les principaux objectifs. Cependant, toutes les procédures de clarification ont le potentiel pour une diminution plus élevée de la couleur que celle réalisée dans la pratique industrielle. Quatre procédures de clarification, notamment la définication par chaulage à chaud, le sulfitage, la carbonatation et la double carbonatation ont été testées pour étudier le comportement de la couleur. La carbonatation n'est pas beaucoup utilisée dans l'industrie du sucre de canne, mais des augmentations périodiques du prix du soufre, des problèmes de qualité de sucre et les préoccupations environnementales ont stimulés les efforts pour remplacer ou compléter le dioxyde de soufre par le dioxyde de carbone qui peut être disponible gratuitement a partir de l'usine de fermentation. La réduction de couleur entre le jus mélangé et le jus clarifié, obtenu au cours de nos tests était en moyenne 35, 47, 44% et 74% pour la définication, le sulfitage, la carbonatation simple et la double carbonatation, respectivement. La durée et la température au cours de la décantation, la présence de bagasse folle et du sol, l’ajout de phosphate et de protéines, tous des facteurs affectant la couleur de jus clarifié durant le chaulage chaud, ont été testés. À de faibles doses de chaux, en dessous d’un kg de CaO/tonne de canne (défécation, sulfitage et carbonation), la réduction de couleur se fait par l'adsorption sur les protéines de la canne coagulées par la chaleur, plutôt que sur le précipité de calcium. Toutefois, la capacité d’adsorption des colorants par le précipite n’est pas bien utilisée pendant la procédure normale. Abaisser la température du décanteur par 11°C limite l'augmentation de couleur du jus dans les décanteurs à presque zéro. Quoique que la décoloration du sulfitage et celle de la carbonatation soient plus ou moins comparables, la stabilité thermique apparemment inférieure du jus clarifié et du sirop produits par la carbonatation peut exiger une étude plus approfondie.
COMPORTAMIENTO DEL COLOR EN CLARIFICACIÓN DE JUGO DE CAÑA POR DEFECACIÓN, SULFITACIÓN Y CARBONATACIÓN

PALABRAS CLAVE: Caña de Azúcar, Color, Clarificación, Sulfitación, Carbonatación.

Resumen

El color es el atributo comercial más importante del azúcar pero, en clarificación de jugo, su remoción usualmente no es considerada entre los objetivos primarios. Sin embargo, con base en los resultados presentados todos los procedimientos estándar para clarificación tienen el potencial para la remoción significativa de color que lo considerado en la práctica industrial. Se probaron cuatro procedimientos de clarificación de jugo, defecación por encalado en caliente, sulfitación, carbonatación y doble carbonatación, y se investigaron varios aspectos del comportamiento del color. La carbonatación no se usa ampliamente en la industria del azúcar de caña pero los incrementos periódicos en el precio del azufre, aspectos de calidad del azúcar y preocupaciones ambientales han estimulado los esfuerzos para considerar el reemplazo o suplemento del dióxido de azufre con el dióxido de carbono, que puede estar disponible gratis de la planta de fermentación. La remoción de color, es decir la diferencia relativa entre color de jugos, crudo y clarificado, obtenida en las pruebas, fue en promedio 35, 47, 44 y 74% para defecación, sulfitación, carbonatación sencilla y doble carbonatación modificada, respectivamente. Se probaron varios factores que afectan el color del jugo claro en el encalado en caliente, como tiempo y temperatura durante la sedimentación, contenido de suelo y bagacillo y adición de fosfato y proteína. Con dosis bajas en el encalado, por debajo de 1 kg CaO/tonelada de caña (defecación, sulfitación y carbonatación) la mayor remoción de color resultó de la adsorción en la proteína de caña coagulada por calor en lugar que en el precipitado de calcio. Sin embargo la capacidad de adsorción del precipitado para los colorantes de la caña aparece sólo parcialmente agotada en el procedimiento normal. Se encontró que el descenso de 11°C en el clarificador limitó el incremento de color del jugo en los clarificadores a cerca de cero. Aunque los efectos decolorantes de sulfitación y carbonatación fueron prácticamente iguales, las aparentemente más bajas estabilidades térmicas del jugo clarificado y la meladura, producidas por la carbonatación, pueden requerir estudios posteriores.
MINIMISING OF DECOLOURISATION COST FOR INVERT CANE SYRUP PRODUCTION USING LOW COLOUR SUGARCANE VARIETIES

By

triartti@gmail.com

KEYWORDS: Colour, Sugarcane, Variety, Purification, Decolourisation.

Abstract

PRODUCTION of invert cane syrup is an alternative diversification product from sugarcane. The main problem with this product is the high cost of the associated decolourisation process for producing syrup with attractive colour for the consumer. This research project was conducted to study the effect of raw cane juice colour from different cane varieties on the colour of clear juice after purification and decolourisation steps as part of the process for the production of invert cane syrup. Purification of the raw cane juice was conducted using carbonatation-phosphatation followed by decolourisation of the clear juice using powder activated carbon (PAC). Sugarcane varieties were grouped into high, medium and low colour varieties having raw cane juice colour >20 000 IU, 10 000–20 000 IU and <10 000 IU, respectively. The correlation between raw cane juice colour and clear juice colour after the purification and decolourisation processes was very high. The colour of clear juice after purification followed by decolourisation using PAC at 1.6% on brix using high, medium and low colour cane varieties were 4500 IU, 2100 IU and 680 IU, respectively. In order to get the same colour as clear juice from low colour cane varieties, additional decolourisation processing was needed for clear juice from the high colour cane varieties. This investigation was able to show that using selective low colour sugarcane varieties in the production of invert cane syrup minimised the cost of decolourisation.

Introduction

Invert syrups are widely utilised by different segments of the food industry such as soft drink and baking industries due to their sweetness and specific physical-chemical properties. Recently, several efforts were conducted to develop a continuous process for making invert syrups from raw cane juice without crystallisation that was economical on a large scale (Serna-Saldivar and Rito-Palomares, 2005; Ginslov and Peter, 2000). Invert cane syrup produced using processes developed by Indonesian Sugar Research Institute (ISRI) still contains minerals and other non sugars such as amino acids and vitamins originating from the cane juice. The challenge of technologies for invert cane syrup production concerns juice purification and decolourisation processes to produce attractive colour in the clear cane syrup.

Several studies have been published on the changes of raw juice colour to the colour of clear juice after purification processes (Sharma et al., 1980; Sharma and Johary, 1984) and the changes of colour over each step of plantation white sugar production (Keskar and Nimbalkar, 1999). Johary and Singh (2001) reported on the effects of sugarcane varieties on juice colour. Of the varieties investigated, sugarcane variety CoS 91269 produced juice with the highest colour (12 985 units) compared with 5730 units for CoS 88230 variety, which produced the lowest coloured juice. Results of the study showed that, when the percentage of CoS 91269 variety in the total crop reduced from 47.55% to 37.33%, the colour of the sugar also decreased from 206.5 IU to 126.5 IU. These results show that the colour of raw juice depends on the variety and has a direct effect on the colour of sugar products.
This research project examined the possibility of minimising decolourisation costs of invert cane syrup production by using low colour cane varieties. The project investigated the effect of raw juice colour from different cane varieties on the colour of clear juice after purification and decolourisation steps as part of the process for the production of invert cane syrup.

Materials and methods

Laboratory experiments were conducted on the juice from various sugarcane varieties. The juices were purified with three different methods. Clear juices from the best purification method were decolorised using powder activated carbon (PAC). A pilot scale experiment was conducted only on the juice from the lowest colour cane variety using the best purification technique, followed by decolourisation using the optimum dose of PAC. The purpose of the pilot scale experiment was to check the consistency of the best result from the laboratory experiment using the larger scale process.

Laboratory experiments

Eight sugarcane varieties with various levels of juice colour were used in the laboratory stage experiments. The cane samples used in this experiment consisted of clean stalk without tops and trash. The cane was pressed twice using a small mill and the raw juice was collected for purification. Cane juice purification was conducted using three different methods namely simple phosphatation process (P); double carbonatation process (DC); and purification using a modified carbonatation-phosphatation process (DCP).

For the simple phosphatation process, raw cane juice was heated to 60°C and 400 ppm P₂O₅ (phosphoric acid) was added. Milk of lime at 5°Baumé was then added to raise the pH to 7 before the juice was heated to 100°C and then settled without flocculant addition. For the double carbonatation process, pH and temperature of the first carbonatation process were 10.5 and 55°C respectively. Milk of lime (8°Baumé) was used for the carbonatation process. The amount of lime milk added on raw juice was 10%(v/v). Raw juice was heated to 55°C and milk of lime was added until pH 10.5 was reached. The rest of the milk of lime was added to the juice during the addition of carbon dioxide to maintain the pH at 10.5. The temperature was kept constant at 55°C. After the reaction, the juice was filtered. Carbon dioxide was added to the filtered first carbonated juice to decrease the pH to 7.0, before the juice was further heated to 75°C and filtered. The purification process using the modified carbonatation-phosphatation process basically followed the double carbonatation process with phosphoric acid (27% v/v) added to the filtered first carbonated juice instead of carbon dioxide to reduce the pH to 7.0, before the juice was heated to 70°C and filtered. All filtration was conducted using filter paper (Whatman No.1). On the DCP process, kieselguhr was used as a precoat on the filter paper during the second filtration after the addition of phosphoric acid.

The clear juice from the purification processes were further decolourised using powder activated carbon (PAC) (analytical grade from Merck with an iodine adsorption value of 1220 mg/g) dosed at various concentrations. The mixture of clear juice and PAC was maintained at 70°C for one minute before it was filtered using Whatman No. 42 paper coated with kieselguhr.

Raw and clear juice samples were analysed for colour, brix (using refractometer), sucrose (measured by double polarisation), reducing sugar (Lane & Eynon method), CaO and MgO content (complexo-metric method), ash (conductivity) and turbidity.

Colour analysis of raw juice, clarified juice, and low colour juice after decolourisation using PAC was done by diluting the samples with distilled water to about 5, 10 or 15 brix or without dilution followed by method of ICUMSA GS1/3-7. The degree of sample dilution depended on the colour of the sample. The absorbance of the sample at 420 nm should be between 0.2 and 0.8. In the case of very low colour juice after decolourisation using PAC, there was no dilution needed for the sample. The turbidity on each juice was measured with a spectrophotometer at 900 nm using 50 mg
SiO₂ per litre of solution as a standard (Ananta and Martoyo, 1989). Raw juice was also analysed for phenolic content using the method described by Clarke et al. (1986) and the correlation between phenolic content and colour in raw juice was determined. The concentrations of CaO and MgO and phenolic content were calculated at 15 brix.

**Pilot scale experiments**

In the pilot plant experiments, cane juice from the lowest colour cane variety was purified using the combined carbonatation-phosphatation process (DCP) detailed above in a batch system. For one trial, 200 L of cane juice from around 400 kg of sugarcane (PS 862) was processed over four batches. Clear juice was decolorised using PAC at a dosage of 1.6% PAC on clear juice brix. The PAC used in the pilot scale experiments was industrial grade with an iodine adsorption value of 1100 mg/g. The clear juice after the PAC treatment was adjusted to pH 5 and evaporated at 70°C to syrup for analysis.

**Results and discussion**

**Laboratory experiments**

Table 1 shows the cane varieties used in this research project and grouped into high, medium and low colour. The varieties with the highest and the lowest colour were also included in Table 1 separately for comparison. The cane was harvested almost at the same maturation i.e. more than 20 brix with an average reducing sugar content of 3.56%.

Seven cane varieties used in this experiment were collected from the same area (Pasuruan Experiment Station). These varieties were grown in similar soils, under similar climatic conditions, and were also cultivated with the same technique. Hence, the various colours in the raw juice reflect the inherent properties of the different varieties. One variety (PS 862) was collected from the Jengkol area. The Jengkol area had land with more porous and better drainage characteristics for good growth of the PS 862 cane and differed from the land characteristics in the Pasuruan area (compact soils and poor drainage).

Raw cane juice from each cane variety was purified using the three different processes (P), (DC) and (DCP). These three purification techniques were chosen with consideration that the clear juice resulting from these processes will be safe for direct consumption. Other purification processes such as sulfitation were not selected because the residual SO₂ in the clear juice was considered harmful to human health.

Table 2 shows the performance of the three clarification processes averaged for all cane varieties. The DCP purification process produced the best results in terms of high purities, low residual calcium and magnesium ions (CaO+MgO) and low turbidity, followed by the DC and P processes. The improvement in sucrose purity for purification using DCP, DC and P were 3.21, 2.98 and 1.05 units respectively and the reduction of CaO+MgO content were 27.6, 22.2 and 39.9% for
the DCP, DC and P processes respectively. Clear juice with low turbidity values resulted from the DC and DCP purification processes.

Table 2—Effect of purification process using phosphatation (P), double carbonatation (DC) and combination of double carbonatation+phosphatation process (DCP) on sucrose purity, CaO+MgO and turbidity.

The changes in colour during each purification process are shown in detail for each group of cane varieties in Figure 1. The results show that the average decrease in colour of the juice from all groups of sugarcane varieties after purification using P, DC and DCP were 14.4, 56.6 and 71.7% respectively. The best colour removal resulted from purification using DCP. A review by Sharma and Johary (1984) indicated that removal of colorants during purification of cane juice took place either by way of precipitation / coagulation or through adsorption on the surface of various precipitates produced during the clarification process. Previous experiments conducted by Sharma et al. (1980) and Sharma and Johary (1984) support the results of this research in that the mud produced during the carbonatation process could adsorb larger magnitudes of colorants as compared to sulfitation and defecation processes. The juice purification process trialed in this research based on simple phosphatation (P) was basically similar to the defecation process with the addition of phosphoric acid (400 ppm P2O5).

![Fig. 1—Changes in juice colour after purification using phosphatation (P), double carbonatation (DC) and a combination of double carbonatation+phosphatation process (DCP) for each group of cane varieties.](image-url)
The laboratory trials clearly showed that the clear juice colour was significantly influenced by the colour of the raw juice. The trials showed that higher raw juice colour resulted in the highest clear juice colour after the purification processes. The clear juice colour from simple purification using P process of the low colour group of cane varieties was similar to the clear juice colour resulting from the high colour group of cane varieties using more complex purification techniques like DCP.

One of the major colorant groups in the cane plant is the phenolic compounds (Clarke et al., 1986). Figure 2 shows the correlation between the colour of raw juice and the phenolic content calculated for each juice at 15 brix. Higher raw juice colours correlated with a higher content of phenolic compounds. The correlation $R^2$ value was 0.77.

![Graph showing correlation between colour of raw cane juice and the phenolic content.]

The clear juice resulting from the DCP purification process was further decolorised using various concentrations of PAC including 0; 0.1; 0.2; 0.8; 1.6; 3.2 and 6.4% on clear juice brix (see Figure 3). The results showed that the colour of clear juice after decolourisation using PAC was influenced by the colour of the clear juice before PAC treatment. The colour of the clear juice after decolourisation using PAC was influenced by the colour of raw juice before the purification process. The magnitude of the colour reduction declined as the concentration of PAC was increased. The lowest colour juice (from cane variety PS 862) reached a minimum value when the PAC reached 1.6% on juice brix. These results showed that not all of the colour could be removed using PAC.

![Graph showing the effect of PAC dose on the colour of clear juice.]

Fig. 3—Clear juice colour from purification using the double carbonatation+ phosphatation process followed by decolourisation using various concentrations of PAC.
Figure 4 shows the colour of clear juice from each group of cane varieties after purification using the DCP process followed by decolourisation using PAC at a dosage of 1.6% on clear juice brix. The colour of clear juice after purification by the DCP process followed by decolourisation using PAC at 1.6% on brix for the high, medium and low colour varieties were 4500 IU, 2100 IU and 680 IU, respectively. In order to get the same colour as clear juice from low colour varieties, additional decolourisation (or higher dosage of PAC as shown in Figure 3) would be required for the clear juice from high colour varieties. This result showed that the cost of decolourisation on invert cane syrup production was able to be minimised using low colour sugarcane varieties.

![Graph showing the average colour of clear juice from each group of cane varieties.](image)

**Fig. 4**—Average colour of clear juice from each group of cane varieties after purification using the DCP process followed by decolourisation using PAC at 1.6% on clear juice brix.

Purification of the lowest colour cane varieties with the DCP process followed by decolourisation using PAC at 1.6% on clear juice brix was further tested in pilot scale trials as part of the process for invert cane syrup production.

**Pilot scale experiments**

The analysis of cane juice over each step of the DCP clarification process, decolourisation and evaporation to produce cane syrup is shown in Table 3. The data are the average of eight trials. Around 400 kg of cane was processed for each trial. The results showed that the average brix of raw juice was 21.1, purity 87.7%, reducing sugar 4.95%, CaO+MgO 372 ppm and colour 9865 IU. The quality of raw juice used in the pilot scale experiments was similar to that of the laboratory experiments. The purification process resulted in the juice purity increasing by 1.36 units, colour decreasing by 70.7%, while the reducing sugar and ash conductivity (% on brix) were almost constant.

After the purification process the clear juice was decolourised using PAC at 1.6% on clear juice brix. The decolourisation step decreased the clear juice colour by 74.6% (average 738 IU). The clear juice was then evaporated. There was a slight increase in colour after evaporation from 737 IU to 991 IU and the thick juice was still very clear with just a slight increase in turbidity.

The low colour thick juice will be used to produce invert cane syrup through sucrose inversion with a final decolourisation step. Sucrose inversion using immobilised invertase is being developed by ISRI. The final decolourisation step on invert cane syrup production uses weak anionic or strong anionic resin regenerated using disodium hydrogen phosphate (Triantarti and Toharisman, 2008).

Note: Turbidity was calculated for juice at 60 brix.

The result of the pilot scale experiment using the lowest colour cane variety (PS 862) showed a consistent result on low colour of clear juice compared with the laboratory result using the same cane variety, purification process and decolourisation process. The results of both laboratory and pilot scale experiments showed that minimising decolourisation costs of invert cane syrup production by using low colour cane varieties was quite promising.

However, the colour of raw juice not only depends on the cane variety but also on many factors such as agro-climatic conditions prevailing during the growth period, land characteristics and cultivation techniques. Before commercial scale production of invert cane syrup can commence, several trials have to be done by planting low colour cane varieties in different areas that will be cultivated and processed to determine the quality of raw juice produced (especially colour). The colour of raw juice is also influenced by the sugarcane maturation during harvesting, time between harvesting and milling and the cleanliness of the cane based on included dirt, tops and trash (Sens and Decagny, 2001). Good management of cane cultivation, harvesting and post harvest practices are very important to get a consistent, good quality sugarcane that produces low colour raw juice.

Conclusions

Cane juice purification using a combination of double carbonatation and phosphatation processes provided the best quality juice (low colour, high purity) that can be used for invert cane syrup production. The colour of clear juice after purification and decolourisation using PAC is influenced by the colour of the raw juice. In the pilot scale experiments, the colour of thick juice produced using low colour cane varieties after purification using double carbonatation and phosphatation processes, followed by decolourisation using PAC at dosage 1.6% on brix of clear juice, reached 991 IU. However, further research is needed to determine cane cultivation conditions which affect the colour of cane juice especially for potential low colour cane varieties.

Résumé

La production de sirop de canne à sucre inverti est un produit de diversification de la canne. Le principal problème avec ce produit est le coût élevé du processus de décoloration, pour la production d’un sirop avec une couleur attrayante pour le consommateur. Cette recherche a été réalisée pour étudier l'effet de la couleur du jus de canne provenant de différentes variétés sur la couleur du jus clair après les étapes de purification et de décoloration pendant la production de sirop de canne à sucre inverti. La purification du jus de canne brut a été menée à l'aide de la carbonatation-phosphatation suivie de décoloration du jus clair à l'aide de charbon actif en poudre (PAC). Les variétés ont été regroupées en couleur de jus haute, moyenne et faible, dans des fourchettes > 20 000 UI, 10 000 à 20 000 UI et 10 000 UI, respectivement. La corrélation entre la couleur de jus de canne brut et la couleur de jus clair après les processus de purification et de décoloration était très élevée. Les couleurs du jus clair après purification suivie de décoloration à l'aide du PAC (consommation 1.6% sur brix) pour les variétés de couleur haute, moyenne et basse ont été IU 4500, IU 2100 et 680 UI, respectivement. Afin d'obtenir la couleur de jus clair provenant de variétés a faible couleur, une décoloration supplémentaire était nécessaire pour les jus clair obtenus a partir des variétés de couleur haute. Ce travail a pu démontrer que l'utilisation de variétés a couleur faible pour la production de sirop de canne à sucre inverti réduit au minimum le coût de la décoloration.
MINIMIZACIÓN DEL COSTO DE DECOLORACIÓN DE JARABE INVERTIDO USANDO VARIEDADES DE CAÑA DE BAJO COLOR

Resumen

LA PRODUCCIÓN de jarabe invertido de caña es una alternativa de diversificación de productos. El problema principal es el alto costo de los procesos de decoloración para obtener un producto atractivo al consumidor. Esta investigación fue orientada al estudio del efecto del color del jugo de diferentes variedades de caña en el color del jugo clarificado después de las etapas de purificación y decoloración como parte del proceso de obtención de jarabe invertido. La purificación se efectuó usando carbonatación- fosfatación seguida de decoloración del jugo claro usando carbón activado en polvo (PAC). Las variedades de caña se agruparon en bajo, medio y alto color con colores en jugo crudo de >20000 IU, 10000–20000 IU and <10000 IU, respectivamente. La correlación entre color de jugo crudo y color de jugo claro, después de los procesos de purificación y decoloración fue alta. El color del jugo claro después de purificación seguida de decoloración usando PAC a 1.6% en brix y usando variedades de alto medio y bajo color fue de 4500 IU, 2100 IU y 680 IU, respectivamente. Para obtener el mismo color del jugo claro obtenido a partir de variedades de bajo color, se requirió procesamiento adicional de decoloración con las variedades de alto color. La investigación mostró que el uso de variedades de bajo color en la producción de jarabe invertido, minimiza los costos de decoloración.
ENERGY CONTENT: A NEW APPROACH TO CANE EVALUATION

KEYWORDS: Energy, Coproducts, Fibre, Cogeneration, Quality.

Abstract

In recent years, the sugarcane industry has been moving from sugar production alone to sugar and energy production with the development of cogeneration and ethanol plants. Although cane fibre has always been considered a problem by the sugar millers, with increasing energy prices, fibre is becoming a major co-product of cane. The energy balance between sugar losses and energy production was evaluated for conventional cane and a new high fibre cane. The energy content of cane and cane products was calculated using their net calorific values. The results show that sugar is the main energy product recovered. Depending on their different uses, varietal comparisons based on energy content could be a new way of comparing sugarcane varieties. In Reunion Island, where cogeneration started in 1992, upcoming changes in French law on carbon credits are likely to modify the price of fibre for energy production in 2009. These changes will lead to the release of new cane varieties for sugar and electricity production, such as the promising eRcane elite cane R92/0804. A new approach to cane evaluation can therefore be based on the energy content of cane.

Introduction

The energy content of sugarcane offers a new approach to cane evaluation. Sugarcane bagasse is now regarded as ‘bioenergy’ and its value can be compared to that of coal. However, to fully exploit the value of bagasse, it is important to change strategies from sugar production alone to sugar and energy production.

This will lead to major changes in the sugarcane industry, such as grower payments for sugar and for fibre, and new varieties with higher levels of sugar and fibre. Cane energy content and energy yield per hectare and per tonne of cane will therefore become important parameters (Botha, 2009). Cane varieties should therefore be optimised for maximum energy production (Lima Verde Leal, 2007).

A new cane variety (R92/0804) that combines high fibre and sugar content has been developed in Reunion Island by eRcane. This variety was crossed (R575 × H72/8597) in 1992 and is now at the end of the breeding program. Agronomical results of five regional trials based on plant cane and two ratoons are presented in Table 1.

The two main varieties cultivated in Reunion, R570 (released in 1978) and R579 (released in 1993), were used as standards for the trials. Compared to the R579 standard, R92/0804 clearly gave better yields (+44%) with slightly lower sugar content in the cane (−3.6%) but a 29% increase in fibre content. Therefore, the overall increase in sugar yield per hectare is around 30%. This new variety appears to be promising in terms of tonnes of sugar per hectare, but the high fibre content should also be taken into account from the millers’ point of view.
The objective was to add an indication of potential energy production to the traditional agronomic comparisons based on sugar yield per hectare. This potential energy production should be linked to the total energy content of cane, which can be divided into three elements: energy in fibre, energy in ethanol and energy in sugar crystals. This study was undertaken to assess the impact of different varieties on the energy recovered in terms of electricity, ethanol and sugar.

**Calculation methodology based on net calorific value of products**

This case is an example of what can be done on the basis of energy content in a country such as Reunion Island, with cane that mainly produces sugar, but also cogenerates electricity and produces rum from molasses.

The energy content of sugarcane and cane products was calculated using net calorific value. Net calorific value (NCV) is more practical than gross calorific value because it does not take into account the latent heat of the vapour. The NCV can be calculated from the chemical reaction on combustion.

The NCV of the sugarcane was calculated as the sum of the net calorific values of fibre, sucrose, glucose and fructose. The net calorific value of the cane fibre was calculated from a bagasse equivalent energy: bagasse weight as twice the cane fibre content and bagasse net calorific value of 4.23 kWh/kg (assumptions made for bagasse composition were 50% moisture, 1.2% ash content and 2.6 brix) with the SASTA Laboratory Manual (Anon, 2005).

The net calorific values of reducing sugars (glucose and fructose), ethanol and sucrose were 3.17, 6.20 and 3.56 kWh/kg respectively.

**Cane and cane product energy content**

Traditional agronomic comparisons of sugarcane are based on extractable sucrose. A simple method for estimating extractable sucrose is to deduct the sugar in the bagasse and the molasses from the sugar in the cane; mud and undetermined losses are not taken into account.

\[
\text{Extractable sugar} = \text{Sugar in cane} - \text{Sugar in bagasse} - \text{Sugar in molasses}
\]

Net calorific value was used to convert the weight of bagasse, ethanol and extractable sugar into energy.

**Net energy content of sugarcane in Reunion Island conditions**

The energy content of cane was calculated according to the fibre, reducing sugars and sucrose contents from the agronomic trials (Table 2).

</table>
Fibre in cane increases bagasse losses but also electricity production

Bagasse weight is directly affected by the fibre content of the cane and by bagasse moisture. Pol in bagasse is assumed to be a result of the milling operation. In sugar mills, sugar losses in bagasse are calculated using the following equation:

\[
\text{Sugar lost in bagasse} = \frac{\text{Sugar in bagasse}}{\text{Bagasse weight}} \times \text{pol\%bagasse}
\]

It can be assumed that, with satisfactory milling operations, bagasse moisture and pol in bagasse can be maintained respectively at 50% and 1%. Hence, the previous equation can be simplified to:

\[
\text{Sugar lost in bagasse} = \frac{\text{Fibre\%cane}}{50\%} \times 1\%
\]

\[
\text{Sugar lost in bagasse} = 2\% \times \text{Fibre\%cane}
\]

This assumption oversimplifies reality but can be used as an easy method. Therefore, with an increase of cane fibre content, sugar lost in bagasse will increase as indicated in Table 3.

Energy from electrical production with bagasse can be estimated with the power delivered by the cogeneration plant to the electrical network.

Cogeneration and power production has been carried out in Reunion Island since the first installation of 80 bar boilers at Bois Rouge Mill in 1992. The cogeneration plants at the two factories in Reunion have two 30 MW turbines in Bois Rouge and two 32 MW turbines in Le Gol. Electricity produced with bagasse in Reunion has a ratio of 0.52 MWh/tonne of wet bagasse (ARER, 2008).

This ratio takes into account sugar mill steam and electrical power consumption. Based on cane fibre content, electricity production can be estimated using this ratio as indicated in Table 3.

| Table 3—Fibre in cane increases bagasse losses but also electricity production (For bagasse pol = 1% and bagasse moisture = 50%). |
|---|---|---|---|
| R570 | Fibre in cane % cane 16.52 | Sugar in bagasse % cane 0.33 | Electricity Production KWh/t cane 172 |
| R579 | 14.77 | 0.30 | 154 |
| R92/0804 | 19.02 | 0.38 | 198 |

Sugar in molasses increases losses in molasses but also ethanol production

The sugar content in molasses can be estimated using the SJM formula with a molasses standard purity of 40 (Table 4).

The total fermentable sugar content was calculated with the results of sugar content in molasses and with an average reducing sugar content in molasses of 7.7% (Reunion average for 2008 crops).

This total fermentable sugar content can be used to estimate ethanol production based on Pasteur Yield (643 L of alcohol / tonne of sucrose) and average distillery performance (86%) as presented in the equation below. Ethanol was converted into kWh with density data (0.791 kg/L) and net calorific value.

\[
\text{Ethanol yield (L/100 t cane)} = \text{Molasses\%Cane} \times \text{Total fermentable sugar\%molasses} \times 643 \times 86\
\]

Ethanol production does not appear to be affected by variety (Table 4). Varietal comparison based on ethanol yield in L/100 t cane or in kWh/t cane is close for the three varieties tested.
Table 4—Sugar in molasses increases losses in molasses but also increases ethanol production (% cane = tonnes sugar/100 tonnes of cane).

Extractable sugar can be converted into energy

The extractable sugar can be calculated from the sugar in cane minus bagasse losses minus sugar in molasses. This extractable sugar can be converted into energy content with the sucrose, glucose and fructose net calorific values, as presented in Table 5. In these trials, R92/0804 has the lowest level of extractable sugar but, due to the high yield per hectare, sugar production is increased by 32%.

Energy based varietal comparison

Energy based varietal comparisons can be made using the net energy content of the cane and the energy recovered in electrical production, ethanol and in sugar crystals.

Results show that sugar is the main energy product recovered (35%) from sugarcane (Figure 1). Energy recovered in electricity and ethanol represents respectively around 15% and 3% of the energy content of the cane.
Results per hectare also show that sugar is the main energy product recovered from sugarcane (Figure 2). According to the agronomic results presented in Table 1, R92/0804 has 34.6% higher yields than R570 and R579 and this leads to greater differences in terms of cane energy content and energy recovered in the different products.

![Figure 2—Varietal comparison based on energy content per hectare.](image)

Current process efficiencies lead to high energy losses between cane energy content and energy recovered. The total energy recovered for R570, R579 and R92/0804 is 50, 52 and 47% respectively.

There are clearly varietal differences and R92/0804 has the highest potential for electrical, ethanol and sugar production compared to the two other varieties. R570 and R579 have the same net energy content per hectare, but R570 appears to produce more electricity and less sugar compared to R579.

A possible limitation of this paper stems from the assumptions made for the calculations (extractable sugar, ethanol and cogeneration yields). The figures could also be completed with data on energy consumption during processing, which varies depending on cane composition.

This new approach to cane energy content highlights that sugar is the main energy component of sugarcane. A practical application for breeders is to develop new selection schemes to increase fibre and sugar content. As for millers, depending on energy prices, the traditional sugar losses can now be seen in terms of energy and economic gains.

**Conclusions**

This new approach to cane evaluation based on cane energy content highlights that sugar is the main energy component of sugarcane. All the parameters presented in this paper can be used on a large scale to compare different cane varieties using existing parameters. Future improvements call for the development of new parameters to replace the different theoretical ratios used at present. All the theoretical assumptions must be proved experimentally and measured in order to assess the overall impact of high fibre cane on sugar processing.

These preliminary results show that R92/0804 can increase the overall energy content, which will result in an increase in sugar and electricity production. Sugar processing is likely to be affected with an increase in sugar losses.

In Reunion Island, the sugarcane industry is moving forward. Bagasse now has value, which
will be paid to the growers for the 2009 crop. The exact payment method is still under study, but it is a sign that sugarcane will no longer be cultivated for sugar alone. This new value will be a complement to the sugar value, which is still the main energy component of cane.

When new varieties with higher levels of sugar and fibre are released, this will have an impact on sugar mills’ performance. Further research is required to evaluate this impact.

Résumé

DEPUIS plusieurs années, l’industrie cannière a évolué d’une extraction du sucre à du sucre et une production énergétique avec le développement de la cogénération et des distilleries d’éthanol. La fibre de la canne a toujours été considérée comme un problème par l’industriel sucrier. Avec l’augmentation du prix de l’électricité, la fibre devient un coproduit majeur de la canne. La balance de l’impact de la fibre sur les pertes en sucre et la production énergétique a été évaluée. Ce document compare les impacts des cannes à forte fibre sur les procédés sur une base de bilan énergétique. Selon les débouchés, la comparaison variétale sur des bases énergétiques peut être une nouvelle façon de sélectionner des cannes. À La Réunion, la cogénération a débuté en 1992 et les futurs changements liés aux lois françaises et aux crédits carbone vont modifier le prix de l’énergie en 2009. Ces changements vont conduire à libérer des nouvelles variétés pour la production sucrière et électrique comme l’élite promise d’eRcane la R92/0804. Une nouvelle approche pour l’évaluation des cannes peut être basée sur le contenu énergétique de la canne. Le contenu énergétique de la canne et de ses coproduits à été calculé en utilisant leur pouvoir calorifique inférieur.
CONTENIDO DE ENERGÍA: UN NUEVO ENFOQUE PARA LA EVALUACIÓN DE LA CAÑA

PALABRAS CLAVE: Energía, Co-Productos, Fibra, Cogeneración, Calidad.

Resumen
EN AÑOS recientes, la industria de la caña de azúcar se ha estado moviendo de la producción de azúcar únicamente, a la producción de azúcar y energía con el desarrollo de la cogeneración y las plantas de etanol. Aunque la fibra en caña ha sido siempre considerada un problema por los operadores de molienda, con los precios crecientes de la energía la fibra se está convirtiendo en un co-producto principal de la caña. El balance de energía entre pérdidas de sacarosa y producción de energía fue evaluado para caña convencional y nuevas cañas altas en fibra. El contenido de energía de la caña y sus productos fue calculado usando sus valores caloríficos netos. Los resultados mostraron que el azúcar es el principal producto energético recuperado. Dependiendo de sus diferentes usos, las comparaciones varietales basadas en su contenido energético podrían ser una nueva forma de comparar variedades de caña. En la isla Reunión, donde la cogeneración inició en 1992, se avecinan cambios en la ley francesa sobre créditos de carbono que podrían modificar el precio de la fibra para producción de energía en 2009. Estos cambios llevarán a la liberación de nuevas variedades de caña para azúcar y para producción de energía, como la promisoria variedad de élite R92/0804. Un nuevo enfoque para la evaluación de variedades podría estar basado en el contenido energético de la caña.
POLARISATION BY FILTRATION FOR CANE PAYMENT AND FACTORY CONTROL

KEYWORDS: Cane Quality, Analysis, Pol, Lead, Filtration.

Abstract

LABORATORY analyses are used worldwide to assess the quality of sugarcane and sugar processing products. Polarimetry is the basic sucrose analysis in the laboratory to assess sugarcane quality and factory performance. Pol measurement requires a clarification step that is usually carried out with lead subacetate. A non-lead method has been developed based on filtration. This filtration method has been assessed for its suitability for cane analysis for payment purposes and for factory products (mixed juice, bagasse, mud and molasses) for process control. Results for pol in cane are on average 0.08% lower with the filtration method than with the standard lead clarification method. Results for factory control show that apparent sucrose entering the mill decreases by 0.08, resulting in an equivalent decrease in undetermined losses. To conclude, polarisation by filtration is suitable for cane payment and factory control and is now used in Reunion Island for these purposes.

Introduction

For many years, the world sugar industry has used laboratory measurements to improve its efficiency, carrying out analyses on sugarcane and on sugar processing products. The analyses of sugarcane are needed to measure cane quality for agronomic and commercial purposes, whereas the analyses on sugar processing products are needed to measure factory balances and sugar losses in the mills and to improve sugar recovery. All the cane analysis methods use polarisation to estimate sucrose as it is an accurate, simple and economical method.

In the past, the polarisation method used lead subacetate but, with the increasing recognition of environmental and health factors, new methods have recently been developed employing other chemicals (Altenburg and Chou, 1991) or using filtration (Hoareau et al., 2008). Lead clarification produces juice with low colour and a polarimeter with a visible wavelength (from 587 to 589.44 nm, pol589) can be used. Filtration does not remove colour and an infrared wavelength (825 to 882.60 nm, pol882) polarimeter therefore has to be used.

In many countries, the sugar content in cane is measured for payment purposes. In Reunion Island, the Centre Technique Interprofessionnel de la Canne à Sucre (CTICS) is responsible for cane analysis for cane payment. The analysis is based on core sampling of each load followed by cane analysis by the press method. Methodological differences should be taken in account to maintain the economic balance between growers and millers. The first trials on non-lead pol started at the end of the 1990s and methods were developed in collaboration with eRcane.

This paper compares results by lead clarification pol (pol589) with filtration pol (pol882) for cane payment systems and factory control.
Materials and methods

Polarisation method for cane payment

Pol measurement

Lead clarification pol (pol_{589}) was carried out on pressed juice using lead subacetate (1.5 g / 250 mL) followed by gravity filtration with Fioroni 1591 filter paper.

Filtration pol (pol_{882}) was carried out on pressed juice using a filter aid (8 g of Clarcel CBL) followed by pressure filtration (Schmidt and Haensch Autofilt) with Fioroni 1105A filter paper. The pol and brix were measured on the same filtrate sample.

An REI Polaser SRC64 polarimeter (825 nm wavelength) was used for cane analysis at CTICS.

Pol in pressed juice with lead or by filtration was used to calculate pol in cane, according to the CTICS protocol (2009).

Cane sampling

Cane analysis by the press method is used for payment purposes in Reunion Island. Experiments were carried out at CTICS during the 2007 and 2008 crushing seasons when 4537 and 6439 samples were collected respectively to compare pol_{589} and pol_{882}. The trials were performed in five delivery stations in different parts of the island (Figure 1).

Fig. 1—Map of CTICS delivery stations in Reunion Island (trials in brown shaded sites).

Polarisation method for factory control

Pol measurement

Lead clarification pol (pol_{589}) was carried out on factory products using lead subacetate (Table 1) followed by gravity filtration with Fioroni 1591 filter paper.

Table 1—Lead clarification pol method for factory products (ARTAS, 1992; ICUMSA, 1994)

A Schmidt & Haensch Polartronic NIR W2 dual wavelength (589.44 nm and 882.6 nm) polarimeter was used for all factory products.

**Sucrose analysis by HPLC and HPAEC-PAD**

Sucrose in juice and molasses was analysed by HPLC (ICUMSA, 2002) and by HPAEC-PAD for mud and bagasse (ICUMSA, 1998). Hoareau et al. (2010) present further details of these methods.

As the lead concentration in the filtrate was around 3.8 g/L, the juice was filtered through an OnGuard II H Cartridge (Dionex) to avoid column damage.

**Factory product sampling**

Experiments on mixed juice and molasses were conducted in the 2001, 2002, 2006 and 2008 crushing seasons with weekly composite samples from the Le Gol and Bois-Rouge factories. These samples were analysed for pol$_{589}$, pol$_{882}$ and sucrose. Bagasse and mud were analysed during the 2008 crushing season.

Statistical analyses have been done with R Development Core Team software (R Development Core Team, 2009).

**Filtration pol is suitable for cane payment**

**Pol by filtration is lower than pol with lead clarification**

Results show that pol by filtration is suitable for measuring pol in cane. During the 2008 crop, 6439 analyses were compared for pol$_{589}$ and pol$_{882}$. A strong correlation was found between the two methods (Figure 2). The regression coefficient is highly significantly different from zero (p value<2.2 $10^{-16}$).

![Fig. 2—Pol in cane measured with lead clarification and with filtration (2008 results).](image-url)
The results of filtration pol are 0.08 lower on average than lead clarification pol (Table 3). The same trials conducted in 2007 showed a difference of 0.07. This average difference takes into account the results of the trials in the five delivery stations. In individual delivery stations, the average differences ranged from 0.06 to 0.13. The sugarcane tonnages delivered to the five delivery stations were used to calculate the 0.08 weighted average.

Filtration pol is now used in Reunion Island for cane payment. From the results in Table 3, there is a statistically significant difference between the two methods (p value=0.0004).

The payment system had to be modified to maintain the economic balance between growers and millers. It has therefore been adjusted with a correction factor of 0.075 that is the average difference between the two years of testing. The new payment system uses the following formula:

\[
\text{Pol \% Cane} = \text{Pol}_{882} \% \text{ Cane} + 0.075
\]

**Explanation of differences between pol by filtration and by lead clarification**

The differences measured between lead clarification and filtration pol can be explained by the removal of glucose and fructose by lead. Sucrose, glucose and fructose were analysed in 35 samples from lead clarified filtrates and filtration filtrates. According to the specific rotation of these sugars, derived pol was calculated (Schoonees, 2003) from the lead clarification pol and filtration pol results (Table 4). In these 35 samples, the pol\%cane differences were 0.09 and the pol\%cane derived differences were 0.07.

Fructose and glucose concentrations are lower in lead filtrates (0.50%) than in filtration filtrates (0.66%). This 0.16% decrease in reducing sugars content decreases the pol measurement by 0.05. The 0.08 differences observed between pol measurements are mainly explained by the removal of reducing sugars by lead.

Table 4—Pol in cane derived and sugar content of filtrates.

<td>-0.09</td>
</tr>
</tbody>
</table>

A possible limitation to the explanation of the differences observed is that the sample selections were not randomised. They were sampled using the maximum and minimum differences observed between lead and non-lead methods. This sampling methodology implies high standard
deviation for the different analyses. The results can be used to explain average differences but should be evaluated with care.

**Filtration pol for factory control**

Comparisons of pol_{589} and pol_{882} were carried out on mixed juice, bagasse, mud and molasses.

**Pol by filtration is different from pol by lead clarification**

Differences between pol by lead clarification and by filtration vary depending on the factory product in question (Table 5). For mixed juice, pol by filtration is lower than pol by lead clarification, meaning that pol by filtration underestimates sucrose by 0.13% cane on average. For bagasse, both pol values are close to the sucrose values. For mud, pol by filtration is closer to sucrose values than lead clarification. For molasses, pol by filtration is lower than pol by lead clarification, resulting in an important underestimation of sucrose.

**Filtration pol for sugar loss measurements**

The results show that filtration pol is suitable for measuring sugar losses but modifies the standard values. The entire sugar mill uses laboratory measurements to make a mass balance for measuring sugar losses. Results based on lead clarification and filtration pol show that sugar losses will be affected (Table 6). As the changes will be the same each week, a relative comparison can be made on a weekly basis.

Mixed juice sugar content will appear to be lower with filtration pol. For sugar mills that use mass balance (Cane + Imbibition = Mixed juice + Bagasse) to calculate pol%cane, the measurement for sugar entering the factory will decrease, resulting in an apparent decrease in undetermined losses. For Reunion Island sugar mills, this implies a decrease of 0.08 in pol%cane.

Sugar losses in bagasse and in mud will not be affected by the change in method. Sugar losses in molasses will decrease by 0.25, resulting in an increase of 0.25 in undetermined losses with the change in method. In Reunion, molasses losses are calculated on a weekly composite sample analysed by HPAEC-PAD, meaning that the pol method will not affect sugar losses in molasses. These differences have been examined in more detail by Corcodel and Hoareau (2009).

* Cane + Imbibitions = Mixed Juice + Bagasse
A possible limitation of this paper is the lack of clear explanation for the differences between lead clarification and filtration pol for factory products. Nevertheless, the polarisation of sugarcane compounds could be more fully investigated.

Pol by filtration has been used for factory control in Reunion Island since 2005. Mill staff are using laboratory results as previously. The main problematic point is the new system of reference used for results concerning molasses.

**Conclusions**

Polarisation by filtration is suitable for cane payment and factory control. Results for pol in cane by filtration are on average 0.08% lower than for lead clarification pol. Factory control figures are modified, with a decrease of apparent sucrose entering the mills, resulting in a decrease of undetermined losses.

Pol analysis without lead is an environmentally friendly, non hazardous method. As polarimetry is used to estimate sucrose levels, non-lead pol is sufficient for payment and factory balance purposes. As the lead standard is disappearing, this new standard can be adopted by sugar technologists.

In Reunion Island, sugar mills started to use filtration pol analysis methods in 2005 for factory control and in 2009 for cane payment.

**Acknowledgment**

We would like to thank all the staff at eRcane for their help in preparing these data, with special thanks to Mélanie David who carried out most of the pol comparisons at CTICS during the 2007 and 2008 seasons.

Résumé

Les analyses sucrières sont utilisées mondialement pour mesurer la qualité de la canne ainsi que des produits de la sucrerie. La polarimétrie est l’analyse fondamentale du saccharose pour mesurer la qualité de la canne et les performances industrielles. La méthode de pol nécessite une étape de clarification généralement réalisée avec de l’acétate de plomb. Une méthode sans plomb a été développée par filtration. Cette méthode par filtration permet l’analyse de la canne pour le paiement et les produits de fabrication pour les bilans de fabrication (jus mélangés, bagasse, écume et mélasse). Les résultats sur la détermination de la richesse indiquent que l’analyse par filtration est inférieure de 0.08 comparé à l’analyse par clarification au plomb. Le résultat sur les bilans de fabrication vont être une baisse (–0.08) de la mesure du sucre en entrée usine qui va conduire à une baisse (–0.08) des pertes indéterminées. Pour conclure, la méthode de polarisation par filtration permet le paiement de la canne et le contrôle de fabrication. Cette méthode est utilisée à La Réunion pour le paiement de la canne et le contrôle de fabrication.
POLARIZACIÓN POR FILTRACIÓN PARA PAGO
DE CAÑA Y CONTROL DE FÁBRICA

PALABRAS CLAVE: Calidad de Caña,
Análisis, Pol, Plomo, Filtración.

Resumen

Los análisis de laboratorio se utilizan a nivel mundial para determinar la calidad de la caña y los productos de su procesamiento. La polarimetría es el análisis básico de sacarosa en el laboratorio para determinar calidad de caña y desempeño fabril. Las mediciones de pol requieren un paso de clarificación que es usualmente efectuado con subacetato de plomo. Se ha desarrollado un método basado en filtración y que no hace uso del subacetato. Este método ha sido caracterizado para determinar su adaptabilidad en análisis de caña con fines de pago y para productos de la fábrica (jugo diluido, bagazo, cachaza y mieles) para control de proceso. Los resultados de pol en caña son en promedio un 0.08% más bajos con el método de filtración que con el método estándar de clarificación. Los resultados para control de fábrica muestran que la sacarosa aparente entrando al molino disminuye en 0.08 lo que resulta en un decrecimiento de las pérdidas indeterminadas. Para concluir, la polarización por filtración es adecuada para pago de caña y control fabril y es usada actualmente en la Isla Reunión para esos propósitos.
CHARACTERISATION OF CUBAN FINAL MOLASSES FROM 1999 TO 2008

KEYWORDS: Molasses, Oligosaccharides, True Purity.

Abstract
SUCROSE loss in molasses is a common concern of the sugar industry worldwide as the largest contributor to total losses. In Cuba the loss is just less than 60%. Various factors influence sucrose solubility increase, among which is the nature of impurities present in the molasses. Molasses from different Cuban mills were characterised during the seasons 1999 to 2008, to determine the constituents of greatest influence in increasing the purity. Samples were analysed for soluble solids (brix), conductivity ash, sludge, sucrose crystals, sucrose, glucose, fructose and oligosaccharides. Impurities, water ratio (I/W) and apparent and true purities of samples studied were determined. The average value of true purity in samples was 43.37%. The biggest difference between samples was the impurities content; for example, the percentage of oligosaccharides ranged over an order of magnitude. The correlation between impurities, water ratio and true purity was confirmed, and it was also found that oligosaccharides percent correlated significantly (p < 0.001) with the above characters. A total of eighteen oligosaccharides was detected in the molasses studied. The presence of each of these species, both qualitatively and quantitatively, differed from sample to sample. Only one of these oligosaccharides showed significant correlation (p<0.005) with molasses sucrose content (pol). The present work highlights oligosaccharide influence on molasses final purity, so these compounds should be taken into account in formulating the Cuban equation for the target purity.

Introduction
In Cuba since the early eighties, the purity of molasses increased well above historical levels. Loss of sucrose in molasses is produced by a number of factors so numerous and in a variety of complex interactions that cannot be studied in a simple manner. Some of these cases probably arise long before the manufacturing process of sugar cane, in its cultivation and harvest (Eggleston et al., 2001). Final molasses provides the largest contribution to the loss of sucrose in the sugar making process. Exhaustion of molasses depends mainly on sucrose solubility, which is influenced by temperature and the composition and concentration of different compounds. It has been established that reducing sugars decrease sucrose solubility and most inorganic salts increase the solubility (Lajos, 2000). It is well known that it is not feasible to remove all the sugar in cane juice entering the factory; however, it is possible to improve sucrose recovery to decrease losses that occur during the manufacturing process; in fact, good sucrose recovery depends on the crystallisation process, which in turn depends on exhaustion of massecuites and molasses.

This has been studied by many researchers in the world looking for impurities that have a higher incidence in sucrose crystallisation, both in the form of crystal (Hormaza, 2003), and crystallisation mechanism (Vaccari, 1998). To find an equation to model the behaviour of molasses purity, it is necessary to calculate values of molasses true purity and other parameters that could influence it, like reducing sugar, ash, etc, and then use data accumulated over time to look for variables with strong correlation with purity to determine the constants of the equation that defines it.
This paper presents a compilation of information in the Cuban Sugar Research Institute on the characterisation of Cuban final molasses of sugarcane over the last decade. In addition, results are shown of statistical data analysis targeting which molasses components influence purity and thereby increase losses of sucrose in the manufacturing process.

Materials and methods

Samples

Final molasses samples produced by different Cuban sugar factories, spread over the country were studied. Samples were constituted by ten-day final molasses samples accumulated at each factory during three harvest periods during the seasons 1999, 2000, 2001, 2002, 2005, 2007 and 2008.

Physical – chemical analysis

Molasses samples were analysed according to ICUMSA methods or Cuban National Bureau standards (2009) according to the following list:

- Brix: refractometric dry substance. ICUMSA method GS4-13
- Sludge (insoluble material): NC 710:2009. It is based on precipitation of insoluble materials contained in final molasses and centrifugation at 3500 rpm for 10 minutes.
- Sucrose crystals: Total insoluble solids are made up of sludge and sucrose crystals that are suspended, so washing the pellet formed after centrifugation with distilled water will enable these two components to be separated and, and by weight difference, the content of crystals can be determined.

High Performance Liquid Chromatography (HPLC) analyses

Determinations for fructose, glucose, sucrose and oligosaccharides were performed in a Knauer HPLC equipment with cation-exchange column EuroKat Ca 300 × 7.8 mm to 85 °C with a water flow of 0.6 mL/min and refractive index detector. A typical chromatogram is shown in Figure 1.

Fig.1—Molasses HPLC cation-exchange characteristic profile. Peaks 1–3 oligosaccharide, 4 sucrose, 5 glucose, 6 fructose.
Determination of oligosaccharide composition on molasses

Determinations of different oligosaccharides present in molasses were made by using an anion-exchange high resolution chromatographic system (HPAEC, Figure 2) with amperometric pulse detector (PAD) Dionex instrument, using a CarboPac 1 column, 300 mm × 7.8 mm with a gradient of 0.05 N sodium hydroxide in 0.1 N sodium acetate to 0.1 N sodium hydroxide in 0.1 N sodium acetate. A hydrolysed dextran was used as a standard to determine the oligosaccharide species polymerisation degree.

Fig. 2—Molasses HPAEC characteristic profile. Differential fractions considered as oligosaccharides have been underlined.

Statistical analysis

Data obtained from chemical–physical analysis as well as chromatographic analyses were processed using the statistical program Statgraf version 5.1.

Results

Characterisation of Cuban final molasses in the period 1999–2008

An average 39 samples of final molasses were analysed per season. All results are expressed as averages of molasses samples analysed in each of the seasons studied. Table 1 shows the results of brix, ash, apparent and true sucrose, glucose, fructose, oligosaccharide, crystals, sludge and impurity/water ratio in molasses analysed.

Brix has ranged between 91% and 82%, showing a clear tendency to decline over the last decade, probably due to extra water addition to molasses after the centrifugal to reduce viscosity.

Sucrose crystal content ranged between 4.3 and 11.5%. A possible explanation for the increase in sugar crystal per centage was the increment of crystal fragility due to crystal habit deformations by a high concentration of oligosaccharide in final molasses (Hormaza, 2003). In 2001, the highest contents of crystals in Cuban molasses were reported which coincided with the highest content of oligosaccharides detected that year. Sludge content in the molasses remained below 2%. Impurity/water ratios ranged from 2.8 to 6.9% respectively while ash content ranged from 9.8 to 15.5%.

Apparent sucrose in Cuban molasses showed an increase of five percentage points over the last decade. Furthermore, sucrose content in final molasses in the period 1999–2008 has averaged between 30% in 2000 to 46% in 2007. Reducing sugars on the other hand maintained little variability over time. As for the rest of the non-sucrose carbohydrates, oligosaccharide net content fluctuated more between harvests.
Table 1—Cuban molasses composition during 1999–2008. Results expressed as % by mass.

The purity of final molasses in the last decade has shown an upward trend, reaching the lowest values (34 true and 36 apparent) in the harvest of 2002. The maximum value of true purity was 50% in 2007 whereas the highest apparent purity was 46% in the harvest of 2008.

![Fig. 3—Trend of true and apparent purities of final molasses in the period 1999–2008.](image-url)
Determination of oligosaccharide species in Cuban molasses

Using high resolution anion-exchange chromatographic techniques with pulse amperometric detector, a total of 18 different oligosaccharides with degree of polymerisation between three and seven units were determined.

Some of those oligosaccharides were identified as gentibiose, leucrose, raffinose, melicitose, neo-kestose, 6-kestose and maltotriose. A total of eleven unidentified species were detected, five of these comprised three monosaccharide units and the remainder with a degree of polymerisation between four and seven. The oligosaccharide composition and frequency of the molasses studied were very heterogeneous, finding between two and ten of these species in them (Table 2).

Statistical analysis

All data obtained from the characterisation of final molasses during the past decade were used for statistical analysis looking for correlations between these variables and the true and apparent purities so that, once localised, it would be useful as a tool for a better understanding of the manufacturing process, providing guidance on what aspects to consider for further development of an equation to predict target purity.

Table 3 shows the Pearson product moment correlations between pairs of variables. These correlation coefficients range from −1 to +1 and measure the strength of the linear relationship between variables.

It also shows the number of pairs of data used to calculate each coefficient. The third row is a P-value which confirms the importance of the statistic of the estimated correlations.

P-values below 0.05 indicate statistical significance of non-zero correlation for a confidence level of 95%.

Influence of variables in real and apparent purities

Multiple regression analysis was performed with true purity as the dependent variable and as independent variables those in which there was a linear non-zero correlation with the first. It was determined that the percent of oligosaccharides and the impurity/water ratios present a statistically significant relationship with true purity at the 99% confidence level with these independent variables responsible for 17.7% of the true purity variability. However, no correlation was found between ash content and reducing sugars with true purity (Table 4).

Using the same method, the existence of a statistically significant relationship (p <0.01) exists between the apparent purity and the two independent variables of glucose and reducing sugars that accounts for 26.5% of the variability of the apparent purity (Table 5).

Influence of oligosaccharides on pol

To determine which oligosaccharides have more influence on the pol in the mashes, all oligosaccharides detected were analysed for Pearson’s product moment correlations and non-zero correlations were obtained between pairs of variables for a confidence level of 95%. A linear regression analysis was undertaken using pol as the dependent variable to determine those independent variables with a linear non-zero correlation with pol.
It was determined that from the oligosaccharides present only one of them (Unknown 8), with polymerisation degree between four and seven, had a non-zero correlation with the pol (p <0.01) so this oligosaccharide, identified with retention time of 26.88 minutes, is responsible for 30 percent of the variability of pol data (Table 6).

Discussion

Results of analyses of Cuban molasses during the last decade have shown that oligosaccharides showed greater variability, reaching a maximum value in 2001 season and resulted in an increment of sucrose crystal content in molasses that year high above average values.

In general, there was a tendency for the oligosaccharide content to increase probably as a result of delays between cut and crush (Ramos, 2002). A similar trend was observed for true sucrose content (Figure 3) due to problems caused by these compounds in the crystallisation process.

Ash and reducing sugars showed little variability in the samples which could explain why no correlation was observed between these variables and purity of final molasses unlike those reported for other regions (Gil et al., 2001; Miller et al., 1998; Smith, 1995). It appeared there was a correlation, with 95% confidence, between the total oligosaccharide content and I/W with true purity (Table 4). Similar results have been reported previously by Rein (2002).

The qualitative and quantitative composition of oligosaccharides in sugarcane juice and in final molasses depends on a lot of causes, both agricultural and industrial. It is characteristic of the variety and age of the plant and tends to increase after harvesting, often by the action of microorganisms (SMRI, 1992). The oligosaccharide composition results found heterogeneous mixtures of between two and ten different oligosaccharides in the molasses samples studied.

In early works on molasses oligosaccharides, Binkley (1964) identified 1 kestose, 6-kestose, raffinose, nistose, planteose and fructosil 1 kestose. Later Morel du Boil (1995) reported different mixtures of sugarcane oligosaccharides, neo kestose, 6-kestose and 1-kestose according to different months of harvesting. The present study detected a total of 18 different oligosaccharides (Table 2), including neo kestose, 6 kestose and 1-kestose as has been reported, but the oligosaccharide species most frequently detected was another unidentified with a similar degree of polymerisation.

The present study showed that one of these species, Unknown 8, correlated with the reading of pol contributing 30% of the variability of the pol. This oligosaccharide, together with the glucose and reducing sugars in the molasses, introduces another source of variability to be considered in determining the apparent purity of Cuban molasses.

Conclusions

Cuban molasses produced in different sugar factories, spread throughout the country, for seven seasons within the period from 1999 to 2008 has been characterised. The analyses have found variables that influence the pol and purity of Cuban molasses. It was demonstrated that, from all of the oligosaccharides detected only one, Unknown 8, was a source of variability in the pol reading. It was also shown that the level of glucose and reducing sugars influenced the apparent purity of molasses and the total content of oligosaccharides and the I/W affects the true purity of these molasses.

MOTS-CLEFS: Mélasse, Oligosaccharides, Pureté.

Résumé
La perte de saccharose dans la mélasse est une préoccupation commune de l’industrie du sucre dans le monde entier comme le plus important contributeur des pertes totales. À Cuba, la perte est au dessous de 60%. L’augmentation de la solubilité du saccharose est influencée par divers facteurs, parmi lesquels est la nature des impuretés présentes dans la mélasse. Les mélasses des différentes usines cubaines ont été caractérisées durant les saisons 1999–2008, afin de déterminer les composantes avec la plus grande influence pour augmenter la pureté. Les échantillons ont été analysés pour les solides solubles (brix), la cendre (conductivité), boues, cristaux de saccharose, saccharose, glucose, fructose et oligosaccharides. Le rapport impuretés / eau (I/W) et les puretés apparaentes et réelles des échantillons étudiés ont été déterminés. La valeur moyenne des puretés réelles dans les échantillons était 43.37%. La plus grande différence entre les échantillons était la teneur en impuretés ; par exemple, le pourcentage d’oligosaccharides variait par un ordre de grandeur. La corrélation entre I/W et la pureté réelle a été confirmée, et on a également constaté que la concentration des oligosaccharides corrélées significativement (p 0.001) avec les caractères ci-dessus. Un total de dix-huit oligosaccharides a été détecté dans la mélasse étudiée. La présence de chacune de ces espèces, tant qualitativement et quantitativement, diffère d’un échantillon à l’autre. Un seul de ces oligosaccharides a montré une corrélation significative (p 0.005) avec le contenu de saccharose de mélasse (pol). Ce travail rehausse l’influence des oligosaccharides sur la pureté de la mélasse finale ; ces composés devraient donc être pris en compte dans la formulation de l’équation cubaine de la pureté cible.
CARACTERIZACIÓN DE LAS MIELES FINALES EN CUBA DESDE 1999 HASTA 2008

PALABRAS CLAVE: Mieles, Oligosacáridos, Pureza Real.

Resumen
LAS PÉRDIDAS de sacarosa en miel final son una preocupación de la industria azucarera a nivel mundial por ser las que más contribuyen a las pérdidas totales. En Cuba la pérdida es un poco menos del 60%. Varios factores influencian el incremento de solubilidad de la sacarosa, entre los cuales está la naturaleza de las impurezas presentes en las mieles. Se caracterizaron las mieles de diferentes ingenios cubanos durante las zafra de 1999 a 2008, para determinar los constituyentes de mayor influencia en el incremento de pureza. Las muestras se analizaron para sólidos solubles (brix), cenizas por conductividad, lodos, cristales de sacarosa, sacarosa, glucosa, fructosa, y oligosacáridos. Las impurezas, la razón con el agua (I/W) y las purezas real y aparente se determinaron para las muestras estudiadas. El valor promedio de la pureza real fue de 43.37%. La mayor diferencia entre muestras estuvo en el contenido de cenizas; por ejemplo el porcentaje de oligosacáridos varió por encima de un orden de magnitud. La correlación entre impurezas, la razón de agua, y pureza real fue confirmada, y se encontró que el porcentaje de oligosacáridos correlacionó significativamente (p<0.001) con los factores anteriores. Se identificaron 18 oligosacáridos en las mieles estudiadas. La presencia, tanto cuantitativamente como cualitativamente, varió entre muestras. Solamente uno de los 18 mostró correlación significativa (p<0.005) con el contenido de sacarosa en las mieles (Pol). El presente trabajo señala la influencia de los oligosacáridos en la pureza de las mieles, por lo que estos compuestos deben ser tenidos en cuenta en la formulación de la ecuación cubana para la pureza objetivo.
AN ANALYTICAL OVERVIEW OF THE HISTORICAL EVOLUTION OF SOME PERFORMANCE INDEXES OF THE COLOMBIAN SUGAR MILLS

By

E.F. CASTILLO, N.J. GIL and L.M. CALERO

Colombian Sugar Cane Research Center – Cenicaña, Cali, Colombia, South America
efcastillo@cenicana.org

KEYWORDS: Analysis, Performance, Review, Standardisation.

Abstract

In 1993, the Colombian sugar industry recognised the importance of creating a reliable Standard Measuring System (SMS) for the sugar factories, with the purpose of developing tools for management processes. This system included sampling, analytical procedures and calculation modules. It was generated in conjunction with experts from Sugar Research Institute in Australia (Ken Miller and Geoffrey Bentley), the chief chemist of each sugar factory and the technical staff from Cenicaña. Since January 1998, the Factory Process Research Program at Cenicaña, together with the staff of the 10 main Colombian sugarcane mills, began the construction of an integrated database, focusing on the registry of 42 process variables measured and/or calculated in each factory. Each variable reported by the sugar mills was based on monthly weighted averages. The predetermined set of variables comprised those related to cane quality, sucrose balance (related to undetermined loss), energy usage and time use efficiency. Because the SMS has a very strong dynamic behaviour, a parallel program for assessing the quality of the reported information was established (Calero, et al., 2006). Over this 10 year period, the improvement in sucrose % cane and factory efficiencies is notable. From 2002 until now, the increment in 0.25 units in sucrose % cane and 1 percent unit in overall recovery (OR) represent an additional production of 69 860 tonnes of sugar for a cane crush of 20 million tonnes per year.

Introduction

The Colombian Sugarcane Research Center (Cenicaña) is a private, non-profit corporation, founded in 1977 by the Association of Sugarcane Growers of Colombia (Asocaña) representing the sugar agro-industry located in the Cauca River Valley. Cenicaña carries out research programs on varieties, agronomical practices and factory processes, and has support services in economic and statistical analyses, information and documentation, computer technology, technical cooperation and technology transfer. It provides laboratory analytical services, administers the Automated Weather Network (AWN) stations, and continually updates the digital cartography of the cultivated area.

The sugar industry in Colombia has three cane growers’ associations, one research centre, one cane technicians’ association, two trade firms, 13 sugar mills and a large number of cane grower enterprises. Five sugar mills established distilleries to produce ethanol at the end of 2005 in response to Law 693 of 2001, which mandated oxygenating vehicular gasoline with 10% (by volume) of fuel ethanol.

Factory performance indices

The standardised monthly inter mill benchmarking started in January 1998. Thirteen sugarcane mills report 42 indices relating to sugarcane quality, time efficiency, sucrose extraction,
boiling house recovery (BHR), overall recovery, and energy usage. This paper shows the trends of the monthly average values of ten mills, during the first ten years of the SMS.

**Crushed cane and sugar production**

In 1999, the variety CENICAÑA Colombia (CC) 85-92 became the first commercial variety in the area planted by the Colombian sugar industry in the Cauca River Valley. Crushed cane has grown from approximately 17 million tonnes of cane annually in 1998 to a maximum value just under 21 million tonnes in 2004. The monthly average of cane crushed was 1 600 000 tonnes, with a minimum of 609 228 tonnes in October 2008 as a result of the blockade of eight sugar mills by cane cutters. Monthly values around 2 million tonnes are frequently obtained in August and September during the dry season (Figure 1).

A greater stability is observed during the years 2002 and 2006 when around 20 million tonnes per year were crushed. This fact is explained by the dry periods experienced during these years with an annual average rainfall of 1000 mm. This was the lowest value registered in the 34 AWN stations placed throughout the Cauca River Valley (Informe anual, Cenicaña, 2008).

![Figure 1—Monthly averages for cane and sugar production in Colombia.](image)

The increased availability of the cane variety CC85-92 from 2002 led to a productivity increase on average of 10% more cane per hectare (tch). Moreover, there was an increase in milling throughput of 7% per day and a 2% increase in the overall time efficiency.

The sugar production per year ranged between 2 million tonnes and 2.4 million tonnes. The Colombian sugar industry produces refined sugar in seven refineries and, raw sugar, white sugar, special direct white sugar (colour below 150 IU) and organic sugar. The amount of sugar depends on the crush rate, cane quality and the factory efficiencies.

The monthly average crush rate was 186 911 tonnes cane per hour, and this ranged between 70 853 and 249 981 tonnes cane per hour. As in the case of total cane crushed, the minimum value was obtained in October 2008, because of the blockade (Figure 1). The yield expressed as kg of sugar of 99.7 pol per 100 kg of cane has varied from 11.30 to 11.93 with a yearly average value of 11.70.

**Cane quality**

The trend to higher content of sucrose % cane (Figure 2) and lower industrial fibre % cane (Figure 3) coincided with the fact that from 2001 the cane variety CC 82-92 became the most
harvested in the industry. In 2008, this variety was harvested in 70% of the cane area. Between 1998 and 2001, the average sucrose % cane and fibre % cane were 13.18% and 15.10% respectively and between 2002 and 2008 the averages were 13.43% and 14.77%. The maximum content of sucrose in cane, 14.62%, was reached in September 2006. During 1996–2002, the Factory Process Research Program at Cenicaña developed a project called ‘Reduction of Sucrose losses between field and factory’. One of the main objectives of this project was to determine the rate of sucrose deterioration due to storage time which ranged from 0.0015–0.02 sucrose % per hour (Briceño, 2006). The mills reduced the storage time from an average of 50 h–60 h down to 30–42 h (Larrahondo and Briceño, 2001).

![Fig. 2—Monthly averages for sucrose % cane in Colombia.](image1)

The industrial fibre includes the cane fibre and the insoluble mud solids measured in mixed juice. The higher values of fibre reported in April, May and December are associated with the rainy periods experienced during these months (Figure 3).

![Fig. 3—monthly averages for industrial fibre % cane in Colombia.](image2)
Reduced extraction at 12.5% fibre.

All the sugar factories have milling tandems and, of the ten mills, three have knives only, three mills have knives and medium duty shredders, two have knives and heavy duty shredders and two have heavy duty shredders only.

The trend of reduced extraction is shown in Figure 4 and is one of the most stable of those analysed with an average of 96.65% and a coefficient of variation of 0.20.

The mobile laboratory to evaluate the performance of individual milling tandems and software developed for Cenicaña to model the extraction processes (Carvajal, et al., 2006; Gómez et al., 2003) had contributed to the stabilisation of the reduced extraction.

The extraction efficiency is directly related to changes in the content of industrial fibre % cane. In the period 2002–2006, industrial fibre was 0.13 percentage points higher and the extraction was lower than the values reported in the two year period 2007–2008.

However, the magnitude of the difference in the extraction was higher than that observed due to the fibre increase only. This may be explained in terms of imbibition % cane, which was reduced on average.

The imbibition rate is not always a function of the industrial fibre content as would be expected. Low imbibition rates with high industrial fibre content are reported during rainy periods, while high imbibition rates with low industrial fibre content are reported during dry periods.

This trend would indicate that imbibition is a function not only of the industrial fibre content but also of the availability of steam which is affected by the bagasse quality expressed in terms of moisture and ash content.

![Figure 4](image_url)  
**Fig. 4**—Monthly averages for reduced extraction at 12.5% fibre.

**Boiling house efficiency**

Since 2001, the BHR has shown good stability and higher efficiencies, with only one data point below 90% as illustrated in Figure 5. Since August 2007, the BHR has stabilised around 92% due to the projects undertaken to reduce the undetermined losses.

In 2006, after the installation of the five distilleries for fuel ethanol production and, as a consequence of the different problems in the fermentation, some of them related with the high
content of volatile acidity of the substrate, Cenicaña conducted a project focused on reducing the undetermined losses (Calero et al., 2009).

The pathway followed in the project covered microbiological, physical and chemical analyses from first expressed juice to syrup, critical analysis of the control strategies used for process variables, process residence time, and suggestions for geometry and size of the pans.

This project helped to reduce the drop in purity between first expressed juice and raw juice from 1.9 in 1998 to 1.3 in 2008 and the drop in purity between clear juice and filtrate juice from 2–3 units to 1–2 units in some mills.

From Figure 6, it is clear that, while the determined losses (bagasse, cake and final molasses) remain relatively constant at around 11%, the undetermined loss shows a decreasing trend.

![Graph of boiling house recovery (BHR) in Colombia.](image)

During the 10 year period under review, the industry has also changed the clarifiers. Three mills have the latest generation SRI clarifiers, but RapiDorr and Dorr 444 clarifiers are also used.

The use of continuous vacuum pans has been adopted in four mills; two for B massecuite and two for A massecuite as well as the use of vertical crystallisers in two of the mills.

These changes have contributed to maintaining the pol loss in final molasses relatively constant despite the changes in cane quality due to the increased percentage of cane harvested mechanically. This has increased from an average of 15% in 1998 to 30% in 2008. Two mills are harvesting around 50% mechanically.

In addition to the technological changes, the main results of the projects to reduce the pol loss in final molasses (Gil et al., 2001a) and the determination of target purity in final molasses (Gil et al., 2001b) include:

- the improvement in the slurry preparation;
- a methodology for measuring the crystal size; and
- a methodology to evaluate the exhaustion of C massecuite.

These results have contributed to reduce the pol loss in final molasses from 6.44% pol in cane in 1998 to 5.99% pol in cane in 2005.

After 2005, five of the ten mills stopped producing final molasses and diverted B molasses to ethanol production.
Overall recovery

Overall recovery performance has been stable at values higher than 87% from the middle of 2001 as illustrated in Figure 7.

During the past seven years, OR increased one unit on average in spite of the increasing trash material processed with the cane and the adverse climatic conditions of the last two years.

This improvement in the factory performance represents, for an average crushing year season of 20 millions tonnes of sugarcane, an additional production of 27 000 tonnes of sugar.

Conclusions

The use of standardised monthly inter mill benchmarking has become a valuable tool for the periodic comparative analysis of information among sugar mills and a fundamental tool for continuous improvement of the industry.
During the past ten years, the sustained improvement in sucrose % cane and factory efficiency was excellent. Since 2002, the increase in sucrose content of 0.25 units and in overall recovery of one unit represents an extra production of 69,860 tonnes of sugar for an average season of 20 million tonnes of cane.

Despite the fact that Colombian field productivity is the highest in the world, and is a product of more than 35 years of research on agricultural packages and varietal breeding, the assessment of sugar factory performance is much more recent and the development of the technology is still at an early stage. Using the developed standardised measurement system detailed in this paper, researchers at Cenicana, technicians from the sugar and ethanol factories, consulting enterprises and so on, are able to formulate reliable factory improvement strategies, increase production capacity of the plants as well as periodic benchmarking assessments.

Many opportunities are open to the Colombian sugar sector. First, its important contribution to the ‘National plan for oxygenated gasoline’, which, at July 2009, is covering 85% of the total demand of bioethanol, and the expected demand for increased production capacity in the future. Finally, cogeneration in sugar mills is becoming an interesting business option, after the Colombian Regulatory Committee on energy and gas developed a set of requirements for Colombian agents to obtain the category of electrical generator.

Acknowledgments
The Chiefs of the Departments of Quality and Compliance, laboratory technicians and sugarcane mill factory directors for the support and commitment for keeping the information system standardised and incorporating it as an essential tool for the analysis of the Colombian sugarcane industry.

Résumé

En 1993, l'industrie sucrière colombienne a reconnu l'importance de la création d'une fiabilité Standard Mesuring System (SMS) pour les usines a sucre, dans le but de développer des outils pour la gestion. Ce système comprenait l’échantillonnage, les procédures analytiques et des modules de calcul. Il a été généré en conjonction avec des experts du Sugar Research Institut en Australie (Ken Miller et Geoffrey Bentley), le chimiste en chef de chaque usine et le personnel technique de Cenicaña. Depuis janvier 1998, le Factory Process Research Program à Cenicaña, avec le personnel de dix usines colombiennes, a commencé la construction d'une base de données intégrée, en se concentrant sur le registre de 42 variables de processus mesurés ou calculés dans chaque usine. Chaque variable donne par les usines est une moyenne pondérée mensuelle. L’éventail de variables prédéterminés comprend ceux liés à la qualité, bilan saccharose (perte indéterminée), utilisation et efficacité de l’emploi du temps. Parce que le système SMS a un comportement dynamique très fort, un programme parallèle pour évaluer la qualité de l'information a été établi (Calero, et al. 2006). Pendant cette période de 10 ans, l'amélioration du saccharose % canne et de l'efficacité à l’usine est remarquable. Depuis 2002 jusqu'à présent, on trouve une augmentation de 0.25 de saccharose % canne et de 1% en récupération générale (OR) ce qui représentent une production supplémentaire de 69 860 tonnes de sucre pour 20 millions de tonnes de canne par an.
REVISION ANALITICA DE LA EVOLUCION HISTORICA DE ALGUNOS INDICES DE DESEMPEÑO DE LOS INGENIOS AZUCAREROS COLOMBIANOS

Por

E.F. CASTILLO, N.J. GIL y L.M. CALERO

Colombian Sugar Cane Research Center- Cenicaña, Cali, Colombia, South America
efcastillo@cenicana.org

PALABRAS CLAVES: Análisis, Desempeño, Revisión, Estandarización.

Resumen

En 1993, la industria azucarera colombiana reconoció la importancia de crear un sistema confiable de medición estandarizado (SMS) para los ingenios azucareros, con el propósito de desarrollar herramientas para la gestión de procesos. Este sistema incluyó, muestra, procedimientos analíticos, y un módulo de cálculos. Este sistema fue desarrollado con apoyo de expertos del Sugar Research Institute de Australia (Ken Miller y Geoffrey Bentley), los jefes de laboratorio de los ingenios y personal técnico de Cenicaña. Desde 1998, el Programa de Procesos de Fábrica de Cenicaña en conjunto con personal técnico de 10 de los principales ingenios azucareros colombianos, empezaron la construcción de una base de datos, que registra 42 variables de proceso medidas y/o calculadas en cada ingenio. Cada variable reportada por los ingenios está basada sobre promedios ponderados mensuales. Estas variables comprenden aquellas relacionadas con calidad de caña, balance de sacarosa, uso de energía y eficiencia en el uso del tiempo. Debido al carácter dinámico del SMS se estableció un programa paralelo para valorar la calidad de la información reportada. Durante estos primeros 10 años, se destaca el incremento en la sacarosa % caña y las eficiencias en las fábricas. Del año 2002 a la fecha, el incremento en 0.25 unidades en la sacarosa % caña y en una unidad porcentual de la recuperación total (OR) representa una producción adicional de 69 860 toneladas de azúcar para una molienda típica de 20 millones de caña por año.
THE EFFECTS OF CENTRIFUGAL AND FACTORY OPERATION IN COLOUR INCLUDED AND OCCLUDED IN PLANTATION WHITE SUGAR CRYSTALS FOR FIVE FACTORIES OF CENTRAL AMERICA

By

F.A. RAMIREZ
Pantaleón
Ingenio La Grecia, Choluteca, Honduras
framirez@engineer.com, framirez@grupomaster.info

KEYWORDS: Colour, Included, Occluded, Centrifugal, Wash Water, Mean Aperture.

Abstract

COLOUR is the most widely accepted and possibly the most important quality parameter of white sugar. It is necessary to know what happens in the various stages of the factory operations to determine the colour inside the crystal (included colour) and colour on the crystal surface (occluded colour). Only surface colour is eliminated by wash water in the centrifugals. This study considers the effects of wash water time on the reduction in colour and the loss through dissolution of the sugar crystals in the batch centrifugals, and the analysis of the occluded (surface layer) and included (inside the crystal) colour for different process conditions such as changing the purities of the C and B magma, using different process cationic flocculants and using different washing times in the centrifugals in five sugar factories of Central America. Experimental equations for crystal loss against washing time are studied in three of the factories. Results indicated the impact of using cationic flocculants, syrup clarification and improving boiling purity for strikes for the five factories. The results indicate that crystal colours of 85 to 135 ICUMSA can be obtained when best practice processes are adopted, However, crystal losses of at least 15% can be expected when wash times of more than 20 seconds with 480 kPag water at 85°C to 95°C is used.

Introduction

Colour and impurities

Colour is the most widely accepted and possibly the most important quality parameter of white sugar. It is necessary to know what happens in the various stages of the factory operations to determine the colour inside the crystal (included colour) and colour on the crystal surface (occluded colour). Only surface colour is eliminated by wash water in the centrifugals and that is why, above a certain level, further increase in the amount of wash water does not result in an improvement of the quality of the sugar (Van der Poel et al., 1987).

Colour in white sugar massecuites comes from colour in raw juice, colour formation in heaters, evaporators and clarifiers, colour formation in tanks and pans, type of factory operations and colour recycling from B and C magma.

In crystallisation operations, impurities have a dramatic effect on the habit and crystal size distribution due to the influence on the kinetics of growth and nucleation. Some examples of the impurities in the sugar crystal are (Genck, 1997) colour molecules, inorganic ash compounds, mother liquor located at the surface of the crystal, air and gas bubbles, mother liquor droplets included in the growing crystal lattice, and polysaccharides and oligosaccharides.

A high supersaturation of the mother liquor during boiling promotes fast growth but it also promotes inclusion of impurities within the crystal lattice. Impurities adsorb onto crystal surfaces and influence interfacial tension. Also, impurities are incorporated more easily into large crystals and at high concentrations like at the end of a strike.
Centrifugal process performance

When considering centrifugal performance, it is possible after several assumptions to idealise the flow of the mother liquor (A, B or C molasses) through a sugar cake by considering the flow down a thin pipe. Grimwood (1996) shows that the small gaps which exist between the individual crystals of sugar in the centrifugal basket are proportional to the average size of the crystals or mean aperture (MA). It is possible to write this expression as follows:

\[
\text{Centrifuge performance} = (\text{MA})^2 \times \frac{G \times \Delta t}{(\text{Mother liquor viscosity} \times L)}
\]  

(1)

Where:

- \( \text{MA} \) = Mean aperture of sugar (average size of sugar crystals), \( \mu \text{m} \).
- \( G \) = force pushing syrup through the sugar cake. \( \text{Ft/s}^2 \).
- \( \Delta t \) = Spin time, s.
- \( L \) = Sugar cake thickness, ft.

During acceleration a water wash is normally applied to the sugar. Washes are applied for 5 to 20 seconds depending on the grade of sugar being produced, wash jets and other operational parameters. The application of wash water has two main beneficial effects, first to increase the purity of the sugar and, secondly, to reduce its final moisture.

As the wash water flows through the cake, it becomes saturated with sugar after the first 50–75 mm and this saturated solution displaces the massecuite mother liquor (Grimwood, 1996). However, washing has the unwanted effect of melting (dissolving) a proportion of the sugar.

According to Grimwood (1996), there are three washing mechanisms that take place in the centrifuge: displacement, diffusion and dissolution.

In displacement wash, the mother liquor filling the gaps between the crystals is displaced by wash liquor; in diffusion wash, dissolved material in the remaining mother liquor adhering to the crystals is transferred (diffuses) into the wash liquor, and in dissolution wash, the surface layers of the crystals are dissolved by the wash liquor.

Methods

Crystal loss

The real amount of crystal sugar that is dissolved in the wash water and ends up in the syrup can be determined by measuring the sugar cake thickness for different wash times, including no washing as the base case for a specific batch centrifuge, strike and factory. Different amounts of wash water were applied for a specific centrifuge in two factories.

For zero or low washing times, the measurements can be taken before the centrifugal is returned to the normal cycle to achieve the desired sugar quality. The temperature and pressure of the wash water was also recorded.

Included colour

It was decided to limit wash water use to a maximum of 25 s because available data show that additional wash water did not improve the quality of the sugar. Further improvement in quality could be achieved with changes to other process conditions such as changing the purity of C magma and B magma, seeding for A strikes, using different process cationic flocculants or colour precipitants, syrup clarification and improving the boiling purity for A strikes for different sugar factories.

Qemitreat SEP (from Qemi International Inc.) decolourant usage was set at 40 ppm on solids. The polymer was diluted 1:1 with water and added to the clear juice tank.

Colour elimination

The colour remaining in the sugar crystal at the end of the cycle can be determined as a function of wash time. For no washing or low washing times, a sample of sugar was taken before the normal cycle was resumed to obtain the desired sugar quality.
Results and discussion

Trials were conducted at five factories to measure the effects on the sugar product from the application of different process conditions, with and without syrup clarification and with and without the use of colour precipitant. The centrifugals used during the trials are listed in Table 1.

Figure 1 illustrates the degree of crystal loss as a function of wash water usage for the Western States centrifugals at factories B, C and D. The centrifugal used at factory B was working at 1020 G. The collected data for factory B represent the averages of 87 separate measurements. The data show a crystal loss of 11.8% when wash water was applied for 20 seconds.

For factory C, the collected data correspond to the averages of 90 measurements. A crystal loss of 15.5% is reported when 20 s of wash water is applied. Factory D has the smallest centrifugal of the three units tested. The collected data correspond to the average of 50 measurements and show a crystal loss above 20% at 20 s of wash water application.

These three trends in Figure 1 show just how much sugar is dissolved when excessive quantities of wash water are used in the centrifugals to achieve low colour sugar.

Figure 2 illustrates how much colour is removed as a function of wash water usage for the same Factory B centrifugal and conditions of Figure 1. It can be seen that, after about 20 s, further
increases in the amount of wash water do not result in any improvement in the quality of sugar in terms of colour. A colour ratio can be defined and represents the colour remaining in the sugar as a ratio of the original colour before any wash water is applied. Thus, after 20 s of wash, the colour remaining is about 16.6% and, after 25 s of wash, the remaining colour is about 10.6% of the original colour. However, the extra 5 s of wash dissolved another 2.3% of the crystal according to the data in Figure 1.

\]

![Fig. 2—Final sugar colour as a function of wash water time for factory B. (Western States centrifugal, 54 x 40, 480 kPag, 85–95°C).](image1)

For factory C, the colour elimination curves as a function of water and cationic flocculant (at 40 ppm on solids) usage are shown in Figure 3 and Table 2. When using cationic flocculant, the sugar colour was about 28% lower than the sugar colour produced without the use of the cationic flocculant. This means that less wash water is required to achieve a certain sugar colour if cationic flocculant is used. For example, if 20 s of wash is required to achieve the required colour without flocculant, then the same colour can be achieved with only 17 s of wash if cationic flocculant had been used in the process and 3% less crystal would have been dissolved in the centrifugals.

Table 3 shows the included colour data collected from five sugar mills and some variations of the processes involved. The best practice is to achieve low impurity concentrations in mother syrup to minimise the probability of including impurities in the growing crystal. This can be done by improving the B and C magma purities, using syrup clarification, using cationic flocculants or decolourants and seeding for A strikes. Factory E has produced a low colour sugar but with the disadvantage of the impact in sucrose recovery and the extra recirculation load in the boiling scheme. This factory sells its sugar to a market that pays a special price for the quality. The benefit of using cationic flocculants is that some colourants are removed from the syrup before going to the boiling house. The key variables for improving sugar quality after syrup clarification are the target purities of C and B magma, due to the colour impact on the A strikes. As seen in Table 3, the crystal sugar process which uses only the juice from the first mill results in a high quality sugar product. The double magma boiling scheme uses seeding for C strikes and uses C magma as a footing for B strikes and B magma as the footing for A strikes.

n.a. = not available

Another process variation, where tanks and pans are available, is to process special strikes using melted B magma (for the best sugar quality), and melted C magma and syrup for the other commercial strikes.

Cane quality has a dramatic effect on sugar quality and included colour. The presence of vegetable and mineral trash, time delay, harvesting systems and cane deterioration, are key factors for a good crystallisation operation because impurities are incorporated more easily at high concentrations. Impurities like polysaccharides, oligosaccharides and other macromolecules that are related to cane quality influence sugar processing and have been implicated in the inclusion of colour in crystals. They also influence the mother liquor viscosity that also affects centrifugal performance.
Conclusions

It is important to determine experimental relationships for crystal loss and sugar colour against wash time for a specific model of batch centrifugal and the material being processed at a factory. The crystal loss of the three factories and centrifugals discussed in this paper varies from 11% to more than 20% with 20 s of wash time.

For factory C, the results show that, by using the same wash time, sugar with 28% less colour is achieved when colour precipitant is used as part of the syrup clarification process.

The key variables after a good syrup clarification and cane quality for improving sugar quality are the target purities of C and B magma.

PALABRAS CLAVE: Color, Incluido, Ocluido, Centrífuga, Agua de Lavado, Apertura Media.

Resumen

EL COLOR es el parámetro de calidad del azúcar blanco más aceptado universalmente y posiblemente el más importante. Se requiere conocer lo que sucede en las varias etapas operativas de la fábrica para determinar el color dentro del cristal (color incluido) y el color en la superficie del cristal (color ocluido). Solamente el color superficial es removido por el lavado en las centrífugas. Este estudio considera los efectos del tiempo de lavado en la reducción de color y la pérdida por disolución de cristales en las centrífugas de batch y el análisis de color incluido y ocluido para diferentes condiciones de proceso tales como purezas variables en magma C y B, uso de diferentes floculantes catiónicos y el uso de diferentes tiempos de lavado en las centrífugas de cinco ingenios centroamericanos. Se estudiaron las ecuaciones experimentales para la pérdida de cristales contra tiempo de lavado en tres de los ingenios. Los resultados muestran el impacto del uso de los floculantes catiónicos, la clarificación de meladura y el mejoramiento de la pureza de las templas para las cinco fábricas. Cuando las mejores prácticas se adoptan, pueden obtenerse colores de cristal de 85 a 135 ICUMSA; sin embargo, pueden esperarse pérdidas de cristal de al menos 15% cuando se emplean tiempos de lavado mayores a 20 s con agua a 480 kPag y 85°C a 95°C.
PROGRESS IN IMPROVING LABORATORY EFFICIENCIES USING NEAR INFRARED SPECTROSCOPY (NIRS)

By

R. SIMPSON and Y. NAIDOO

Sugar Milling Research Institute,

KEYWORDS: NIRS, Molasses, Massecuites, Syrup, Clear Juice.

Abstract

The laboratories of the Sugar Milling Research Institute have the responsibility of maintaining and improving the standards of analytical work within the SMRI and throughout the Southern African sugar industry. Based on development work conducted by the SMRI, the use of NIR spectroscopy has been approved for the analysis of C molasses for both factory control and cane payment purposes and has resulted in considerable savings in analytical costs. Development work is ongoing and samples of clear juice, syrup, B, C massecuite and A, B molasses have been analysed by traditional methods for sucrose, pol and brix, and the results used to develop NIRS calibrations for rapid multi-component analysis. The precision of the NIRS predictions appears to be excellent, comparable to the laboratory method tolerances, and it is suggested that this technology can be used by relatively unskilled personnel in a factory environment to produce reliable data at relatively low cost.

Introduction

The major sugar companies of South Africa have been expanding their operations in the Southern African sugar industry. The laboratories of the Sugar Milling Research Institute (SMRI) provide analytical services to the region and, with increased demand, it has been appropriate to develop near infrared spectroscopy (NIRS) methods for the rapid multi-component analysis of intermediate factory products.

Much of the earlier work at the SMRI was reported by Schäffler and De Gaye (1997) and Schäffler (2005) and was based on work initiated at CSM Suiker (de Bruijn, 1997).

A Foss NIR Systems 5000 spectrometer was used to acquire spectra but was prone to bias jumps and required adjustment, updating the calibration dataset and standardisation as the instrument was aging.

In the 2007–2008 season, the SMRI purchased a Bruker Near Infra-red Spectrometer and interfaced this with a Metrohm 838 auto sampler. No calibration modification was required when a major component such as a source lamp was replaced unlike previous experiences by Schäffler (2000).

Calibrations were developed for molasses and mixed juice and the comparison with earlier work was reported by Simpson and Oxley (2008). The NIRS analysis of molasses has subsequently been adopted for cane payment purposes by the South African sugar industry.

The implementation of NIRS analysis for molasses at the SMRI has resulted in major time and cost savings.

This coupled with the desire to provide analysis for factory control purposes performed by relatively unskilled laboratory staff has extended the scope of calibration development to include additional intermediate products and this work is the subject of this paper.
Experimental

Instrumental: Near Infra Red Spectrometer (NIRS)

The NIRS system is comprised of a Bruker Multi-purpose Analyser (MPA) fitted with a Metrohm 838 autosampler. No temperature control unit was attached to the MPA. However, the NIRS laboratory was maintained at 20°C by air-conditioning at all times.

All spectra were obtained in absorbance mode in the scanning range 800 to 2500 nm using a Hellma flow-through sample cell with a path length of 1 mm. The NIRS software used for spectral processing and calibration creation was OPUS Version 6.

This included Opus Lab, which provided a simple interface with mouse-click operations for controlling automated NIRS analysis. This interface was used throughout for sample analysis.

Samples

The 2008–2009 season weekly composite samples of clear juice, syrup, B, C massecuite and A, B molasses were sent to the SMRI from five different geographically located Southern African sugar factories viz. Malalane (ML), Felixton (FX), Noodsberg (NB), Nakambala (NK), Umzimkulu (UK). These samples were analysed for sucrose, pol (lead clarified) and brix.

Handling of clear juice and syrup samples

Weekly factory composites of clear juice and syrup samples submitted to the SMRI were analysed by NIRS. Syrup samples were diluted at 50 grams to 200 grams of which 150 grams was lead clarified for pol and the remaining 50 grams was filtered for brix. A 5 gram portion of syrup was diluted to 30 grams and analysed by gas chromatography (GC) for sucrose.

In addition, an unfiltered portion of the clear juice composite was submitted to the NIRS laboratory. Syrup samples were diluted at 20 g to 100 cm$^3$ for NIRS analyses. Each sample was analysed in triplicate and a NIRS spectrum for each obtained using Opus Lab. The predicted results from the three spectra were averaged to give the final predicted NIRS results.

All laboratory results were generated using the Official Methods (Anon, 1985 and 2005). Pol was measured on the Schmidt & Haensch Universal Polartronic using the wavelength 589 nm and lead clarification (Anon., 2005: Method 1.7). Brix was measured by refractometry. Sucrose was determined by gas chromatography (silylation-only) method (Anon., 2005: Method 1.9).

Handling of B, C massecuite and A, B molasses

Weekly composite samples of B, C massecuite and A, B molasses samples submitted to the SMRI were manually homogenised and sub-sampled. A single sub-sample was used for all test methods and the NIRS sample preparation. The samples were clarified and filtered for pol and brix analyses (Anon., 1985).

The massecuite and molasses samples were diluted and tested for fructose, glucose and sucrose by high performance anion exchange chromatography (Anon., 2005: Method 6.6). B massecuite was diluted at 14.5 grams to 100 cm$^3$ and C massecuite was diluted at 14 grams to 100 cm$^3$.

Each prepared sample was analysed in triplicate and a NIRS spectrum was obtained for each. The predicted results from the three spectra were averaged to give the final predicted NIRS results.

A quality control procedure was set up using three molasses samples of established composition with each batch of samples tested.

These were used to monitor the NIRS performance on a weekly basis. All laboratory results were generated using SASTA approved test methods (Anon., 2005). Polartronic measurements were made using the wavelength 589 nm and lead clarification (Anon., 2005: Method 6.1).

Brix was measured by refractometry in all cases (Anon., 2005: Method 6.1). Sucrose was determined by high performance anion exchange chromatography (Anon., 2005: Method 6.6).
Calibrations

Calibrations for C molasses were done with Bruker’s *OPUS QUANT* Software. This software uses multivariate data analysis to combine a large amount of spectral information with the corresponding reference values. Partial least squares (PLS) regressions were used to draw up the calibrations.

A calibration model was built using 50% calibration samples and 50% of the test samples were used to validate the model. Where the number of samples was less than 300, the method of cross validation was used to develop the equations. Spectra were added to the initial calibrations during the course of the season to make the models more robust.

Results and discussion

The cross validation results for clear juice, syrup, B, C massecuite and A, B molasses, presented in Tables 2 to 7 (Appendix A) show the correlation between laboratory and NIRS results for pol, brix and sucrose.

The prediction data are summarised in Table 1. The data from Tables 2 to 7 are presented graphically for sucrose in Figures 1 to 6, and the regression lines, slopes and 95% certainty limits for the respective analyses are given.

The results for sucrose were chosen to illustrate data as NIR prediction results for HPLC and GC analytical techniques are often not easy to reproduce with the required accuracy for payment purposes. The prediction data for clear juice gave excellent precision results as all three analyses produced a SEP of better than 0.08 units.

Excellent precision results were achieved for syrup pol and brix (SEP of 0.14 and 0.11, respectively). The RSQ of 0.995 for sucrose was most acceptable. Most products showed good overall predictions (SEP 0.02 to 0.45).

The tables in Appendix B illustrate excellent slope, bias and correlation coefficient squared (RSQ) statistics for the three components.

RSQ results were most acceptable (0.91 to 1.00). Comparing the standard error of prediction (SEP) to the precision of the laboratory method is a measure of the NIRS predictive capability and in all cases was found to be adequate for factory control purposes.

Future work
- Develop fructose and glucose calibrations for all intermediate factory products.
- Improve the A massecuite sample preparation to develop better correlations.
- Install the NIRS at a mill laboratory with the SMRI universal calibration. This equation would need to be adjusted for local conditions to avoid any bias and maintain the 95% confidence limits with weekly quality control checks. These checks would be based on samples with the conventionally established composition.
- Develop a proposal for implementing the NIRS in a factory laboratory for assessment on the economic impact and the potential for online use. Investigate a ‘master-slave’ relationship between the SMRI and the mills as an option to maintain and update calibrations.

Conclusions
The implementation of routine mixed juice and molasses analysis by NIRS is expected to reduce the time spent by the SMRI laboratory analysts by 80 percent i.e. from 128 hours per week to 24 hours per week and has already been implemented for final molasses at the SMRI. However, factory process managers will also benefit immensely from reliable data produced in a fraction of the time taken for conventional analysis. This work shows that calibrations can be developed for a number of intermediate factory products. The maintenance of the calibrations would require technically competent individuals but routine analysis could be done by relatively unskilled personnel. Due to the geographical location of the mill laboratories, the transportation of samples, particularly those that deteriorate is problematic and expensive. Provided that the mill laboratory has a NIR spectrophotometer, samples could be scanned and spectra sent to the SMRI for interpretation of the results, if technically competent staff are not initially available.

Results would then be returned to the mill laboratory via the internet. With the development of sucrose calibrations, factories could convert from pol to sucrose based performance/payment calculations without costly and complex GC or HPAEC analytical requirements. It would also allow benchmarking based on sucrose for the entire region and not only the South African mills.

Acknowledgements
Thanks are due to the SMRI analytical staff and their efforts in sample co-ordination, scanning, and simultaneous data collection. The continued support and assistance of Bruker South Africa, in calibration management and improvement, is gratefully acknowledged.

MOTS-CLEFS: NIRS, Mélasse, Massecuites, Sirop, Jus Clarifié.

Résumé
Les laboratoires du Sugar Milling Research Institute ont la responsabilité de maintenir et améliorer les normes du travail analytique au sein du SMRI et dans les industries sucrières du sud de l’Afrique. Un travail de développement mené par le SMRI a permis l'utilisation du NIRS pour l'analyse de la mélasse C pour le contrôle en usine et pour le paiement de la canne; ceci a donné des économies considérables dans les coûts d'analyse. Le travail de développement continu; des échantillons de jus clarifié, sirop, massecuites B et C, et mélasses A et B ont été analysés par les méthodes traditionnelles pour déterminer le saccharose, le pol et le Brix; les résultats ont été utilisés pour développer des étalonnages pour le NIRS, donnant ainsi des analyses multiples rapidement. La précision des résultats du NIRS semble être excellente; elle est comparable à la précision des méthodes conventionnelles de laboratoire. On suggère que cette technologie peut servir pour un personnel relativement non qualifié dans un environnement d’usine, pour produire des résultats fiables à coût relativement faible.
PROGRESOS EN EL MEJORAMIENTO DE LAS EFICIENCIAS DE LABORATORIO CON EL USO DE ESPECTROSCOPÍA DE INFRAROJO CERCANO (NIRS)

PALABRAS CLAVE: NIRS, Mieles, Masas Cocidas, Meladura, Jugo Clarificado.

Resumen

LOS LABORATORIOS del SMRI (Sugar Milling Research Institute) tienen la responsabilidad de mantener y mejorar los estándares del trabajo analítico dentro del Instituto y en toda la industria azucarera sudafricana. Con base en trabajo de desarrollo dirigido por el SMRI, el uso de espectroscopía NIR ha sido aprobado para el análisis de mieles C tanto para control fabril como para fines de pago de caña y ha generado considerables ahorros en costos de análisis. El trabajo continúa y muestras de jugo clarificado, meladura, masas B, C, y mieles A y B se han analizado con métodos tradicionales para sacarosa, pol y brix y los resultados se usaron para generar calibraciones de NIRS para análisis rápido multi-componente. La precisión de las predicciones del NIRS fue excelente, comparable a las tolerancias del método de laboratorio y sugirió que esta tecnología puede ser usada por personal relativamente inexperto en un ambiente fabril para producir datos confiables a un costo relativamente bajo.
NEW IDEAS FOR IMPROVING EFFICIENCY IN THE PACKAGING AREA

By

J.A. URRUTIA and J.A. DIAZ
Polatecnia SA de CV

KEYWORDS: Packaging Area, Overs Screening, Overs and Fines Screening, Overs Milling, Conveying of Sugars.

Abstract
LOOKING for more efficiency in the packaging area where the final product is handled, the performance of different machines for screening was studied, conveying the final product and also the milling of the overs separated by screening. In making the study of these unit operations, information was collected in different sugar mills and the different alternatives for screening the sugar were compared. A higher efficiency was achieved by using a gyratory reciprocating screener and losses of between 1 and 3% of the on-spec sugar were avoided when compared with the performance of other technologies for this operation. The possibility of milling the overs obtained in the screening process was also studied and compared with the traditional dissolution of this material. A milling test was conducted using plantation and refined sugar and 10–20% of the sugar that would normally dissolve and goes to molasses was recovered. Finally, some results obtained in conveying using vibrating conveyors as opposed to screw conveyors are discussed. It was found that recoveries of sugar between 0.5–3.0% were obtained with vibratory conveyors, as opposed to belt conveyors. In the case of screw conveyors, degradation in the order of 1–3% of the size was found. It is concluded that there is an opportunity for the technologist to recover more sugar in this area using the most efficient technology.

Introduction
For many reasons related to the constant increase in capacity of the sugar mills in the Mexican sugar industry and in other countries, the factories have shown a preference to make investments to lower energy consumption and in process equipment like centrifugals, crystallisers, vacuum pans, etc.

This situation has postponed for years projects in the sugar packaging area, and only in the last decade with the increased requirements of the customer concerning the final product and the reprocessing of sugar has the packaging area been looked at (Urrutia, 2000; Mathlouthi and Roge, 2004; Hartmut and Burkhards, 2008; Reichling, 2008).

To improve the particle size distribution it is necessary to reduce the overs and fines in the sugar especially the fines that can cause hardening (Lu et al., 1977). An efficient screener with gyratory-straight line motion offers a more efficient separation and low maintenance cost system for the sugar industry (Bergerhoff, 2006; Thouvard, 2006).

In analysing this situation, the packaging area of the plant could be a real opportunity to improve the plant efficiency.

Materials and methods
Screening of overs
Samples were taken in different sugar mills where various technologies were being used to screen the sugar before packaging. The machines being used were as follows:
• A static screen positioned at the end of the drum dryer.
• A high slope vibratory machine positioned at the dryer discharge.
• Other vibratory machines that were circular, flat or rectangular with an angle of 30° to the horizontal and positioned at the dryer discharge.
• Machines with gyratory motion at the feed end and straight-line motion at the discharge end with a little slope and low frequency motion and positioned at the dryer discharge.

In all cases, three samples were taken at the overs outlet during an hour of stable operation and then composited. The composite was then subdivided into three portions and analysed using a laboratory sieve machine and a 10 mesh (1.7 mm) screen.

**Screening of overs and fines**

Samples were taken in the non-screened inlet and the product outlet at Ingenio Tres Valles and Ingenio El Potrero where high efficiency screeners are used on the dryer outlet to eliminate the overs (>20 mesh, 0.85 mm) and fines (<80 mesh, 0.18 mm). In both cases, the machines have gyratory motion at the feed inlet and straight-line motion at the discharge end with a little slope and low frequency motion.

**Milling of overs**

During these tests, samples were collected at the overs outlet screener in two sugar mills where one mill produces refined sugar and the other plantation sugar. In both cases, the machines use gyratory motion at the feed inlet and straight-line motion at the discharge end with a little slope and low frequency motion.

A milling test was conducted with a Pin Mill model Simpactor 3B equipped with an 11 kW motor and operated at 1000 r/min for refined sugar and 2000 r/min for the plantation sugar samples.

**Sugar conveying**

**Belt conveyor**

In this case, data were collected from three factories by weighing the amount of sugar collected from the floor that had been spilt by the conveyors.

**Screw and vibratory conveyors**

Sugar samples were collected at two sugar mills from the inlet and exit of a 10 m long screw conveyor. Samples collected every 10 minutes for one hour were composited and sub-sampled. The samples were then sieved through a 70 mesh (0.212 mm) sieve. Similar samples were collected from 10 m vibratory conveyors at two other sugar mills.

**Results and discussion**

**Screening to separate the overs**

In the case of the screening to eliminate the overs, we collected the sugar retained in 10 mesh screen in several different sugar factories that used different screeners and we measured the fraction passing at 10 mesh screen that represents on-spec sugar that was retained or lost with the overs. Results of the sieve analyses for the three different machine types are shown in Table 1. The data are the proportion of on-spec sugar removed with the overs portion in relation to the total screened sugar.

The gyratory reciprocating motion screener shown in Figure 1 is commonly used in the USA sugar industry, and in Mexico they are used in 25 sugar mills and in eight factories in Colombia and three factories in Peru.

Fig. 1—Gyratory reciprocating motion screener.

**Screening to separate overs and fines**

Table 3 shows the data of the screening of the sugar from two sugar mills that produce refined sugar using a gyratory reciprocating screener. The data represent the percentage of sugar in each size fraction. The efficiency of the screener allows the mills to output sugar containing overs and fines of about 2% only.

In both cases the final product is ready to:

- Fulfil the requirements of the companies that produce mixtures with flour of similar size for making bread, cereals, cookies and need sugar with a little overs and fines.
- Supply this sugar to any market with little risk of lumping during storage and transportation.

Ingenio Tres Valles did not receive any claim for lumps during the last campaign, because the sugar met every test with temperature between 32 and 35°C and with a very low content of fines. In the 2007–2008 crop a plate cooler was used without a screen and they received few claims (Urrutia et al., 2008), and finally in the last crop the product was sent to many places through an agreement with Cargill.

Reichling (2008) established that, when sugar with low fines content is packaged at temperatures near the storage environment, no lumping will occur during storage and transportation.

The results in the elimination of overs shown in Table 1 indicate that the machine with the gyratory motion at the feed end and straight-line motion at the discharge end is more efficient at maximising the compliance level than the other screener tested. Since these results were obtained in the easier application, it did not justify making a test using the other screeners for the more difficult and expensive application to eliminate both the overs and fines.

**Handling the overs of the sugar**

Taking into account that by using a high efficiency screener, the separation of the overs without any on-spec sugar is guaranteed, then options to handle the overs can be evaluated. Normally almost all the sugar mills dissolve the overs obtained by screening of the product. It is common in the industry to dissolve the overs in several places of the factory depending on whether it is refined or plantation sugar being produced and the criteria of management. The effective sugar loss depends on where in the process the sugar is dissolved and can be between 10–20%. A 10% loss is a reasonable assumption for this discussion.

In any calculation, a loss of 10% of overs is an area of opportunity since this represents about 1% of the sugar and the loss of 0.1% of the sugar produced.

A second option is to mill the overs to produce a sugar with a similar size to the product sugar. A pin mill made in mild steel and equipped with a 11 kW motor was investigated for this option (see Figure 2).

![Fig. 2—Pin Mill model Simpactor 3B with 11 kW motor.](image-url)
**Refined sugar**

A sample of overs separated in a high efficiency screener was obtained from Ingenio Tres Valles and processed through the milling machine. The sieve data for both the sample of overs collected and the sample after milling are given in Table 4. The milled material had a very good particle size distribution with 66.7% in the size fractions between –16 mesh and +80 mesh.

</tbody>
</table>

**Handling the milled sugar**

In view of the results obtained through milling, it is worthwhile considering options to use the milled sugar. These options include:

1. Given that the overs are only 1% of the total sugar produced the best way to handle the milled sugar is to mix all the milled sugar with the screened on-spec sugar. The new overs and fines represent only a very small proportion of the total product.
2. The milled sugar could be sent to the inlet of the screener and, in this way, remaining overs will be separated and the milled sugar and the fines will pass with the on-spec sugar.
3. Send the milled sugar to a separate bin based on its quality. The technologist can mix the sugar according to the product specification required at the time.
Table 6 shows the increase in colour when 1% of milled sugar is mixed with 99% of on-spec sugar. The increase is within the error range of the method.

However, there are at least another two ways to utilise this material to allow the sugar technologist to select the most appropriate choice according to the particular conditions.

<table>

<td>+1.13</td>
</tr>
<tr>
<td>Plantation</td>
<td>600</td>
<td>500</td>
<td>1335</td>
<td>+8.35</td>
</tr>
</tbody>
</table>

In an exercise to examine financial implications of milling the overs fraction, the only consideration was the loss related to the dissolution of the sugar and not other costs such as water consumption or additional energy used.

The investment recovery time of this project is very fast as is seen in Table 7. In the worst case for a sugar mill that produces about 20 t/h, less than one crop is needed to pay for the machine, using a very conservative estimate of the loss of sugar by dissolution.

This is a real opportunity area to improve the efficiency in the packaging area with only a minimal investment.

</table>

Note: 1% of overs in the sugar, 10% loss of sucrose by dissolution, price of sugar is USD500/t, and price of the mill is USD30 000 FOB for a sugar mill in the zone of Cordova, Veracruz, Mexico.

Sugar conveying

For this test, three types of conveyors (screw, belt and vibratory) of a similar 10 m length were tested. Since this is the final step in the product handling system, careful handling is required.

With belt conveyors it is possible to lose a substantial portion of the sugar to the floor. Tests showed losses of up to 1 t per 8 h in sugar mills producing 1000 t/day of sugar.

This loss represents 0.3% of production. In other mills, losses of up to 0.6% were measured.

Closed conveyors like screw or vibratory conveyors do not experience this magnitude of loss. A saving of up to 500 kg for each 1000 t of sugar is possible and represents USD45 000 in one crop.

In looking at the problem, an exercise was undertaken under the assumption that only 0.1% of sugar is lost using belt conveyors.

Table 8 shows that if vibratory conveyors are used to replace belt conveyors, the investment is recovered in less than one crop, and in the future years no financial losses will be realised.
Table 8—The cost of 0.1% losses using belt conveyors.

Screw and vibratory conveyors

Screw and vibratory conveyors are closed conveyors that usually do not create any loss by spillage. An example of a vibratory conveyor is shown in Figure 3.

Fig. 3—Example of a vibratory conveyor.

Tests were conducted on two screw conveyors and two vibratory conveyors to assess whether either type of conveyor could cause crystal damage and increase the fines content in the sugar. The results in Figure 4 show that both screw conveyors that were tested caused crystal damage while the vibratory conveyors caused no damage.

Fig. 4—Creation of fines during sugar conveying in screw and vibratory conveyors.
In this case the disadvantage is not related with a loss of sugar, but the lower quality sugar through the particle size characteristics of the product because the sugar conveyed by screw has an increased quantity of fines.

Conclusions

There are new opportunities for improving the efficiency in the packaging area that include:

- Using gyratory reciprocating screeners, 70 t of on-spec sugar can be recovered if a vibratory screener is used or 100 t of sugar if a fixed screen is replaced. The cost of the investment would be recovered in less than one crop.
- Compliant sugar with good grain size and low fines becomes available to send to any place without the risk of lumping when high efficiency screeners are used to eliminate overs and fines.
- The milling of overs instead of dissolution is a project with a fast recovery time. In the worst case for a sugar mill that produces about 20 t/h, the recovery time is less than 18 weeks. This is a real opportunity area to improve the efficiency in the packaging area with only a small investment.
- Using vibratory conveyors, it is possible to eliminate losses of 0.1% that represent a loss of 80–400 t of sugar per crop compared with belt conveyors because the vibratory conveyor does not produce fines during the conveying of sugar. If existing screw conveyors that can generate up to 3% fines are replaced, then the benefit is much more significant.

NUEVAS IDEAS PARA EL MEJORAMIENTO DE LA EFICIENCIA EN EL ÁREA DE EMPAQUE.

Por
J.A. URRUTIA y J.A. DIAZ
Polatecnia SA de CV
aurrutia@polakgrupo.com

PALABRAS CLAVE: Área de Empaque, Tamizado de Azúcar, Molienda de Retenidos, Transporte de Azúcar.

Resumen
En la búsqueda de mejores eficiencias en el área de empaque, donde se maneja el producto final, se estudió el desempeño de diferentes equipos de tamizado, de transporte de producto final y de molienda de los materiales retenidos en los tamices. Para el estudio de estas operaciones unitarias, se reunió información de varios ingenios y se compararon diferentes alternativas para tamizado de azúcar. La mayor eficiencia se obtuvo con el uso de un tamiz giratorio y reciprocatante, eliminando entre 1 y 3% de las pérdidas de azúcar dentro de especificaciones comparado con el desempeño de otras tecnologías para esta operación. Se estudió la posibilidad de moler el material retenido en el proceso de tamizado y se comparó con la disolución tradicional de este material. Se efectuó una prueba de molienda con azúcar blanco y refinado y se recuperó un 10–20% del azúcar que normalmente se disuelve y va a las mieles. Finalmente, se discuten algunos de los resultados obtenidos en el transporte de azúcar usando conductores vibratorios en lugar de transportadores de tornillo. Se encontró que se recuperó entre 0,5–3,0% del azúcar cuando se usaron conductores vibratorios en lugar de conductores de banda. En el caso de los transportadores de tornillo, se encontró una degradación de tamaño de cristal del orden de 1–3%. Se concluye que hay una oportunidad de recuperar más azúcar en esta área usando tecnología más eficiente.
ON-LINE MONITORING OF FACTORY PROCESSES

Morgenroth@ipro-bs.de

Abstract

THE KNOWLEDGE of mass and energy flows in a cane sugar factory is a crucial aspect in order to enhance the plant performance and detect process deficiencies. The development of the Advanced Monitoring System (AMS) based on the Sugars software allows nowadays visualising the sugar process by connecting the software to the process and laboratory information system. The AMS was first introduced in 2004 to the sugar industry. Experience gained over the last few years is reported in this paper. Besides the creation of the mass and energy balance, the system can be used for data reconciliation with special regard to measured flows, temperatures and pressures as well as laboratory analytical data. Calculated and measured data are compared to facilitate improvements to process performance and reliability. The AMS requires approximately 100–150 data points (cane mass flow, analytical data, pressures and temperatures) to characterise and display the actual process operations with high accuracy. The AMS is a process monitoring tool allowing the sugar engineer to validate the operation and performance of the process. By defining benchmark values (key performance indices), it is possible to monitor and subsequently improve the performance of process equipment and the processes.

Introduction

The Advanced Monitoring System (AMS) is a software package which was specifically developed for the sugar industry (Morgenroth and Pfau, 2004). The AMS package consists of the Microsoft® Visio® program and the Sugars™ program combined with a data exchange add-on that allows the importing and exporting of various types of process information.

Microsoft Visio is used for the graphical and operating data display of the sugar processing stations, for example, extraction, purification, evaporation and crystallisation.

The Microsoft Visio program is linked with the Sugars program to calculate mass flows, temperatures, purities, etc. Approximately 100–150 data points from the laboratory and process control system (e.g. dry substances, purities, temperatures, pressures and flows) are imported via an Extensible Markup Language (XML) file.

The XML file is created on demand by the Management Execution System (MES) of the factory and subsequently imported to the AMS. Following the import of data, the AMS calculates a closed mass and energy balance of the factory.

It is possible to do balances for daily, weekly or monthly production overviews. The AMS helps process engineers and operators to analyse the operation and performance of each processing station as well as the entire factory.
Applicability

The AMS is flexible regarding the type of factory to be analysed because it uses individual station modules that can be arranged to suit the process being simulated. Typical applications are cane sugar factories, beet sugar factories and sugar refineries. The distillery process can also be displayed with regard to simulated mass balances. Some parameters that are usually fixed (like heating surface areas) can either be integrated as constants into the model, or imported in accordance with the requirements. For example, the area of active heating surface could be imported.

Figure 1 shows an open model property window for a heat exchanger. The outlet temperature and the operating heating surface are imported into the model by the AMS from the MES database. As a result, the calculated heat transfer coefficient (k-value) is shown in correlation to the optimum k-value.

Fig. 1—Heat exchanger with open model property window.

Description of on-line monitoring performance steps

Approximately 100–150 measured analytical, temperature, pressure and flow data values from the sugar process of the factory are required in order to perform a consistently balanced model of the complete sugar manufacturing process. It is important that the quality of imported or measured process variables and analytical data is high, meaning sensors need to be checked regularly for accuracy and process samples need to be treated in accordance with modern laboratory routines and analytical methods. In some countries, gravimetric brix measurements are still common and they cannot be used as a basis for the mass and energy balances. In such cases, the laboratory needs to switch to internationally recognised analytical methods.

A MES integrating the process control and the laboratory system provides the basis for data handling and transfer. The appropriate monitoring intervals need to be determined and this aspect is managed in the MES as the availability of different data types can vary. While process variables such as flows, pressures and temperatures are usually available instantly, averaged values can be easily created.

Analytical data are more difficult to collect as this information is usually not provided online, but instead by the laboratory once each analysis has been completed. The measurement intervals depend on the importance of the measured values for general factory control as well as the available man power and laboratory policy. Time intervals for analytical data usually vary between two hours and one week.
The task of the MES is to gather all the required data on demand for a selected time frame. The MES creates an XML data file that is subsequently imported to the AMS and processed in order to calculate a mass and energy balance. In the case where no analytical data have been measured within the selected time frame, it is necessary to decide if typical values will be used for the calculations or if the last available data should be used. The last available data are usually used in such cases.

To achieve a highly accurate mass and energy balance of the sugar process, a relatively constant operation of the factory is required. This is usually not a problem in modern beet sugar factories or refineries, but stoppages are much more common in cane sugar factories. Therefore, it is required to choose a time interval that is long enough to gather adequate data, but short enough to exclude longer stops or low capacity periods. Short stops of less than 20 minutes and flow fluctuations do not impact on the mass and energy balances if calculated averages of process variables are used to smooth out short term variations.

Typically once a day, fresh data from the previous day are imported and then used for the process display and analysis.

Other data like heating surfaces can be fixed in the model but also can be imported to reflect actual heating surfaces in use for cases where individual heaters or evaporators are taken off-line for cleaning or complete evaporation trains are stopped, e.g. for cleaning.

Other available process data (especially flows) not required for the mass and energy balance itself can be imported to verify the calculated data. For example, usually only the cane processing rate is imported as a mass flow measured by a weighing scale to the program. All other flows are calculated in order not to rely on data such as volumetric flow measurements. The AMS helps to compare calculated and measured data and allows data reconciliation. Experiences have shown that often more than 50% of the process flow measurements as well as many temperature and pressure sensors are in error. The reasons for these errors are typically scaling on probes and instrument sensors and incorrect installation of instruments. By comparing the AMS results with process data from instruments and sensors, significant variations can trigger the need for recalibration.

The AMS model also can be used to examine different operating scenarios and the impact of these changes to the process. For example, the impact of using different process values on the steam demand can be easily examined by shifting the vapour extraction to a different effect. Also, a colour balance can be performed by the program. This feature can be used to predict the final sugar colour or it can be used to model different operating scenarios.

The detailed view of the process and its performance allows quick detection of weak points like underperforming equipment or process units as well as inaccurate process values. This allows correction or adjustments to the operation of the process to achieve improved processing results. By on-line access of the XML data exchange file, the monitoring of processes can be done over the internet at any time.

Examples

The following examples are provided to give an understanding of how the AMS works. Selected examples are displayed here for processing stations (and single processes). Table 1 details the legend for the subsequently displayed figures. Figure 2 shows a five effect evaporation station operating with falling film plate evaporators in a cane sugar factory. Similar evaporation set ups are already employed in a couple of cane sugar factories. Clarified juice enters the 1st effect with a brix of 13.6 and a temperature of 116°C and leaves the evaporation station with a brix of 65 and 97.2°C.

The properties of the clarified juice including purity, brix and mass flow (black values) are calculated by the simulation model. The violet values show the measured values imported from the laboratory and process for comparison purposes.
It is possible to compare the measured values (temperatures, brix, mass flows) with the calculated values (black). Normally the difference between the calculated and measured values should not be more than 1–3%. This comparison enables the process or instrument engineer to check for defective flow meters or temperature transmitters. The green values are imported values from the process and the laboratory.

In the example shown in Figure 2, the vapour pressures and operating heating surfaces for each effect and the syrup brix are necessary to do the mass and energy balance and display selected values of the evaporation station. As a further feature of the AMS, key performance indices (KPI) are shown (brown values). For the evaporation station, effective temperature differences and k-values for each effect are calculated. These KPIs enable the process engineer to check the performance of the evaporators and to determine the amount or severity of fouling. The actual k-values calculated from the measured process variables can be compared with theoretical benchmark values and the resulting actual/optimum ratio is displayed (as a percentage). This KPI can be used to trigger the cleaning process.

Figure 3 shows the performance of an A centrifugal station in a cane sugar factory. The input values for purity, temperature and mass flow of A massecuite to the centrifugals are calculated by the AMS (black values). Analytical data including purities and dry substances for the A Molasses and A Sugar are imported to the simulation model (green values) from the MES. The
A simulation model calculates the flows for A Sugar, A Molasses and the wash water amount to the centrifugals. These calculated values can be compared with measured values (violet) from the process and differences like the wash water amount in the example can be detected. The wash water amount to the centrifugals (5.8% on massecuite) and the crystal losses (20.0%) are calculated to provide KPIs and give the process engineer in the factory the ability to easily and quickly check the performance of installed equipment. Large crystal losses without an increase in wash water can indicate the need to change the centrifugal screens.

**Fig. 3—Simulation of an A centrifugal station.**

Figure 4 shows the power station of a cane sugar factory.

**Fig. 4—Power station simulation.**
In Figure 4, two 9 MW backpressure turbo generators and a 92 bar (abs), 520°C, 100 t/h boiler are shown. Only seven import values are necessary to simulate this power station (green values). The simulation provides data on the mass flows and properties of live steam from the boiler, exhaust steam to process, steam to turbo generators or feed water amount.

The KPIs for this example are shown for the specific steam consumption and the different isentropic efficiencies of the turbo generators. Figure 4 shows turbo generator 1 is operating at a lower performance compared to turbo generator 2 (based on isentropic efficiency) because it is running only partially loaded. Also, while not displayed, the live steam demand on cane could be easily calculated as an additional KPI.

In the case where a distillery is attached to the factory, the mass balance of the distillery process can be simulated and displayed (Figure 5) to show the amount of ethanol produced in addition to mass balances of sugar and power for the entire factory.

**Conclusions**

The installation of AMS in a cane or beet sugar factory or in a sugar refinery offers the possibility to monitor processes closely and provide instant performance data on demand. It is possible to obtain a lot of KPIs for different equipment like centrifugals, heat exchangers, evaporators, turbo generators, etc. The operators or the process engineers are able to visualise the real process in the adapted simulation model for daily, weekly or monthly imported data. The AMS has been operating since 2005 in three cane sugar factories in Brazil and assists the management in analysing and optimising the performance and operation of processing stations and the entire factory.

**Acknowledgements**

The authors would like to thank the management and employees of the Zilor company, Brazil for entrusting the installation of the AMS in their factories and the excellent partnership that was the basis for the successful application of the system.

Résumé

LA CONNAISSANCE des débits de masse et de l'énergie dans une usine à sucre est un aspect crucial afin d'améliorer les performances et de détecter les anomalies du processus. Le développement de l'Advanced Monitoring System (AMS) basé sur le logiciel Sugars permet la visualisation du processus, en connectant les systèmes d'information du processus et du laboratoire. L'AMS a été introduit en 2004 dans l'industrie sucrière. L'expérience acquise au cours des quelques dernières années est décrite dans ce document. Le système permet la création de bilans massique et énergétique et peut être utilisé pour le rapprochement de données basées sur des débits mesurées, des températures et des pressions ainsi que les données d'analyse de laboratoire. Les données calculées et mesurées sont comparées pour faciliter les améliorations des performances et la fiabilité. L'AMS nécessite environ 100–150 points de données (débit massique de canne à sucre, données analytiques, pressions et températures) pour caractériser et afficher les opérations de processus réel avec une grande précision. L'AMS est un outil permettant à l'ingénieur de valider le fonctionnement et les performances du processus. En définissant les valeurs de référence (indices de performance clés), il est possible de surveiller et d'améliorer les performances des équipements et des processus.

Resumen
El conocimiento de los flujos de masa y energía en un ingenio es crucial para mejorar el desempeño y detectar deficiencias de proceso. El desarrollo del Advanced Monitoring System (AMS), basado en el programa Sugars, permite actualmente la visualización de los procesos por medio de la conexión del software al sistema de información de proceso y laboratorio. El AMS se introdujo en el 2004 a la industria azucarera. En este trabajo se reporta la experiencia ganada durante este corto período. Además de la creación del balance de masa y energía, el sistema puede ser usado para reconciliación de datos, con especial interés en las mediciones de flujos, temperaturas y presiones así como en los datos analíticos de laboratorio. Se comparan los datos calculados y los medidos para facilitar mejoramientos al desempeño de los procesos y a la confiabilidad. El AMS requiere aproximadamente 100–150 datos (flujo de caña, datos analíticos, presiones y temperatura) para caracterizar y presentar las operaciones reales de proceso con alta precisión. El AMS es una herramienta de monitoreo que permite al ingeniero validar la operación y desempeño del proceso. Con la definición de valores de benchmarking (indicadores clave de desempeño) es posible monitorear y mejorar en consecuencia el comportamiento del equipo y los procesos.
IMPLEMENTATION OF ON-LINE NEAR INFRARED (NIR) TECHNOLOGIES FOR THE ANALYSIS OF CANE, BAGASSE AND RAW SUGAR IN SUGAR FACTORIES TO IMPROVE PERFORMANCE

Abstract

BSES LIMITED has a long history of developing and commercialising NIR technology for sugar industry applications spanning plant breeding, laboratory and online sugar factory use. This paper traces the development of online NIR systems with FOSS Pacific, for the real-time analysis of cane, bagasse and sugar, describing a range of applications currently applied within sugar factories. The Cane Analysis System (CAS) was developed primarily to measure real-time fibre content of a cane consignment for payment purposes. This enables payment on the overall quality of a consignment rather than making assumptions from average figures. CAS uses a FOSS Direct Light 5000 instrument, with ancillary systems developed for sample presentation, data analysis and integration with mill control systems. Further CAS applications for ash, dry matter, pol and brix in both cane and juice, as well as commercial cane sugar (CCS), were subsequently developed. Data from these calibrations have successfully been used to audit mill laboratories, derive cane quality indices, implement automated control strategies, develop alternative payment systems and provide data on individual farms/blocks, enabling targeted solutions for areas with productivity issues. Based on this platform, online bagasse (BAS) and sugar analysis systems (SAS) were developed. BAS measurements can provide quality-based assessments of bagasse suitable for feed-forward to boiler stations. When linked with a CAS on the same milling train, the effects of mill settings, maceration control and cane quality on pol extraction are determined in real-time, enabling the development of strategies to maximise extraction. SAS calibrations are used to monitor and control critical processes in the production of LoGIcane™, the world’s first low glycemic index sugar which was commercialised and released in Australian in 2009. The development of online NIR measurement systems for sugar factories has seen quality, payment and control strategies established, which are not possible using normal laboratory data. Almost 30 systems have been installed worldwide, and further uses for online NIR data continue to be developed by existing users in conjunction with BSES and FOSS.

Introduction

In recent times, near-infrared (NIR) spectroscopic instrumentation has been developed for the rapid and reliable analytical determination of parameters of interest within petrochemical (Larrechi and Callao, 2003), beverage (Rodriguez-Saona et al., 2001), food (Dodds and Heath, 2001) and pharmaceutical industries (Carlsson and Janne, 1995). Routine NIR analyses have significant advantages over traditional wet chemistry techniques, particularly in terms of labour and consumable costs, throughput, non-destructive sample preparation and analysis, potential generation of real time on-line results and reduced risk where hazardous materials or procedures are involved.
These advantages refer specifically to the analysis itself, whereas further benefits can be obtained from applying the real time data obtained for process control, payment systems and the prediction of multiple constituents from single spectral measurements.

With respect to sugar industry applications, there are well-documented descriptions of at-line NIR spectroscopic techniques used for plant-breeding purposes (Berding et al., 1989; Brotherton and Berding, 1995, 1998). These analyses were primarily performed on shredded or fibrated cane, and were followed by further reports providing data on other substrates derived from sugarcane and various factory streams including molasses and mixed juice (Brotherton and Berding, 1995; Schäffler et al., 1993; Simpson and Oxley, 2008).

The successful plant breeding applications led to an expansion of research activities at BSES Limited, culminating in the development of on-line NIR systems for sugar mill applications. These applications have been developed in conjunction with FOSS as providers of NIR hardware, and have been commercially released as the Cane Analysis System (CAS) and the Sugar Analysis System (SAS). An analogous Bagasse Analysis System (BAS) is currently undergoing development prior to commercial release, although two prototype systems are operational at Mulgrave Central Mill (Cairns, Australia) and the Costa Pinto Mill (Brazil). This paper describes past and recent applications derived from these on-line NIR measurement systems.

Materials and methods

Experimental

Chemicals: Folin-Ciocalteu reagent and (+)-catechin standard were purchased from Sigma-Aldrich (St Louis, MO) with sodium carbonate obtained from Labserv (Melbourne, Australia). All chemicals used were analytical grade.

Polyphenol Analysis: 40 g of raw sugar sample was accurately weighed into a 100 mL volumetric flask. Approximately 40 mL of distilled water was added and the flask agitated until the sugar was fully dissolved after which the solution was made up to final volume with distilled water. The polyphenol analysis was based on the Folin-Ciocalteu method (Singleton and Rossi, 1965) using a protocol adapted from the work of Kim et al. (2003). In brief, a 50 µL aliquot of appropriately diluted raw sugar solution was added to a test tube followed by 650 µL of distilled water. A 50 µL aliquot of Folin-Ciocalteu reagent was added to the mixture and shaken. After 5 minutes, 500 µL of 7% Na₂CO₃ solution was added with mixing. The absorbance at 750 nm was recorded after 90 minutes at room temperature. A standard curve was constructed using standard solutions of catechin (0–250 mg/L). Sample results were expressed as milligrams of catechin equivalent (CE) per 100 g raw sugar.

Analytical results for pol, brix, ash, fibre, moisture were generated using standard methods within the Australian sugar industry (BSES, 1991). Bagasse samples were analysed for lignin content according to the methods published by the US National Renewable Energy Laboratory (2008).

System description

On-line NIR systems were developed based on the NIRSSystems 5000 scanning monochromators with direct light attachment and the InfraSoft International (ISI) chemometrics package. The attached scanning head is sealed against the mill chute for both CAS and BAS installations while, for the SAS configuration, it is mounted above the conveyor belt which transports raw sugar from the dryer. For all configurations, the substrate is scanned through a heat-treated toughened glass window mounted within a stainless steel housing. Vibration dampening systems are installed within both the scanning head unit and the NIR instrument cabinet, which is also fitted with an air-conditioning system and an uninterruptible power supply. The system is integrated with the mill payment and control computers, and software was developed to process relevant mill signals, control scanning equipment and to distribute data to the appropriate mill.
systems. This software also interfaces with mill tracking systems to ensure that individual consignments of cane are recognised, and is capable of registering various errors, alarms and internal checks to provide result integrity.

An important feature of these systems is their setup within a secure networked environment. In this way, online diagnostics, system checks, uploading of new and/or upgraded calibration equations and data storage can be handled by remote operators either over a local/wide area network or via the internet. Methods developed for sampling, analysis, NIR scanning, equation development, equation validation and the evaluation of system performance have been described previously (Staunton et al., 1999).

Cane Analysis System (CAS)

The CAS system has been well described previously and many applications of CAS data have been reported. It was originally envisaged primarily as a means of determining the fibre content of individual consignments of cane supplied to the mill, thereby providing a way of moving away from class fibre systems or payment methods in which cane fibre values were averaged or given assumed values. Upon the development of the system, it became rapidly apparent that the ability to provide real time data provided strong incentives to examine additional options, develop useful calibrations and apply them to gain direct benefit in both the mill and the field.

In particular, CAS data have been used to develop online cane analysis systems for fibre analyses (Staunton et al., 1999), payment purposes (Staunton et al., 2004), cane-quality schemes (Pope et al., 2004), and for process control purposes using fibre rate control (Jones et al., 2002). There are currently 23 CAS installations worldwide supporting these applications within sugar mills.

Sugar Analysis System (SAS)

An earlier report outlined the initial development of the SAS system (Bevin et al., 2002), where an instrument configuration similar to that developed for CAS was used to measure various sugar parameters within sugar mills and at bulk sugar terminals. This report also outlined control charting techniques and comparisons of NIR versus laboratory analyses. For mill applications, the SAS sampling head is mounted over a sugar conveyor belt (Figure 1). The plough shown on the right hand side of the setup has been designed to maintain a particular depth of sugar on the belt as it passes under the scanner from right to left, thereby minimising data scatter and error. A description follows of the development of specific SAS equations for process control and quality monitoring of a low glycemic index (GI) sugar product produced at Mossman Central Mill during the 2008 crushing season.

![Fig. 1—Typical mounting system for the SAS scanning head over a sugar conveyor belt.](image-url)
LoGiCane™ is the world’s first all natural low GI cane sugar product and was developed in Australia by Horizon Science. It was produced on a large scale for the first time during the 2008 season at Mossman Central Mill and was officially launched in March 2009 (Burke, 2009). LoGiCane™ has been independently tested and certified by the Glycemic Index Foundation in Australia with a low GI of 50, whereas white sugar has a medium to high GI of 65.

Low GI foods provide a health benefit by producing gradual increases in blood glucose and insulin levels following consumption, thereby having implications for weight control and diet choice for people with type 1 and type 2 diabetes.

The GI of LoGiCane™ is reduced due to the presence of various natural components of sugarcane, particularly polyphenols and minerals, which have been added back during the production process.

Assays for these components are vital to characterise polyphenol and mineral levels across the production process and within the final product. In conjunction with Horizon Science and Mossman Central Mill, BSES developed an online process control solution for LoGiCane™ production using SAS technology.

The SAS instrument installed not only measures traditional sugar parameters such as pol, moisture, ash, colour and reducing sugars, but also provides data on the concentrations of polyphenols, minerals and a measure of antioxidant capacity.

These critical measurements provide instant process feedback, enabling the development of process control solutions based on the SAS data, as well as systems to ensure product consistency.

Calibration and validation plots for the prediction of total phenolics in sugar are shown in Figures 2 and 3. The calibration results were very good and included spectral results from two separate laboratory instruments.

When applied to the SAS instrument, the validation results contained some bias, scatter and skew; however, the results proved to be adequate for process control and would improve with further development. Importantly, the calibration developed contains no data from the online SAS instrument.

The validation results are demonstrating effective calibration transfer even at this early stage of development. As this development process continues (viz. inclusion of on-line SAS data and instrument variation in the global calibration), significant improvements in equation performance are expected.

N = 162
\]

Fig. 2—Calibration plot for total phenolics in sugar at Mossman Central Mill. Phenolic units are mg catechin equivalents per 100 g sugar.
Bagasse Analysis System (BAS)

The development of BAS instrumentation has been described previously (Staunton and Wardrop, 2006) and the system will be available commercially in the near future. The previous report described in some detail the system development, sampling, analysis and preliminary factory applications for calorific value estimation of bagasse to aid boiler operation as well as the determination of online pol extraction across the milling train where both CAS and BAS installations are present. Here data are presented for online pol extraction from the 2008 crushing season obtained from the two prototype BAS installations at Mulgrave Central Mill (Australia) and Costa Pinto Mill (Brazil), where both milling trains also have CAS installations at the front end. Early developmental work on an online lignin determination on bagasse is also presented.

Online pol extraction

The Mulgrave Central Mill BAS installation is currently in its fifth year of continuous operation, having been installed during the 2005 season. In order to develop a measure for online pol extraction, appropriate calibration equations and software were developed to calculate pol extraction using real time data from the mill tracking systems and the CAS and BAS units and applying the following formula which assumes no loss in fibre (Staunton and Wardrop, 2006).

\[
Polextraction = 100 \times \left(1 - \frac{Pol_b \times Fibre_c}{Fibre_b \times Pol_c}\right)
\]

where: \(c = \text{cane, } b = \text{bagasse.}\)

The 2008 crushing season laboratory validation statistics for a selection of CAS and BAS calibrations are shown in Table 1. The low levels of bias observed and the fact that standard errors of prediction (SEP) are lower than the equation error control limits (ECL) show that the CAS calibrations performed close to or within expectations in terms of analysis accuracy and precision. The BAS validation statistics show relatively poor slope and coefficients of determination due to the relatively high SEPs, combined with restricted ranges in parameter values. This is especially true for pol%bagasse and is due, in part, to the difficulties involved in collecting representative samples of bagasse that span a sufficient range of pol%bagasse values.
Table 1—Calibration equations and validation statistics for Mulgrave Central Mill CAS and BAS installations.

The pol extraction validation results are shown in Figure 4. Both the slope and the correlation coefficient for the linear regression were considered to have utility, especially when considering the relatively small population size, the narrow range of values for the extraction data and the relatively high standard errors of prediction reported for BAS constituents.

Even with these limitations, online pol extraction by NIR represents a significant advance in the monitoring of milling train performance and has the potential to advance the understanding of the key parameters affecting extraction, leading to better process control and more consistent extraction outcomes.

Fig. 4—Validation plot for online pol extraction at Mulgrave Central Mill.

A typical 24 hour trend for calculated online pol extraction is shown in Figure 5. This trend shows that, across this period, relatively constant pol extraction of around 97% was achieved.

However, the graph does show particular examples where extraction has dropped by up to 2–3% before returning to the average extraction value.

These variations are attributed to a step decrease in cane quality (with no or little change in pol%bagasse) and the return of the extraction value back to the average reflects a return to better quality cane in the following consignment.
Currently, Mulgrave Central Mill uses NIR determined prepared cane pol to fibre ratio to determine milling train maceration levels, where the maceration\%cane fibre is varied within a defined operating range depending on the measured quality of incoming cane.

This is an example of a feed forward control system, whereas the application of real time online pol extraction data provides a potential feed forward maceration control system.

In an analogous fashion, online pol extraction predictions were developed and assessed at the Costa Pinto Mill during the 2008 season.

Calibration statistics for the CAS and BAS equations are shown in Table 2. There were a number of significant challenges to overcome in order to replicate the system that had been developed in Australia at Mulgrave Central Mill.

In particular, the equations used on the CAS and BAS systems were initially developed and constructed using Australian methods and data.

As expected, Costa Pinto Mill uses slightly different analytical procedures and sampling methods, which by definition will lead to slightly poorer agreement with the NIR data (i.e. higher SEP values).

The ECLs have been calculated from Australian data which include processes such as automated juice sampling and fully audited laboratory methods. The corresponding Costa Pinto data were generated by manual sampling and, as such, an increased sampling error and therefore increased ECL was expected.

The magnitude of acceptable ECL errors has not yet been determined and will require more data and larger populations of cane scanned in order to better represent them.

Further difficulties in drawing direct conclusions between the two installations are due to the differences in tracking systems employed. The tracking system is a critical element of online pol extraction determination since any measure of extraction requires the analysis of cane and bagasse from the same input cane. This cannot occur simultaneously due to the time lag involved along the milling train, but this time lag can be determined approximately by monitoring the progress of dye through the milling train. The measured time delay is used to synchronise CAS and BAS response for the same cane parcel. At Mulgrave Central Mill, cane is delivered to the mill in individual consignments which can be traced back to individual farms and blocks. As such, there is little difference in cane quality across several measurements within single consignments. Conversely, at Costa Pinto, the cane being crushed may have been sourced from several farms/blocks and mixed prior to milling, thereby increasing the variability in the pol extraction results from consecutive measurements.

In order to validate the online pol extraction measurement, a set of 24 samples was collected for complete cane and bagasse analysis (Figure 6). These samples were identified using a BSES tracking system (NCS Tracking) from CAS to BAS. The results were very good with 95% of NIR data appearing within 1 unit of the lab extraction value. This level of accuracy is more than adequate for application across process monitoring and control functions. Further, the validation results provide confidence that the variation shown within a typical 24 hour trend for NIR calculated pol extraction is real (Figure 7).
Fig. 7—Typical online pol extraction trend for a continuous 24 hour period at Costa Pinto Mill.

Despite the fact that these results have not been generated across large numbers of samples, there are important trends that are apparent. The results for NIR calculated online pol extraction are very similar at both sites, demonstrating that the technique is applicable across any milling train and is a robust measurement despite existing differences between the mills and their milling trains. Based on the similarities observed, we conclude that the measurement itself does not appear to be adversely affected by variations in cane variety, harvesting methods or the mill preparation of shredded cane.

Further, the authors expect that similar measurements should be applicable to any milling or diffusion extraction process, providing the ability to generate real time pol extraction. Access to this data will allow a mill to better understand pol extraction trends and to determine various optimised mill settings and maceration strategies which importantly can be altered in real time, in response to variations in the incoming cane supply and the observed extraction trends.

**Online lignin determination**

Since BAS installations must be located at the end of the milling train, they are ideally located for the real time analysis of bagasse which could be potentially employed for value adding processes other than as a boiler fuel. Bagasse has potential feedstock applications for many downstream applications including lignocellulosic applications, furfural production, lignin applications (Doherty et al., 2008) and others (Banerjee and Panday (2002). With this in mind, it was decided to explore the potential of BAS installations to serve as fibre or biomass analysers for parameters of interest to other processes. The starting point for this examination was the determination of lignin content, as it was envisaged that these data could have applications within lignocellulosic processing as well as impacting on the quality of bagasse as a boiler fuel for energy and cogeneration processes.

In 2006, eleven bagasse samples were sampled from Mulgrave Central Mill, analysed for lignin content and matched with existing NIR scans from the BAS instrument. They were further
characterised using a FOSS XDS laboratory NIR instrument at BSES Indooroopilly. A further 21 bagasse samples were characterised by laboratory NIR spectra only. The NIR scans from both instruments were pooled to develop an initial calibration.

This was an admittedly small data set which was potentially prone to overfitting, but was considered sufficient to generate a calibration which could provide indicative trends but not high quality quantitative data.

This equation was used without validation and, as such, the precision and accuracy of the predictive equation are unknown. This renders the data generated as qualitative only and capable of indicating trends rather than providing quantitative data.

Figure 8 shows the equation applied to the Mulgrave Central Mill BAS installation within a 24 hour period during 2009, and is representative of the variation observed during any such period.

The online trend indicates considerable lignin variation within the bagasse, and that there are observable step changes in lignin content occurring between cane consignments.

Additionally, there is good clustering of lignin results within individual consignments and good sample definition. These are encouraging results and will be further developed, along with other equations for potential online biomass analysis.

![Typical online lignin content trend for a continuous 24 hour period at Mulgrave Central Mill.](image)
The relative trends in lignin content were examined by determining the unweighted arithmetic mean lignin value for all data observed, and dividing the individual values obtained by this value to produce a range of mean centred results. Using this calculation, a value of 1.0 indicates a result which was the same as the overall mean.

The cane supply at Mulgrave Central Mill is tracked from the field to the factory, thereby allowing the allocation of each bagasse scan to individual farms, blocks and varieties. This permits the analysis of lignin content across multiple varieties, crop classes and environmental situations, as well as permitting cross-correlations with productivity data. When applied to a continuous 2 week operation at Mulgrave Central Mill which covered some 1600 individual cane consignments during the early part of the 2009 season, an indication was gained of the variation in lignin content across cane variety and crop class.

Figure 9 shows the mean centred lignin content data for this period, and also indicates the tonnages of each variety crushed and the relative standard deviation for each of the variety averages. This shows that, across all varieties, the total variation was +/− 20% from the mean. The variation within varieties was approximately half of that and was of a similar magnitude for most varieties, irrespective of the tonnages processed. This tends to indicate that there are meaningful differences between lignin content for Australian commercial sugarcane varieties, and that the variation might be enough to warrant consideration of the intended use for the bagasse. Further, such data allow the mill to more accurately value bagasse for different downstream options. One possible scenario might see bagasse of higher lignin content deliberately used as boiler feed material, with lower lignin content material diverted to lignocellulosic digestion or fermentation systems where reduced lignin content may reduce process difficulties. In this way, online NIR data would be used to direct bagasse in a way which would maximise benefits to the sugar mill.

The ability to determine lignin content by NIR methods also has implications for plant breeding processes, especially with increasing interest in the development of energy canes for both cogeneration and for lignocellulosic biofuel/chemical production. Such methods could be applied at earlier stages of selection to identify varieties with desirable cellulose and lignin contents that are suitable for application as energy canes. More work is needed to improve the performance of this NIR calibration, but initial results are promising.
Conclusion

Online NIR systems have been developed in different configurations for the analysis of cane, sugar and bagasse process streams. They offer tremendous advantages for the continuous, real time provision of analytical data which can be used for quality, process control and payment situations. These data are backed up by laboratory analysis in order to continuously validate and track NIR performance. Recently developed applications of NIR methods have been described for the prediction of sugar and bagasse parameters which can provide significant benefits to the sugar mill.

Acknowledgements

The authors would like to thank all those who have assisted with the sampling and analysis of data presented in the paper. Particular thanks go to Mulgrave Central Mill staff (Glenn Pope, Jeff Snoad and Nadine Thomas), Paul Naylor (BSES), Viviane Paulenas (P. A. Sys Engenharia e Sistemas, Brazil), Rodrigo de Campos (P. A. Sys Engenharia e Sistemas) and Luis Fernando Antunes (Cosan S.A.) for their assistance in sample collection and analysis for the BAS work program, and Tracy Hay (Horizon Science) and Graham Butland (Mossman Mill) for assisting with sampling and analysis to support the SAS work program. The authors would also like to thank Cosan S.A. management and Costa Pinto Mill staff for providing a suitable site and significant support for the trial of CAS and BAS instruments.

Résumé
BSES LIMITED a longtemps été associé au développement et a la commercialisation de la technologie NIR pour l'industrie sucrière; son savoir-faire comprend le développement variétal, les utilisations au laboratoire et en ligne dans l'usine. Ce papier retrace le développement de systèmes NIR en ligne avec FOSS Pacific, pour l'analyse en temps réel des cannes, de la bagasse et du sucre; on décrit une gamme d'applications actuellement appliquée dans les usines sucrières. Le système d'analyse de la canne (CAS) a été développé principalement pour mesurer la teneur en fibres en temps réel d'un lot de canne pour le paiement. Cela évite de se servir de chiffres basés sur des moyennes: le paiement est base sur la qualité du lot lui-même. CAS utilise un instrument FOSS Direct Light 5000 avec des systèmes auxiliaires développés pour la présentation de l'échantillon, l'analyse des données et l'intégration avec les systèmes de contrôle du moulin. On a aussi développé des systèmes pour les cendres, matière sèche, pol et Brix pour la canne, le jus, et le sucre commercial en canne (CCS). Les résultats provenant de ces étalonnages ont été utilisés avec succès pour tester la fiabilité aux laboratoires, pour obtenir des indices de qualité de canne à sucre, pour mettre en œuvre des stratégies de contrôle automatisé, pour développer des systèmes de paiement alternatif et fournir des données sur les exploitations individuelles, permettant des solutions ciblées pour les zones avec des problèmes de productivité. Basé sur cette plate-forme, les analyses en ligne de la bagasse (BAS) et du sucre (SAS) ont été mises au point. Le BAS permet un meilleur contrôle pour l’alimentation des chaudières. Lorsqu'il est lié à un CAS sur le train de moulins, les effets du réglage des moulins, de la macération et de la qualité de la canne sur l'extraction sont déterminés en temps réel, permettant le développement de stratégies visant à optimiser l'extraction. Les étalonnages SAS sont utilisés pour surveiller et contrôler les processus critiques dans la production de LoGlCane™, le premier sucre du monde avec un index glycémique faible, qui a été commercialisé en Australie en 2009. Le développement de systèmes NIR en ligne dans les usines sucrières a améliore la qualité du paiement et des stratégies de contrôle, ce qui serait impossible a partir de données normales de laboratoire. Presque 30 systèmes ont été installés dans le monde et de nouvelles applications pour le NIR en ligne continuent à être développées par les utilisateurs existants en conjonction avec BSES et FOSS.
IMPLEMENTACIÓN DE TECNOLOGÍAS DE INFRARROJO CERCANO EN LÍNEA (NIR) PARA EL ANÁLISIS DE CAÑA, BAGAZO Y AZÚCAR CRUDO EN INGENIOS PARA MEJORAR EL DESEMPEÑO

PALABRAS CLAVE: Espectroscopía NIR, Análisis en Línea, Análisis de Bagazo, Análisis de Azúcar, Control de Proceso.

Resumen

BSES LIMITED tiene una larga trayectoria en el desarrollo y comercialización de tecnología NIR para aplicaciones de la industria azucarera que cubren mejoramiento varietal, laboratorios y aplicaciones en la fábrica. Este trabajo recorre el desarrollo de sistemas en línea NIR con FOSS Pacific para el análisis en tiempo real de caña, bagazo y azúcar, describiendo un rango de aplicaciones usadas en ingenios. El sistema de análisis de caña (CAS) fue desarrollado en principio para medir en tiempo real el contenido de fibra de la caña para fines de pago. Esto posibilita el pago basado en la calidad global en lugar de aplicar supuestos a partir de cifras promedio. El CAS usa un instrumento FOSS Direct Light 5000, con sistemas auxiliares desarrollados para presentación de la muestra, análisis de datos e integración con los sistemas de control fabril. Posteriormente se desarrollaron aplicaciones del CAS para cenizas, materia seca, pol y brix tanto en caña como en jugo y para el cálculo del CCS. Los datos de estas calibraciones han sido utilizados para auditar los laboratorios de las fábricas, derivar los índices de calidad de caña, implementar estrategias de control, desarrollar sistemas de pago alternativos y suministrar datos sobre parcelas y fincas individuales permitiendo soluciones específicas para áreas con problemas de productividad. Con base en esta plataforma se desarrollaron sistemas para análisis de bagazo en línea (BAS) y análisis de azúcar en línea (SAS). Las mediciones BAS pueden suministrar caracterizaciones de bagazo basadas en calidad, aptas para control por adelanto de las estaciones de calderas. Cuando se conecta con un sistema CAS, en el mismo tren de molinos, los efectos de los ajustes, control de imbíbición y calidad de caña en la extracción de pol, se determinan en tiempo real, posibilitando el desarrollo de estrategias para maximizar extracción. Se usan calibraciones con SAS para monitorear y controlar procesos críticos en la producción de LoGlcane™, el primer azúcar en el mundo con bajo índice glicémico que fue liberado y comercializado en Australia en 2009. El desarrollo de sistemas de medición en línea NIR para ingenios azucareros ha generado el establecimiento de estrategias de calidad, pago y control, las cuales no hubieran sido posibles con el uso de datos de laboratorio normales. Casi 30 sistemas se han instalado a nivel mundial, y se están desarrollando aplicaciones adicionales para la información NIR en línea por parte de los usuarios existentes, en conjunto con BSES y FOSS.
EVAPORATION PROCESS IMPROVEMENT USING PRECALCULATED VALUES FOR JUICE INJECTION FLOW TO FIFTH EFFECT

KEYWORDS: Effective Heat Transfer Area, Juice Injection, Syrup Concentration, Evaporation Process.

Abstract

This work presents a method for improving the evaporation train performance through a pre-calculated value for injection of clarified juice at the last effect. Previously, when the concentration of syrup was above set point, the juice injection valve remained fully open causing an upset in the stability of levels of the last effect vessels as well as in the temperatures. With measurements of juice flow going to the pre-evaporators, saturated vapour flow, temperatures, as well as effective heat transfer areas (EHTAs), values for the outcomes of each effect as well as condensate flows are calculated. In order to estimate vapour bleeding, the EHTA for each effect is calculated through heat transfer coefficients, estimated condensate flows and measured vapour and juice temperatures. EHTAs and the area of the calandria tubes in contact with steam must match and this is the criterion to estimate condensate flows. Computed values come directly from mass and energy balances over the evaporator set as a whole. Temperature corrected values for latent heat and heat capacity at constant pressure at each effect are used. Factory tests using the syrup flow calculated to control the juice injection valve at the fifth effect demonstrated operation with less overshoot in vapour and juice temperatures on last effect, stability of levels of the last effect vessels, and the brix of the syrup became more stable. These improvements show that this model of the evaporation process yields a value for the flow of syrup that is useful to make the juice injection valve dependent not only on the concentration of the syrup but also on the performance of the whole evaporator set. As the syrup flow increases, more clarified juice can be injected into the final effect and vice versa, and less juice is injected as the syrup flow decreases.

Introduction

Motivated by the optimisation of the evaporation station, the investigation group started to develop concentration profiles for all vessels involved. They discovered that the fourth effect vessel always reached up to 73 brix, meanwhile the output of the last effect was being diluted to 50–55 brix. The reason was that the valve controlling the injection of clarified juice opened 100% in a very short time, even though the evaporation throughput was minimal. The temperature and the amount of the juice injected caused instability in the level, syrup concentration oscillations and reduced the capacity of the fourth and fifth effect vessels.

Evaporation station description

There are two trains of evaporators at La Unión Sugar Mill, one for the raw sugar line and the other for the white sugar line. Each set consists of nine vessels. The white sugar line takes juice only from the first mill, and the rest of the juice and imbibition water go to the raw sugar evaporator line.

Juice is pumped into the first effect from a separate tank for each line. To this effect, the exhaust steam is added in parallel, that is, to the four vessels from the same source as shown in Figure 1. The liquor concentrated in the first effect is sent to the feed of the second effect, and so on through all five effects. Inside each effect the juice is fed in series from one vessel to the following.
Fig. 1—Vapour and juice flow diagram.
Traditional brix control applied

The control used to maintain the concentration of the syrup at a constant value, usually 65 Bx, is located at the end of the evaporators. A sample of the syrup comes out from a fixed point, its measured value (DT) is taken to a proportional plus integral control block which acts on two automatic valves whose control logic to maintain the given set point is as follows:

- If the measured brix is above the set point, the controller acts on the clarified juice injection control valve to the entrance of the last evaporator, governing clarified juice injection to reduce the concentration, or
- If the syrup brix is below set point, the controller acts on the syrup recirculation valve, also on the last evaporator, which recycles syrup back to the inlet of the last effect to evaporate it again, so the brix set point will be reached.

The regulation of these valves is done one at a time, which means that the valves will never be acting at the same time, if the injection valve is regulating, the syrup recirculation valve will be closed and vice versa.

The model-based brix control

A limit was imposed on the juice injection valve to make its 100% opening correspond to the maximum calculated syrup flow observed, which was around 60 kg/s. If the evaporation throughput diminished for any reason, the valve would follow the new limit (closes a corresponding percentage) regulating clarified juice injection to the fifth effect.

For about half an hour on two different days, brix samples were obtained from consecutive vessels to build the brix profiles shown in Tables 1 and 2, at the same time the new control was applied. These do not show any abnormal concentration in the 4th effect as would have been if the profile were done for example half an hour earlier, as can be seen in Figures 3 and 6, when there were periods of syrup brix below set point as well as signs of instability in the rest of the graphs.

All of the other brix profiles done by the investigation group showed a strayed pattern in the 4th effect with concentrations greater than 70 brix.

The graphs from Figure 2 to Figure 4 show the behaviour of the process variables involved when the control was applied for 48 minutes from 14:14 to 15:02 on 04/05/09, during the time the concentration profile of Table 1 was performed.

Figure 2 shows stabilisation of the levels in vessels 5, 6, 7 and 8 fifteen minutes after the controller started to work. Figure 3 shows stabilised syrup concentration, the regulation applied to the injection valve as well as total effective heat transfer area stabilisation. Figure 4 shows the absence of overshoots on the temperatures in vessels 6, 7 and 8 ten minutes after the control was applied (vessel 9 was being washed at the time).
The graphs from Figure 5 to Figure 7 show the behaviour of the process variables involved when the control was applied for almost an hour, from 10:24 to 11:21 on 5–05–09.
The effects on the performance of the evaporator set are greater on the experience the following day. During this time the concentration profile of Table 2 was performed and the stabilisation on levels is evident in Figure 5. The cycling of the syrup recirculation valve with unregulated juice injection valve is shown in Figure 6 for the period immediately before the application of the control, when the PID control was not able to control the process, coincidentally
with instability of the last effect level (vessel #9).

Of course, it is possible that the PID control was not properly tuned and it acted as an ON-OFF control. Other experiences were performed anyway on those last days of the sugarcane harvest, but were few because the cane supply was low. These results are not shown here because no brix profiles like those of Tables 1 and 2 were collected. The experiences could not be made when the syrup recycling valve was opened, and it was necessary to wait for the juice injection valve to open in order to apply the controller.

**Some comments on effective heat transfer areas**

A very important concept in the development of this model is that of EHTA, because it supplies the criteria to estimate, at any time, the amount of vapour bleeding to the evaporator set. The concept has to be refined since the heat transfer coefficients of the evaporators at La Union Sugar Mill are in the process of being measured this coming harvest, and the values used are the standards found in literature. The temperature differences were also too large and logarithmic mean temperature differences should be used. However, its immediate consequence is to show which effect is being bled and to what amount, since otherwise those areas were totally oversized as compared to those not being bled and proportions between effective and ‘real’ (calandria tubes areas) are kept.

**Conclusions**

- The proposed model offers a good approximation of the vapour bleeding effects on the evaporation train.
- The advantages of continuous instead of traditional batch operation come mainly from the fact that these kinds of simple models can be applied for control, which lead to simple and better operation.
- The equation found (24), computes the flow of syrup with the advantage that this value is not affected by the level regulation control on the last effect, as the flow of syrup being measured is obviously affected.
- Introduction of the controlled clarified juice into the process accelerates the dynamics in order to achieve steady state conditions on this naturally stable process. On equation (4), \( \tau = \frac{V}{F_{op}} \approx 6 \text{ min} \) is visibly reduced, as can be observed in Figure 4, by just keeping syrup flow as constant as possible (with help of the clarified juice to remove variations of flow), since clarified juice brix at the entrance of first effect seldom varies, once imbibition has been set, unless wash water from crystallisers is discharged.

**Acknowledgments**

Thanking is not enough to acknowledge the scientific atmosphere that supported this investigation. The initiative came from CARTIF, then it crystallised on a course on semi-physical models with phenomenological substrate to the staff of engineers by PhD Hernán Alvarez. Thanks are owed also to Ing. Carlos Rene Cifuentes of the industrial division, to the instrumentation engineering manager Ing. Estiven Recinos, and finally to the evaporation plant group of engineers: Inga. Claudia Barrientos, Ing. Milton Cifuentes, Ing. Omar Escobar, Ing. Edgar Ochoa and Ing. Otto Paau.

**REFERENCE**

A model for the evaporator set

A model was proposed to calculate the effective heat transfer area by means of the total heat transferred, the heat transfer coefficient and the vapour-juice temperature differentials. One of the by-products of these calculations was the amount of juice not evaporated from each effect which, in the case of the last effect, resulted in the amount of syrup produced and the capacity of governing the clarified juice injection valve with this predicted value.

Model assumptions

- By watching the syrup leaving the final effect, it was evident that it was not too viscous, therefore its properties were still very close to those of the water. So it was decided to assume that heat capacities of juice were those of water and only after watching the results could it be decided what corrections should be made. Otherwise, brix at each vessel should be measured to adjust heat capacities. It was found that the model worked and, after looking for precision, we found that with a brix span of 10 °Bx the heat capacity difference between juice coming and leaving a vessel was less than 5% as computed on internet site http://www.sugartech.co.za/heatcapacity/index.php. In this way, uncertainties coming from brix variations were avoided.

- Mass and energy balances were stated assuming no accumulations or losses of energy and/or matter on vessels, that is, we assumed stability in temperatures and levels. However, for the first effect only, a transient term was included, just to get an idea of the improvements achieved when the controlled variable (clarified juice to fifth effect) is added to the equations, which obviously is a feedback term because it was calculated in terms of the syrup flow which in turn is calculated from values of clarified juice and saturated vapour flow.

Measurements already on site, and those added for our goals, were all steam flows (before and after vapour bleeding), all juice flows into and out of each effect as well as all vapour, juice and condensate temperatures.

Process flows around evaporator station (kg/s)

where \( P_p = a_0 + a_1 T + a_2 T^2 + a_3 T^3 + a_4 T^4 \)

**Development of the model**

Transfer area for the first effect is calculated from the expression used to define convection heat transfer:

\[
A_{2F} = \frac{F_E \lambda_E}{U_{1F}(T_E - T_2)} \tag{1}
\]

where \( F_E \) is exhaust steam flow measured through the condensates produced, \( \lambda_E \) is latent heat of vaporisation of water at exhaust steam temperature \( T_E \), \( T_2 \) is juice temperature from first effect, and \( U_{1F} \) is the heat transfer coefficient of first effect.

To determine the flow exiting first effect vessels, an energy balance equation is used on the juice side:

\[
\rho V C_{p2} \frac{dT_2}{dz} = \rho F_{c2} \lambda_{c2} - \rho F_{c2} C_{p2} T_2 - \rho F_{c2} \lambda_{c2} + Q \tag{2}
\]

where \( Q \) is the convection heat, namely \( UA[LMTD] \). On the vapour side:

\[
\rho V_{c2} C_{p,c2} \frac{dT_{c2}}{dz} = \rho F_{c2} \lambda_{c2} - \rho F_{c2} C_{p,c2} T_{c2} = Q \tag{3}
\]
From mass balance equation, we made the simplifying assumption that the flow of vapour \( F_E \) is of the same value as the flow of condensates used in the previous equation. Assuming also \( V_{CE} \), the amount of condensate remaining in the calandria to be 0 we obtain from (3) an expression for \( Q \) and substituting this into (2), after rearranging terms, we get:

\[
\frac{V}{F_{EP}} \frac{dT_2}{dt} + T_2 = \frac{F_{IP} C_{P1}}{F_{EP} C_{P2}} T_1 - \frac{F_E C_{P2}}{F_{EP} C_{P2}} T_{cE} + \frac{F_E C_{P2} T_{cE}}{F_{EP} C_{P2}} - \frac{F_{IP} A_{1F}}{F_{EP} C_{P2}}
\]

(4)

This is an equation of the form:

\[
\frac{dy}{dt} + y(t) = Kx(t)
\]

(5)

where \( \tau = \frac{V}{F_{op}} \approx 2 \) min (volume of calandria is roughly 9 m\(^3\) and flow of juice from first effect is 4.5 m\(^3\) per minute),

whose integrating factor is:

\[
p(t) = \exp \int \frac{dt}{\tau} = e^{\frac{t}{\tau}}
\]

(6)

and the solution is:

\[
y(t) = y_0 e^{-\left(\frac{t - \tau}{\tau}\right)} + \frac{K}{\tau} \int_{t_0}^{t} e^{\frac{t - \tau}{\tau}} x(t) dt
\]

(7)

As soon as three times \( \tau \) (\( \approx 6 \) min.), steady state conditions exist. However, on closed loop, this time will be diminished substantially and (4) can be simplified by:

\[
F_E \lambda_E + F_{IP} C_{P1} T_{L1} = F_{IP} \lambda_{1F} + F_{oP} C_{P2} T_{2} + F_E C_{P2 E} T_{cE}
\]

(8)

From mass balance equation, we get \( F_{IP} = F_{oP} - F_{op} \) so Eq. No. (8) becomes an expression to calculate \( F_{op} \):

\[
F_{op} = \frac{F_{IP} \left( \lambda_{1F} - C_{P2 E} T_{2} \right) - F_E \left( \lambda_E - C_{P2 E} T_{cE} \right)}{\left( \lambda_{1F} - C_{P2 E} T_{cE} \right)}
\]

(9)

This equation can easily be checked for two extremes.

1. In the case \( F_{op} \) turns out to be zero we have all juice transformed into vapour:

\[
F_E \left( \lambda_E - C_{P2 E} T_{cE} \right) = F_{IP} \left( \lambda_{1F} - C_{P1} T_{L1} \right)
\]

(10)

2. If \( F_E \) is too small, we would have no evaporation which means: \( F_{IP} = F_{oP} \), the approximation \( C_{P1} \approx C_{P2} = C_{P} \) as usual, and substituting these two expressions into (9) to yield the known expression for heating a liquid:

\[
F_E \left( \lambda_E - C_{P2 E} T_{cE} \right) = F_{IP} C_{P} \left( T_2 - T_{L1} \right)
\]

(11).
Transfer area for second effect or Duplex is calculated the same way, except that care must be taken because the first effect vapour flow that enters into the vessels is not anymore \( F_{oP} - F_{oP} \) and has to be measured because of vapour bleeding. By means of gauging condensate tanks for exhaust steam as well as for first effect vapour, in the experiment the following relationship has been found:

\[
F_{1F}' = 0.6 F_E
\]  

(12)

and

\[
A_{2F}' = \frac{0.6 F_E \lambda_{4F}}{U_{2F}(T_{2F} - T_a)}
\]  

(13)

At this point, use of the concept of EHTA is starting to be important, as explained at the end of the main body of the paper. To measure the flow of vapour bleeding, we would have to make major changes in the distribution of tanks and tubes at the bottom of the evaporator set, because at this time they are mixed and pumped to the boiler. At other times, we also tried to measure the vapour, but the problem was with the sensors, since changes of pressure were too small to be measured. What is being proposed is that the model has to be calibrated constantly because the flow of clarified juice \( F_{iP} \) and the flow of Exhaust Steam \( F_E \), have different time-scale variations. In this experiment, the values (0.6, 0.33, and 1) were used to take account of vapour bleeding, but it will necessarily have to be changed according to the comparison criteria, that is, comparing EHTAs (effective heat transfer areas) computed with the areas of the tubes of heat exchangers in contact with steam. In future experiments, maybe this can be automated by setting up a range of valid variations of EHTA as compared with ‘real’ values of the sum of the areas of the tubes of the calandria.

By means of similar expressions to (8) and (9), we get the output flow of second effect:

\[
F_{oD} = \frac{F_{oP}(\lambda_{2F} - C_{P2} T_a) - 0.6 F_E (\lambda_{4F} - C_{P41F} T_{c1F})}{(\lambda_{2F} - C_{P2} T_a)}
\]  

(14)

This is the flow of juice to the 3rd effect vessels. To determine vapour flow of the second effect (later, the same procedure was applied to first effect), we compared on stable conditions the effective area of third effect, which was around 13,000 m², to the measured area of the heat exchanger tubes, roughly 4600 m², and observed an approximate 3 to 1 ratio which means that 66% vapour bleeding was made to this effect. Thus:

\[
F_{2F}' = 0.33(F_{oP} - F_{oD})
\]  

(15)

The effective area for the third effect as well as the juice flow are computed from the following equations:

\[
A_{3F} = \frac{0.33(F_{oF} - F_{o2F}) \lambda_{2F}}{U_{2F}(T_{2F} - T_a)}
\]  

(16)

\[
F_{oD} = \frac{F_{oP}(\lambda_{3F} - C_{P3} T_a) - 0.33(F_{oP} - F_{oD})(\lambda_{2F} - C_{P41F} T_{c1F})}{(\lambda_{2F} - C_{P2} T_a)}
\]  

(17)
Vapour bleeding on third effect was ignored by mistake (see Figure 1), but coincidently $T_5$ was improperly installed, as shown on simulation stage (not included in this paper because it was a simple excel sheet), compensating for the mistake, so the equation remains as:

\[
F_{GF}^c = F_{OF}^c - F_{GF}^F
\]  
(18)

\[
A_{GF} = \frac{F_{GF}}{U_{GF}(T_{GF} - T_B)}
\]  
(19)

\[
F_{OF}^c = \frac{F_{DF}(\lambda_{GF} - C_{PC4F}T_4) - F_{GF}(\lambda_{GF} - C_{PC4F}T_{cGF})}{(\lambda_{GF} - C_{PC4F}T_B)}
\]  
(20)

\[
F_{GF}^c = F_{OF}^c - F_{GF}^F
\]  
(21)

\[
A_{GF} = \frac{F_{GF}}{U_{GF}(T_{GF} - T_B)}
\]  
(22)

\[
F_{OM} = \frac{F_{OF}(\lambda_{GF} - C_{PC4F}T_4) - F_{GF}(\lambda_{GF} - C_{PC4F}T_{cGF})}{(\lambda_{GF} - C_{PC4F}T_B)}
\]  
(23)

After doing all substitutions, we get for $F_{OM}$:

\[
F_{OM} = \sum_{j=1}^{17} K_j F_{IP} + \sum_{j=1}^{28} K_j' F_{IP}^F
\]  
(24)

where $F_{IP}$ is juice flow and $F_{IP}^F$ exhaust steam,

\[
\tau_i = \prod_{j=1}^{2} \frac{\lambda_{GF} - C_{PI}T_i}{(\lambda_{GF} - C_{PI}T_i + 1)T_{i+1}}
\]  

and

\[
\tau_j = \prod_{i=0}^{4} \frac{\lambda_{GF} - C_{PC4I}T_{CIF}}{(\lambda_{GF} - C_{PC4I}T_{CIF} + 1)T_{i+1}}
\]
PREDETERMINATION DU JUS INJECTE DANS LE CINQUIÈME EFFET POUR AMÉLIORER L’ÉVAPORATION

Par

MOTS-CLEFS: Transfert de Chaleur Effectif, Injection de Jus, Concentration du Sirop, le Processus d’Évaporation.

Résumé
Ce travail présente une méthode pour améliorer la performance des évaporateurs par l’injection prédéterminée de jus clarifié dans le dernier effet. Auparavant, lorsque la concentration du sirop était au-dessus de la norme, la vanne d’injection de jus restait complètement ouverte, affectant la stabilité des niveaux des dernières effets ainsi que les températures. On mesure les débits de jus aux pré évaporateurs, le débit de vapeur, les températures, ainsi que les surfaces pour le transfert de chaleur (EHTAs), pour calculer la performance de chaque effet ainsi que les débits des eaux condensées. Afin d’estimer les prélèvements de vapeur, la EHTA pour chaque effet est calculée par l’intermédiaire de coefficients de transfert de chaleur, des débits d’eaux condensées, et les températures de la vapeur et du jus. Les EHTAs et la surface des tubes de la calandre en contact avec la vapeur doivent correspondre et c’est le critère pour estimer les débits des eaux condensées. Les valeurs calculées proviennent directement de bilans de masse et d’énergie pour le train complet d’évaporateur. Les températures sont corrigées pour les effets des chaleurs latentes à pression constante pour chaque effet. Des essais en usine avec le sirop calculé pour contrôler la vanne d'injection du jus au cinquième effet ont donné une consommation de vapeur, des températures et un Brix plus stables au dernier effet. Ces améliorations montrent que ce modèle d’évaporation donne de bons résultats pour le train d’évaporateurs. Comme le débit de sirop augmente, plus de jus clarifié est injectée dans l'effet final et vice versa.
USO DE LA MEJORA DEL PROCESO DE EVAPORACIÓN PRECALCULADOS VALORES PARA LA INYECCIÓN DE JUGO EL FLUJO AL EFECTO QUINTO

PALABRAS CLAVE: Transferencia de Calor Efectiva Espacio, Jugo de Inyección, Jarabe de concentración, Proceso de Evaporación.

Resumen
Este trabajo presenta un método para mejorar el rendimiento del tren de evaporación por medio de valores pre-calcados del jugo claro de inyección en el último efecto. Con anterioridad, cuando la concentración de la meladura estaba arriba de la consigna, la válvula de inyección de jugo acostumbraba quedarse todo el tiempo abierta ocasionando inestabilidad en los niveles de los vasos en los últimos efectos así mismo en las temperaturas. Con mediciones del flujo de jugo a los pre-evaporadores, flujo de vapor saturado, temperaturas y las áreas efectivas de transferencia de calor AETCs se calculan los productos de cada efecto así como los flujos de condensados. Para estimar las sangrías o extracciones el AETC para cada efecto se calcula por medio de los coeficientes de transferencia de calor, flujos de condensado estimados y temperaturas medidas de jugo y vapor. AETCs y las áreas de los tubos de la calandria en contacto con el vapor deben ser iguales y este es el criterio para estimar los flujos de condensados. Los valores calculados salen directamente de balances de masa y energía sobre el tren de evaporadores como un todo. Se usan valores corregidos por temperatura del calor latente y la capacidad calorífica a presión constante en cada efecto. Mediante pruebas en campo usando el flujo de meladura calculado para controlar la válvula de inyección de jugo en el quinto efecto se consiguió una operación más estable en las temperaturas del vapor y del jugo del último efecto, estabilidad en los niveles de los vasos de los últimos efectos y el brix de la meladura más estable. Estas mejoras muestran que este modelo del proceso de evaporación produce un valor para el flujo de meladura que es útil para hacer que la válvula de inyección de jugo claro no solo dependa de la concentración de la meladura sino también de la producción total del tren de evaporadores. Mientras el flujo de meladura aumenta, más jugo clarificado se puede inyectar en el quinto efecto y viceversa, se inyecta menos jugo si el flujo de meladura disminuye.
DRD—DEDINI REFINADO DIRETO (DEDINI DIRECT REFINED) IMPROVEMENTS IN REFINED AND CRYSTAL WHITE SUGAR PRODUCTION

By

KEYWORDS: Crystal White Sugar, Direct Refined Sugar.

Abstract
In addition to its application in the production of granulated refined sugar directly from clarified cane syrup in sugar mills, the Dedini Direct Refined (DRD-Dedini Refinado Direto) can be applied as an improvement in white sugar plants and conventional refineries, allowing production of white sugar from syrups of very high colour. This paper describes the tests conducted with DRD applied to the clarification of high colour syrup obtained from the juice of a new variety of sugar cane (RB92579), widely planted in the northeast of Brazil, which has great productivity but characteristically produces a strongly coloured juice. A study of the relationship between the colour in the final crystal sugar or refined sugar and the colour of the syrup, comparing results obtained in several parts of Brazil and references in the literature, is also presented. This paper also points out the excellent performance of DRD in tests carried out in Brazilian northeast sugar mills, in which it successfully performed the decolourisation of several highly coloured syrups obtained from sugarcane mixtures with different RB92579 content.

Introduction
Between 2005 and 2007 Dedini Indústria de Base S/A (Olivério and Boscariol, 2006 and 2007) presented a new process for granulated refined sugar production directly from syrup, called Direct Refined Process (DRD- Dedini Refinado Direto) (Figure 1). One of the key factors of this process is the capacity of the resins used in this process to retain coloured compounds.

The Brazilian northeast sugar mills experience difficulties in the production of white crystal sugar when processing the new cane variety RB92579. It was considered that the DRD process could assist the mills to produce white sugar. Although this variety of sugarcane is highly productive for the conditions of this region, it has high quantities of coloured compounds that lead to the production of high colour syrups, and consequently, highly coloured crystals. Mantelatto (2005) presented a vast bibliographic review and a detailed study of the process of mother liquor migration to the crystal, correlated with the velocity of crystallisation. If the objective is to obtain white sugar from highly coloured syrup, it is evident that a syrup treatment to reduce the level of colour is necessary. The DRD process together with good sugar house procedures can be important tools to obtain low colour white crystal sugar.

This paper presents the results of DRD pilot plant tests running with the highly coloured syrup after clarification. Colour loading versus saturation curves and the performance of resin columns operating with syrup containing different percentages from the cane variety RB92579 are also discussed. Finally, correlations of crystal colour obtained as a function of syrup colour for sugar mills in different regions of the country are provided, which are compared with data in the literature, and with the sugar obtained from juice decolourised by the DRD process. A simulation of
the use of the DRD process is presented, as a guide in the production of white crystal sugar (<150 IU) for highly coloured syrup.

Materials and methods
The DRD process: refined sugar without a refinery
A schematic of the DRD process is shown in Figure 1. It is designed to produce refined sugar directly from clarified syrup without the need to produce raw sugar and then remelt and recrystallise it as is the practice in a conventional refinery.

In the DRD process, the main unit operation is syrup decolourisation. This operation is performed by high capacity ionic exchange resins. To evaluate the behaviour of these resins in the decolourisation process of highly coloured syrup, tests were performed in a pilot unit, presented in Figures 2 and 3 at the sugar mills Usinas Caeté and União Indústria S/A respectively, located in São Miguel (AL) and Primavera (PE), both in the northeast of Brazil.

The steps involved in the decolourisation process were developed in partnership with Rohm and Haas. It comprises a system of three stages in series (DRD1, DRD2 and DRD3) of ionic exchange resins designed to work under the characteristic conditions of clarified syrup. The basic characteristics of the DRD resins are presented in Table 1.
Fig. 3—Photograph of the DRD pilot plant.

Table 1—Basic characteristics of the ion exchange resin utilised in the DRD process.

Operation

The pilot plant operated with clarified syrup with a brix of around 60 to 65 and 70–75°C. Firstly, the syrup passed through a sand pressure filter in down flow at a pressure around 2.5 bar, to remove gross particles as well as turbidity compounds to avoid plugging of the resin beds with suspended solids. The filtered syrup passed through the three columns in the up flow direction. The purpose of the first resin column is to soften the syrup, the second to perform decolourisation and the third to perform final polishing to guarantee syrup of the necessary quality for efficient crystallisation. The pilot plant operated with a mean flow of 350 L/h with operating cycles at around 30 h. At the end of each cycle, the resins went through a regeneration process with caustic brine solution (10% NaCl and 0.02% NaOH) and returned to operate in a new decolourisation cycle. The resins were submitted to various operating cycles, in which it was possible to establish that their efficiency in the removal of colour was maintained at around 50 to 70%.

At the sugar mill Usina Caeté, the influence of the cane variety RB92579, a source of high colour juice as seen in Figure 4, on the performance of the system of resins was evaluated.

Fig. 4—Clarified juice from cane variety RB92579.
Results and conclusions

Figure 5 shows the influence of the quantity of cane variety RB92579 on the syrup colour. It can be observed that the increase in colour of the syrup can be linked with the proportion of RB92579 processed. Figure 6 shows the influence of the quantity of cane variety RB92579 on the A-sugar colour. It can also be observed in Figure 6 that the increase in colour of the A sugar is partly due to the increase in the cane RB92579 processed and the high level of colour in the syrup. The high and variable colour loading makes it difficult to maintain the colour of the A white sugar below 150 IU. It was proposed to use the DRD process to assist the production of A white sugar with a consistent colour level equal to or below 150 IU. The results of using the DRD process to reduce syrup colour during the processing of RB92579 are presented.

Tables 2 and 3 present an example (cycle 14) of DRD syrup decolourisation in the Caeté Sugar and Alcohol Mill. The DRD pilot plant ran for a total of 22 cycles. The DRD system operated with the press sand filter filled with sand, followed by the cationic column (DRD1), first anionic column (DRD2) and a second anionic column (DRD3).

Figure 7 illustrates the reduction in colour as the syrup progresses through the DRD process. Clarified syrup from a flotation clarifier with a colour of 8856 IU was sampled as it passed through each resin column. In this example, the colour of the final decolorised syrup was 1846 IU, a removal efficiency exceeding 70%.
Table 4 shows example data (cycle 2) for the DRD plant decolourising syrup at União Indústria Sugar and Alcohol Mill.

The DRD pilot plant ran for a total of 25 cycles. In this case, the DRD system operated with the press sand filter filled with sand and 150 L of DRD2 and 150 L of DRD3 anionic resin, followed of cationic column (DRD1), first anionic column (DRD2) and a second anionic column (DRD3). This option was possible because the factory had a syrup belt press filter after the syrup clarifier. Thus, the syrup feed in the DRD process had a low level of turbidity and solids in suspensions. This was done to aid syrup purification since the colour of the raw syrup was very high.

Table 5 was compiled with colour data from Table 4 together with the volumes of syrup fed through the columns.

**Table 5**—Variation of colour as a function of volumes of syrup feed. V = volumes of syrup feed; F0 = colour of syrup input to sand press filter; F1 = output of sand press filter (150 L DRD2 resin and 150 L DRD3 resin), F2 = output of cationic column (200 L DRD1), F3 = output of first anionic column (200 L DRD2), F4 = output of second anionic column (150 L DRD3 resin).

The graphs in Figures 8, 9, 10, and 11 present the results correlating the colour load absorbed by the resin system versus the volume of syrup fed into the columns in relation to the volume of resin, denominated by bed volumes (BV), and syrup colour as a function of the BVs in one of the cycles studied during the trials at Caeté Sugar and Alcohol Mill and União Indústria Sugar and Alcohol Mill, respectively.
Considering that the resins can operate up to 60–70% of saturation (see the load capacity of resins in Table 1), in the case of anionic resins on DRD it is possible, as can be seen in Figures 8 and 10, to operate with a colour load which could reach a level as high as 60 000–65 000 IU. This demonstrates the capacity to bear high rates of colour adsorption, even for syrup containing high initial colour loads.

As seen in Figures 8 and 10, the colour accumulated in the resins conforms to a linear behaviour with the BV fed to the columns. The different slopes of the curves indicate different load factors depending on the characteristics of the resin and also the affinity between colour compounds and functional group of the resins. The Figures thus obtained were used to design the system on an industrial scale.

In Figure 12, the colour removal efficiency values of the system are correlated as a function of the proportion of the cane variety RB92579 in the cane being supplied to the factory. As indicated by the data, the extra colour loading introduced by RB92579 has no effect on the colour removal efficiency of the resins. Moreover, it was observed that the resin system was capable of maintaining a removal efficiency in the range of 50 to 70%, even when processing this variety of cane with higher clarified juice colour.

It was shown that the DRD-Dedini system could be used successfully both as an aid in the production of white sugar and for the production of refined sugar by using clarified syrup as the feed to the decolourisation process.

To compare the levels of removal attained in the various colour removal processes in crystallisation, the colour of the sugar obtained was regressed against the colour of the syrup or liquor of the Brazilian sugar mills as follows:

(1) DRD System (Olivério and Boscariol, 2006 and 2007), refined sugar obtained from decolourised syrup: $y = 0.007 \times + 17.65$;
(2) Thompson et al. (2006) refined sugar;
(3) A white crystal sugar – Us. Mogiana: \[ y = 47.73 \cdot \exp (1.31 \cdot 10^{-4} \cdot x) \];
(4) White crystal sugar – Us Sta Isabel: \[ y = 19.96 \cdot \exp (2.10 \cdot 10^{-4} \cdot x) \];
(5) White crystal sugar – Us. Caeté: \[ y = 46.88 \cdot \exp (0.98 \cdot 10^{-4} \cdot x) \];
(6) White crystal sugar – Us. União Indústria: \[ y = 42.20 \cdot \exp (1.31 \cdot 10^{-4} \cdot x) \];
(7) Controlled cooling crystallisation of liquor obtained from raw sugar (VHP and VVHP) and cane syrup, (Mantelatto, 2005): \[ y = 0.0214 \cdot x + 8.80 \].

Fig. 10—Colour load accumulated in the ion exchange resins as a function of the bed volumes fed at União Sugar and Alcohol Mill. F1 = outlet of column DRD1; F3 = outlet of column DRD2; F4 = outlet of column DRD3.

Fig. 11—Colour of syrup as a function of bed volumes passed through the ion exchange columns at União Sugar and Alcohol Mill. F0 = clarified syrup colour; F1 = outlet of filter; F2 = outlet of column DRD1; F3 = outlet of column DRD2; F4 = Outlet of column DRD3.

The models were obtained considering the moving average of three points. As can be observed from the data presented in Figure 13, the colour removal factor in the crystallisation of juice coming from the DRD system was excellent, when compared with the other systems.
presented. As an example, the curve corresponding to União Indústria in Figure 13 indicates that the colour of the syrup must be about 8000 to 9000 IU to produce white crystal with a colour of 150 IU.

Finally, DRD technology proved to be an improvement to the white sugar process, even for high colour syrups. From the study conducted, in addition to the studies previously conducted (Olivério and Boscariol, 2006 and 2007), it could be concluded that the DRD system can be advantageously used both in the production of granulated refined sugar and for the production of white crystal sugar (colour < 150 IU).

Résumé

EN PLUS de son application pour la production de sucre raffiné directement à partir de sirop de canne clarifié dans les usines a sucre, le Dedini Direct Raffiné (DRD-Dedini Raffiné Direto) peut être introduit pour améliorer la production du sucre blanc et l’opération des raffineries conventionnelles, permettant la production de sucre blanc à partir de sirops de couleurs très élevées. Ce papier décrit des essais concernant l’application du DRD pour la clarification de sirops de hautes couleurs obtenus à partir d’une nouvelle variété de canne (RB92579), populaire dans le nord-est du Brésil, qui a un bon rendement mais produit un jus fortement coloré. Une étude de la relation entre la couleur du cristal de sucre ou du sucre raffiné et celle du sirop, tout en comparant les résultats obtenus dans plusieurs régions du Brésil et les références dans la littérature, est présentée. Ce document souligne également l’excellente performance du DRD pendant des tests effectués dans les usines du Nord-est brésilien; le DRD a permis une bonne décoloration de sirops fortement colorées, obtenus à partir de cannes contenant différents pourcentages de B92579.
DRD—REFINADO DIRECTO DEDINI MEJORAMIENTO EN LA PRODUCCIÓN DE AZÚCAR BLANCO Y REFINADO

Resumen

ADemás de su aplicación en la producción de azúcar refinado directamente de meladura clarificada, el Refinado Directo Dedini (DRD-Dedini Refinado Direto) puede ser aplicado como un mejoramiento en las plantas de azúcar blanco y en las refinerías convencionales, permitiendo la obtención de azúcar blanco a partir de meladuras de color muy alto. Este artículo describe las pruebas realizadas con el DRD aplicado a la clarificación de meladura de alto color obtenida del jugo de una nueva variedad de caña (RB92579), sembrada ampliamente en el noreste de Brasil con alta productividad pero que produce jugo con alto color. Se presenta también un estudio de la relación entre color del azúcar blanco y refinado y el color de la meladura, comparando con los resultados obtenidos en varias partes de Brasil y con los reportados por la literatura. También se señala el excelente desempeño del DRD en pruebas realizadas en ingenios del noreste brasileño, donde se obtuvo exitosamente la decoloración de varias meladuras altamente coloreadas obtenidas de mezclas de caña con diferentes contenidos de RB92579.
SUCROSE LOSS IN STORAGE OF GREEN BILLET CANE

By

M. SASKA, S.L. GOUDEAU and I. DINU
Audubon Sugar Institute, Louisiana State University Agriculture Centre, St. Gabriel, Louisiana, USA
msaska@agcenter.lsu.edu

KEYWORDS: Sugarcane, Loss, Deterioration, Temperature, Storage.

Abstract
Sucrose lost during storage of green billet cane was measured for different storage times and temperatures; in cane that was hand-cleaned before storage (2007) and in (normal) cane used just as delivered by combines (2008). The storage conditions were characterised by the time (hours) of storage within four temperature ranges: <17°C, 17–22°C, 22–27°C and >27°C, representing cold, cool, moderate and warm storage conditions. Within the four ranges, the sucrose loss in normal cane was 0.08, 0.13, 0.27 and 0.32% of the initial sucrose per hour; or an increase in the rate of sucrose loss of about 0.03% initial sucrose per hour per each °C temperature rise. Probably because of the higher enzymatic activity in tops and leaves, the losses in hand-cleaned cane were lower. Based on the developed equations, total sucrose loss in cane storage at a 10 000 t/day factory was estimated to be 1200 t in one eighty-day season. The temperature within cane stored in a factory cane yard and cane trailers was measured. Cane stored in trailers was found to cool overnight (6 pm to 6 am) on average by 0.3°C /h but the temperature of cane stored in piles increased by about 0.1°C/h. This was interpreted as evidence of substantial heat generation during cane storage. However, based on the measured overnight temperature profiles, it was concluded that the difference in sucrose loss between storage in trailers and cane piles alone is not large enough to justify conversion to trailers-only storage.

Introduction
Despite several previous studies (Clarke, 1991; Birkett et al., 1998; Godshall, 1999; Legendre et al., 2000; Eggleston, 2002), data on sucrose loss during cane storage in Louisiana have not been available. A program was therefore organised, with these guidelines set forth:

- measure sucrose loss directly, rather than its indicators, e.g. dextran, ethanol, mannitol, etc.;
- limit the study to green (un-burnt) billet cane;
- cover the range of temperatures and times relevant in Louisiana, viz. 5–35°C and 24 hours or less;
- determine cane weight changes in storage and include them in calculation of the sucrose loss;
- determine sucrose with HPLC rather than polarimetry to avoid errors from changing invert.

In 2007, the tests involved combine-harvested cane that was hand cleaned before storage and contained no leaves or tops while, in 2008, green billet cane was tested just as delivered by combine (normal cane).
Results

Sucrose loss in storage

Full detail of the procedures can be found in the online edition of ASSCT Journal (Saska et al., 2009). In each test, cane was randomly divided into three batches; one was crushed immediately, and two after storage at two different temperature regimes. All juice and bagasse was collected, weighed and analysed. An overall mass balance was performed, as well as mass balances on the cane components: water, fibre, sucrose and invert sugars.

Table 1—Average cane composition, before and after 24-hour storage. Combined data from 2007 (hand-cleaned cane) and 2008 (normal cane).

<table>

<td>0.6</td>
<td>0.7</td>
</tr>
</tbody>
</table>

Sucrose % cane on average decreased, while, with few exceptions, invert sugar levels increased during storage (Table 1). Because of the slow heat transfer within billet cane, temperature of the cane (recorded with data loggers) varied in each experiment with time and could not be defined by a single value. In Figure 1, the recorded dimensionless cane temperature \((T - T_{\text{initial}})/(T_{\text{final}} - T_{\text{initial}})\) at two locations A and B within the storage container is plotted against time (test 6/2008, \(T_{\text{initial}} = 5^\circ\text{C}, T_{\text{final}} = 32^\circ\text{C}\)).

Fig. 1—Measured dimensionless temperature profiles (thick points) in cane storage, and a heat transfer model (thin line) applied to location A. \(\alpha\) is the thermal diffusivity of billet cane in \(\text{m}^2/\text{s}\) (test 6/2008)

For the purpose of fitting the data, the storage temperature was characterised by the time (hours) within four temperature ranges: \(<17^\circ\text{C}, 17–22^\circ\text{C}, 22–27^\circ\text{C} \text{ and } >27^\circ\text{C}\), representing cold, cool, moderate and warm conditions. The sucrose loss (in % initial) was defined as

\[
\Delta S = a_1 \cdot T_1 + a_2 \cdot T_2 + a_3 \cdot T_3 + a_4 \cdot T_4 \quad \text{Eq.1}
\]

where \(T_i\) is the time in hours within each of the four temperature intervals, respectively and \(a_i\) is the corresponding coefficient obtained by fitting the data. The coefficients represent sucrose weight loss (% initial) per hour in the four temperature intervals (Table 2).
Table 2—Measured sucrose loss per hour in stored green billet cane.

</tbody>
</table>

In normal cane, the measured sucrose loss was higher than in hand-cleaned cane. This may be at least in part due to higher enzymatic activity in tops and leaves than in the stalk. The scatter in the 2008 data in normal cane was larger than in 2007 (data not shown) because of greater heterogeneity of cane with trash. In the temperature range 17–27°C, the effect of temperature on sucrose loss is about 0.03% initial sucrose/°C.h. The recent data from Reunion (Corcodel and Mullet, 2007) fall mostly within this temperature range. Their reported sugar loss in green whole-stalk cane (1% per day) is about three times less than our results for green billet cane. As an example, for a factory storing 5000 t of cane overnight, eighty 12-hour storage periods per season, that is 960 hours in total, and equally distributed among the four temperature intervals (i.e. 240 hours below 17°C, 240 hours between 17 and 22°C, etc.), equation 1 predicts a loss of 1200 t sucrose in one eighty-day season, worth over $400 000.

**Temperature and heat transfer in stored billet cane**

In 2008, two cane trailers were fitted with temperature probes and data loggers. A total of 16 overnight periods were evaluated (Table 3) when the trailers were left in the field overnight loaded with cane. On average, the cane in the trailers cooled by 0.3°C/h, at about half the rate of the ambient temperature drop. In contrast, the temperature of cane in the factory yard (concrete slab) measured in 2007 increased in each test, on average by 0.1°C/h, despite the dropping night-time temperature, as the heat generated within cane exceeded the heat loss. For the temperature profiles listed in Table 3, the average overnight temperature of cane in piles is about 2°C higher than in the trailers. With a storage capacity 5000 t cane, the sucrose loss about 0.03 x 500 t sucrose x 2°C x 12 hours or about 3.5 t/day of sucrose higher. This difference alone may not be large enough to justify conversion to trailer-only storage, but the reported high cost of operating front-end loaders in cane yards may be enough to consider such investment.

In order to optimise temperature conditions in storage, heat transfer in stacked cane needs to be measured. An example in Figure 1 of the temperature profiles in cane storage at two locations (A = 4 and B = 40 cm above the container bottom) illustrates the time scale that it takes for the cane to heat up from ~5 to 32°C. A one-dimensional, semi-infinite slab model (thin line) applied to position A indicates thermal diffusivity in the range of 5x10⁻⁵ m²/s. Heat transfer modelling can in the future be used to assist the design of cane transport and storage and reduce sucrose losses.

Table 3—Average cane and air temperature profiles during 12-hour storage (6 pm to 6 am) in a factory cane yard and two cane trailers. Temperature of cane stored in piles increased overnight, while cane in trailers cooled.

PERTES DE SACCHAROSE PENDANT LE STOCKAGE DES CANNES VERTES TRONCONNEES

Par

M. SASKA, S.L. GOUDEAU et I. DINU
Audubon Sugar Institute, Louisiana State University Agriculture Centre,
St. Gabriel, Louisiana, USA
msaska@agcenter.lsu.edu

MOTS CLEFS: Canne a Sucre, Pertes, Détérioration, Température, Stockage.

Résume

La perte de saccharose au cours du stockage de cannes vertes tronçonnées a été mesurée pour des stockages de différentes durées et à des températures différentes; des cannes nettoyées manuellement avant le stockage (2007) et des cannes livrées normalement par des moissonneuses (2008). Les conditions de stockage ont été caractérisées par le temps (heures) de stockage dans quatre plages de température: 17°C, 17–22°C, 22-27°C et > 27°C, qui représentent des conditions de stockage aux températures froides, fraîches, modérées et chaudes. Dans les quatre fourchettes, la perte de saccharose des cannes livrées normalement a été 0.08, 0.13, 0.27 et 0.32 % du saccharose initial par heure; ou une augmentation du taux de perte de saccharose de 0.03 % du saccharose initial par heure par chaque °C. Probablement en raison de l'activité enzymatique plus élevée dans les bouts blancs et les feuilles, les pertes pour les cannes nettoyées à la main ont été inférieures. Basé sur les équations développées, la perte totale de saccharose durant le stockage de la canne pour

une usine de 10 000 t/jour a été estimée à 1 200 t pendant une saison de quatre-vingt jours. La température au sein de la canne à sucre stockée sur la plate-forme et dans les remorques a été mesurée. La canne stockée dans des remorques refroidie pendant la nuit (6 h à 6 h) en moyenne de 0.3°C par heure, mais la température de la canne stockée en tas sur la plate-forme a augmentée de 0.1°C/h. Cela a été interprété comme une preuve d’un dégagement de chaleur substantiel au cours de ce stockage de la canne. Toutefois, selon les profils de température d’un jour à l’autre, il a été conclu que la différence de perte en saccharose entre stockage sur la plate-forme et dans les remorques n’est pas suffisante pour justifier la conversion vers un stockage en remorques seulement.

PÉRDIDAS DE SACAROSA EN EL ALMACENAMIENTO
DE CAÑA COSECHADA MECÁNICAMENTE EN VERDE

Por
M. SASKA, S.L. GOUDEAU y I. DINU

Audubon Sugar Institute, Louisiana State University Agriculture Centre,
St. Gabriel, Louisiana, USA

msaska@agcenter.lsu.edu

PALABRAS CLAVE: Caña, Pérdida, Deterioro, Temperatura, Almacenamiento.

Resumen
Se midió la sacarosa perdida durante el almacenamiento de trozos de caña para diferentes tiempos y temperaturas; en caña que fue limpiada a mano antes de almacenarla (2007) y en caña tal como fue entregada por las cosechadoras (2008). Las condiciones de almacenamiento fueron caracterizadas por el tiempo (horas) de almacenamiento con cuatro rangos de temperatura: <17°C, 17–22°C, 22-27°C y >27°C, representando condiciones frías, frescas, moderadas y cálidas. Dentro de los cuatro rangos, la pérdida de sacarosa en caña normal fue de 0.08, 0.13, 0.27 y 0.32% de la sacarosa inicial por hora; o un incremento en la tasa de pérdida de sacarosa de cerca de 0.03% de la sacarosa inicial por hora y por cada °C de incremento de temperatura. Probablemente debido a la mayor actividad enzimática en hojas y cogollos, las pérdidas en caña limpiada a mano fueron menores. Con base en las ecuaciones desarrolladas, la pérdida total de sacarosa en almacenamiento de caña en una fábrica de 10 000 t/día fue estimada en 1200 t para una zafra de 80 días. Se midió la temperatua dentro de la caña almacenada en el patio y en vagones. Se encontró que la caña almacenada en vagones se enfrió en la noche (6 pm to 6 am) en promedio 0.3°C/h pero la temperatura de caña apilada en patio se incrementó cerca de 0.1°C/h. Esto se interpretó como una evidencia de generación sustancial de calor durante el almacenamiento. Sin embargo, con base en los perfiles de temperatura medidos durante la noche, se concluyó que la diferencia en la pérdida de sacarosa entre almacenamiento en vagones y en patio, por sí sola, no es suficientemente grande para pasar a almacenamiento sólo en vagones.
SPITTLEBUGS INJURY ON SUGARCANE
INCREASED SUGAR COLOUR

KEYWORDS: Saccharum spp.,
Mahanarva fimbriolata, Clarification.

Abstract

SPITTLEBUGS may cause a reduction in sugarcane quality, problems with juice clarification and lower the VHP sugar quality by increasing phenol compounds and colour. A randomised complete-block design experiment with three replicates was conducted. The first factor tested was spittlebug injury to cane stalks with a control (0%) and different levels of infested stalks (15, 30 and 60%). The second factor tested was the timing of harvest; May-June and October of the 2007/2008 season. The highest spittlebug injury levels resulted in decreased sugar quality and reductions in brix, pol and pH and increased fibre, colour and total acidity. For clarification, better results were achieved in the second harvest period and demonstrated in a significant reduction in total acidity of extracted juice and low levels of phenol compounds and sugar colour. Spittlebug injury increased sugar colour. During May-June, the 30% level of spittlebug injury resulted in increases in phenol compounds (41%) and sugar colour (39%).

Introduction

The increase in green cane harvesting contributed to a significant increase in the population of Mahanarva fimbriolata (Stål) (Hemiptera: Cercopidae). Infestations caused by this pest affect cane quality (Gonçalves et al., 2003). The aim of this study was to evaluate the effect of spittlebugs on the quality of the raw material, the purification process, phenol concentrations and the colour of sugar.

Material and methods

The experiment was carried out at a commercial sugarcane area in Guariba, SP region, (Lat 21°21’S, Long 48°13’W) using a mechanically harvested 4th ratoon of variety SP80-1842 during the 2007/2008 season.

The study was arranged in a randomised complete-block design in a 4 x 2 factorial arrangement with three replicates. The first factor to test was the level of damage with healthy stalks (0%) and with 15, 30 and 60% infestation levels. The second factor to test was the two harvesting periods:

- May-June (when the crop age was 11 months, low temperature and dry soil conditions); and
- October (when the crop age was 14 months, with high rainfall and temperature conditions).

The composition of damaged stalks to simulate mechanical harvesting was in accord with Gonçalves et al. (2003).

The stalks were manually harvested, defoliated and topped at the apex bud and allocated to one of the four sample lots based on the infestation level. The juice was extracted by using a hydraulic press to press 500 g of disintegrated cane for one minute at 250 kg/cm² pressure to simulate the extraction of juice in roller mills (Tanimoto, 1964) for analysis and sugar production.
The cane and juice characteristics were determined with:

- Juice brix at 20°C and apparent sucrose by sacarimetric determination (Scheneider, 1979);
- Juice pH measured using a digital pH meter ‘Digimed DMPH–2’ from Tecnal, Brazil;
- Juice acidity expressed in g H₂SO₄/L and juice colour (Copersucar, 2001);
- Fibre is calculated from the brix and purity of the juice extracted by the hydraulic press and the wet and dry weights of the bagasse plug and juice purity (%) (Consecana, 2008);
- Moisture by drying cane bagasse at 65°C for 48 h and then weighing; and
- Total phenol compounds as described by the Folin and Ciocalteau (1927) method.

The extracted juice was reduced to 18 brix prior to purification. In the clarification process, 300 mg/L of phosphoric acid was added to the juice and the pH was corrected to 7.0 with cold lime at 6 Bé. The treated juice was then heated to boiling point and 2 mg/L of a flocculant (Mafloc 985) was added and the juice transferred to a 1 L graduated cylinder for decantation of the flocculated mud in a lamp-heated system. The mud settling rate, mud volume and added lime were recorded and the turbidity (transmittance at 620 nm), brix (Scheneider, 1979), colour (Copersucar, 2001) and pH of the clarified juice were determined.

Clarified juice with an average 16 brix, was concentrated to 60 brix effecting a rotating evaporator to produce syrup. This material was stored at –20°C until the next stage of crystallisation.

The massecuite was produced with adapted reactor with 5 L of capacity and control of temperature (61±2°C). The nucleation of crystals was made with seed process. Refined sugar (<0.5 mm) was added, to growth to 0.7–1.0 mm. After seeding, the process was conducted on metastable zone of supersaturation with feeding 60 brix syrup.

To optimise the crystal growth, the massecuite was put in a 2 L beaker with intermittent agitation by spatula at 1 min intervals. After massecuite temperature dropped from 60 to 55±2°C, the centrifugation was made to separate sugar and molasses with use of 1 kgf/cm² for 2 seconds of steam to clean sugar on start of process.

The crystals were previously drawn with forced ventilation (40°C) and agitation. After, for complete draw, the process continues in an oven (30°C), without air circulation, for 12 h. The production of VHP sugar was 300 g for each experimental parcel. On-product was made: a) ICUMSA colour (CTC, 2005); b) total phenol compounds: 26 g of sugar in 100 mL of distilled water and the method of Folin and Ciocalteu (1927) with adaptation, using 0.5 mL of extract. The data were expressed in mg of total phenol compounds per kg of sugar.

The data were submitted to ANOVA and means were compared by Tukey test (P=0.05). The significant quantities (% of damaged stalks) parameters were submitted to regression analysis (Banzatto and Kronka, 2006).

**Results and discussion**

The analysis of variance indicated that elevated spittlebug damage caused a reduction in brix (F=3.5110; P<0.05), pol (F=9.2224; P<0.01) and pH (F=18.9835; P<0.01) in juice and increased the level of Tanimoto fibre (F=5.7908; P<0.01). The reduction in quality of sugarcane by insects was observed by various studies including, for example, Gonçalves et al. (2003), Ravaneli et al. (2006) and Madaleno et al. (2008).

For regression analysis, it was observed that there was a reduction in quality mainly during the second period (Figure 1). Damaged stalks (30%) reduced brix by 3% in May–June; 6% in the first and 4% in the second period for pol; 0.5% and 2.3% between periods for pH; and increased by 5.5% for Tanimoto fibre in October.
For the clarification process, it was observed that the level of damaged stalks did not influence any of the analysis parameters. However, there were increases in sedimentation speed (P<0.05), lime volume used (P<0.01), pH of clarified juice (P<0.01) and turbidity (P<0.01) from May–June to October.

The spittlebug damaged stalks significantly reduced the sugar quality. There were increases in colour (P<0.01) and total phenol compounds. In the two harvest periods, more colour (P<0.01) and phenols (P<0.01) were found in May–June. This result might have been affected by the better purification process in October.

During the first harvest period, when the clarification process was not adequate, the sample of 30% damaged stalks resulted in a 41% increase in total phenol compounds and a 39% increase in sugar colour as shown in Figure 2.
Trade contracts (Amstar and Savannah Raw Sugar Contract), have been used since 1984, and include penalties for non-compliance with quality criteria that include sucrose content, moisture, ash, crystal size, dextran and colour (Chen and Chou, 1993).

mjrmut@fcav.unesp.br

MOTS-CLEFS: Saccharum spp., Mahanarva fimbriolata, Clarification.

Résumé
Le «Spittlebug» peut causer une réduction de la qualité des cannes, des problèmes de clarification, et peut réduire la qualité de sucre VHP en augmentant les phénols composés et les couleurs. Une expérience basée sur des principes statistiques, avec trois réplicates a été effectuée. Le premier facteur testé a été le degré de l’attaque des «spittlebugs» sur la tige; on a choisi un contrôle (0%) et différents niveaux de tiges infestées (15, 30 et 60%). Le deuxième facteur testé était la date de la récolte; mai–juin et octobre de la saison 2007–2008. Les plus hauts niveaux de blessures par «spittlebugs» ont entraîné une diminution de la qualité du sucre, des réductions des brix, pol et pH et une augmentation de la fibre, de la couleur et de l’acidité totale. De meilleurs résultats ont été réalisés en clarification pendant la deuxième période de récolte; on a trouvé une diminution significative en acidité totale des jus et de faibles niveaux de phénols composés et une couleur de sucre plus basse. La présence du «Spittlebug» augmente la couleur du sucre. En mai et juin, le niveau de 30% de blessure a cause une augmentation des composés de phénol (41%) et de la couleur de sucre (39%).

INCREMENTO EN EL COLOR DEL AZÚCAR POR CAÑA DAÑADA POR SALIVAZO

Por

mjrmut@fcav.unesp.br

PALABRAS CLAVE: Saccharum spp., Mahanarva fimbriolata, Clarificación.

Resumen
El salivazo puede causar una reducción en la calidad de la caña, problemas en la clarificación de jugo y disminución de la calidad del azúcar de alta pureza por el incremento de compuestos fenólicos y el color. Se efectuó un diseño experimental de bloques completos al azar con tres repeticiones y el primer factor probado fue el daño a los tallos, con un control (0%) y diferentes niveles de infestación (15, 30 y 60%). El segundo factor fue el tiempo de cosecha, Mayo-Junio y Octubre de la zafra 2007–2008. Los mas altos niveles de daño resultaron en menor calidad del azúcar y reducciones en brix, pol, pH y en un incremento de fibra, color y acidez total. En clarificación, los mejores resultados se obtuvieron en el segundo periodo de cosecha, evidenciados en una reducción significativa en la acidez total del jugo extraído y menores niveles de compuestos fenólicos y color de azúcar. El daño por salivazo incrementó el color del azúcar. Durante Mayo-Junio, el nivel de daño del 30% resultó en incremento de compuestos fenólicos (41%) y de color del azúcar (39%).
BAGACILLO FLOTATION CELL

By

N. PRABHAKAR and G.S.N. MURTHY
Nava Bharat Ventures Ltd, Samalkot, India
np@nbv.in

KEYWORDS: Bagacillo Removal, Flotation.

Abstract
INCREASED sugarcane preparation to achieve better milling efficiency results in a significant increase in bagacillo in raw juice. For removal of the bagacillo, rotary screens and vibroscreens have gained much importance in the recent past. However, there is certain limitation for the removal of bagacillo as the screens do not allow the separation of fine bagacillo particles of size less than 0.32 mm. Raw juice generally contains some occluded air and the same when pressurised during pumping to juice heaters, gets dissolved at the pump delivery. Raw juice having dissolved air and heated up to 70°C, when released to atmosphere in a cell, causes flotation of the bagacillo. Such a concept was tried in a 150 t/h capacity sugar mill with very encouraging results.

Introduction
Bagacillo, the fine fibre component of bagasse produced due to increased cane preparation remains in the screened mixed juice. About 70–90% separation is observed with the existing static and rotary screens. Static and rotary screens are used extensively to screen fibre from juice. But static screens are less preferred and outdated due to their inconsistent performance. The particle cut-off size in a pilot rotary screen was found to be 0.32 mm. (Manson and Ames, 1982).

The residual bagacillo and other suspended matter lead to processing difficulties and finally affect adversely the quality of the product sugar (Crane et al., 2004). Saccharin in bagacillo imparts yellow colour by reacting with lime. Bagacillo can cause severe clogging problems in heat transfer equipment and centrifugals. Bagacillo is also sometimes found in product sugar. Hence, effective bagacillo removal before clarification will have a very significant benefit to produce good quality sugar. Recently, different filters have been developed to screen bagacillo content (Crane et al., 2004). But these filters are associated with high energy consumption and low availability due to the need for frequent cleaning at the rated juice flow.

The fine bagacillo particles in the juice have a propensity to entrap tiny air bubbles (Crane et al., 2004). This property of bagacillo helps in its separation through flotation. Further, the elevated temperature of juice releases dissolved air and the decreased viscosity results in effective flotation of bagacillo as scum in a flotation cell.

The flotation technique was tried in Deccan Sugars, a 3600 tcd sugar mill in Andhra Pradesh, India following double sulphitation process for the manufacture of plantation white sugar. Very encouraging results were obtained and are presented in this paper.

Description of the flotation cell
The flotation cell shown in Figure 1 is similar in construction to a syrup clarifier. The cell has a volume of 4.9 m³ and is operated at juice flow rate between 70 t/h to 126 t/h. The bagacillo flotation cell is placed before the liming and sulfitation process as illustrated in Figure 2. The scum is scraped by the top mounted scrapers driven by 0.4 kW motor. The scum collected in the annular chamber diverts onto the vibroscreen driven by a 1.1 kW motor, which screens bagacillo from scum. The screened bagacillo falls by gravity into the mud minger where mud from the Graver type juice clarifier is mixed with bagacillo before sending it to the rotary vacuum filter. Juice from the vibroscreen joins the juice stream for liming and sulfitation.
Results and discussions

The bagacillo content in the screened mixed juice before and after flotation cell was measured by separating the bagacillo using an 80 mesh (175 μm aperture) size screen from a 1000 mL mixed juice sample.

The fibre content was dried to equilibrium and measured to determine the bagacillo content in mixed juice. Twenty four samples were analysed in the course of the campaign to study the performance of the flotation cell. The results are shown in Figures 3, 4 and 5.

Bagacillo content in screened mixed juice before flotation was observed to be varying from 3 to 20 g/L. This residual bagacillo content may not be fully removed in the clarification process. As noted earlier, it is often found in the product sugar.

Considerable bagacillo separation was achieved through the flotation process. Bagacillo removal in the flotation cell varied from a minimum of 8.2% to a maximum of 64%. However, 20-35% bagacillo removal was consistently achieved in the flotation cell.

The purity of the juice was found to increase at the outlet of the flotation cell indicating separation of non-sucrose components through flotation. The brix of the juice was measured using a brix spindle and the pol was measured by a Schmitz and Hanson saccharimeter.
Separation efficiency could be further improved in the existing system with minor modifications such as increasing the volume of the bagacillo flotation cell. Introduction of a nano-bubbling generator into the flotation cell to improve the efficiency of the system is also under consideration. There is, however, a possibility of higher thermal losses in the flotation cell.

Fig. 3—Trend showing bagacillo content in screened mixed juice before flotation.

Fig. 4—Trend showing bagacillo removal efficiency of the flotation cell.

Fig. 5—Trend showing increase in juice purity with increase in bagacillo removal.
Conclusion

Through this study, it is clear that bagacillo separation through flotation is possible. The flotation cell along with diffusion system can also be installed before juice heating. Since there is no elevation of juice temperature for dissolved gases to be released, diffusion may help to impart efficient bagacillo separation.

Success of this system will increase the quality of sugar and improve heat transfer efficiency in the heat exchangers. Low efficiency juice heat exchangers can be replaced by heat exchangers having high turbulence and heat transfer coefficient.

Bagacillo flotation cell could be an economical solution to removing bagacillo content effectively. Further research and study into the mechanics of flotation is required to improve the efficiency of the flotation system.

N. PRABHAKAR et G.S.N. MURTHY
Navoï Bharat Ventures Ltd, Samalkot, Inde
NP@nbv.in

MOTS-CLEFS: Elimination de la Folle Bagasse, Flottaison.
Résumé

L’AUGMENTATION de la préparation des cannes pour atteindre une meilleure efficacité aux moulins se traduit par une augmentation significative de la folle bagasse dans le jus. Pour éliminer la folle bagasse on se sert de tamis rotatifs et vibratoires. Toutefois, il y a des limitations pour l'élimination de la folle bagasse comme les tamis ne permettent pas la séparation des particules de taille inférieure à 0,32 mm. Le jus contient généralement de l’air qui se dissout aux pompes. Le chauffage du jus contenant de l’air en solution jusqu’à 70°C, permet la flottaison de la folle bagasse, dans une cellule, quand l’air s’échappe vers l'atmosphère. Ce concept a été étudié dans une usine a sucre de capacité de 150 t/h avec des résultats très encourageants.

CELDA PARA FLOTACIÓN DE BAGACILLO

Por

Nava Bharat Ventures Ltd, Samalkot, India
np@nbv.in

PALABRAS CLAVE: remoción de Bagacillo, flotación.
Resumen

EL INCREMENTO de la preparación de caña para obtener mejores eficiencias de extracción resulta en un significativo incremento del bagacillo en el jugo crudo. En el pasado reciente los tamices rotatorios y los vibratorios han ganado importancia en la remoción de bagacillo. Sin embargo, hay limitaciones dado que los tamices no logran la separación de partículas menores 0.32 mm. El jugo crudo generalmente contiene aire ocluido que es presurizado y disuelto a la salida de las bombas hacia calentadores. El jugo con aire disuelto y calentado a 0°C, cuando se lo libera a la atmósfera en una celda, causa la flotación del bagacillo. Este concepto se ensayó en un ingenio de 150 t/h con resultados muy promisorios.
THE USE OF THE COLOBSERVER® ON LINE COLOUR MEASUREMENT SYSTEM TO AUTOMATE A SUGAR BLENDING PROCESS

By

C. TRINTIGNAC and B. GAILLAC
Iteca Socadei, France
Coraline.trintignac@iteca.fr

KEYWORDS: On-Line, Colour, Measurement, Quality, Colobserver®, Process Optimisation, Blending.

Abstract
Nowadays all sugar mills need to improve their instrumentation and process equipment to keep production costs and energy consumption as low as possible while aiming for a specific quality. The Busco sugar plant has to produce and bag different qualities of sugar as per their customers’ specifications. Thus, Busco asked ITECA to install a Colobserver® and to automatically manage the complete sugar blending process. Different blending schemes were developed in cooperation with the plant to comply with the numerous qualities used by the production. We particularly focused on the automation monitoring and to their associated operating alarms to ensure a perfect operation in a completely automatic mode. All the parameters can be adjusted independently. Today the Colobserver® installed at the Busco plant as well as many other sugar refineries worldwide provides the tailor-made tools that allow refineries to comply with the required quality and to optimise process management. Refineries are also able to track and record their complete production quality, which is very much appreciated by end clients.

Introduction
The Colobserver® is designed to monitor the sugar colour continuously and directly on the process for wet and dry sugar applications.

In the Philippines, Busco Sugar Refinery used to blend its different coloured sugars manually to obtain the requested qualities at the bagging station. It involved frequent laboratory control which could not follow colour drifts in real time to ensure an absolute quality. To increase the constancy of this blending and to automate its process, Busco decided to set up an on-line-colour analyser: the Colobserver®.

The Colobserver® is able to measure sugar colour with great accuracy and, thanks to its integrated PLC, automatically manages the sugar blending process (Gaillac, 2009; Gaillac and Trintignac, 2008; Gaillac and Trintignac, 2009).

Colobserver® description
Colobserver® is sited directly above the sugar to control the total conveyor width. It uses an optical system allowing colour measurement by reflectivity. An important advantage of the use of a video sensor is the possibility to freely adapt various types of lenses according to the size of the region to be measured. Thanks to this technology, the system can easily be adapted on several kinds of conveyor as shown in Figure 1.

Developed with special care to meet the HACCP standard, the stainless steel made device is designed to work on all kinds of conveyor that are found in the sugar industry. It ensures three functions in real-time:
• Monitoring automatically the blending of the colour into the different silos;
• Accurate measurement of the sugar coloration calibrated according to the plant laboratory; and
• Detection and quantification of brown lumps or bad coloration of the sugar

Methodology

The Colobserver® was located on a screw that fed the elevator just before the silo of the bagging station. Its PLC controls the speed of each of the rotary valves which extract the sugar from each of the four silos supplying sugar to the bagging station (see Figure 2).

Different blending schemes were developed in cooperation with the plant to comply with the numerous qualities used by the production:

Bottler – 30 IU max;
Premium – 30–45 IU max; and
Standard – 45–100 IU.
The colour range into each silo is as follows:
W1a & W1b – 7 to 35 IU;
W2 – 60 to 100 IU; and
W3 – 100 to 200 IU.

The sum of all the rotary valve speeds has to be equal to 120 Hz so that there is a constant feed rate to the screw.

As per the requests made by the production manager, the plant laboratory adjusts the colour setpoint on the computer of the Colobserver® to fill the silo with the correct sugar, so that the right quality is sent to the bagging station. The programming logic and data flows for the Colobserver® are described in Figures 3 and 4.

Fig. 3—Program logic for the Colobserver®.
Fig. 4—Information flows for the Colobserver® system.

The Colobserver® considers the height level of sugar in the silos and intelligently proportions sugar to ensure an optimisation of the silo management, so that the obtained colour is always the requested one.

We particularly focused on the automation monitoring and to their associated operating alarms so as to ensure a perfect operation in a completely automatic mode. All the parameters can be adjusted independently.

Conclusion

Today the Colobserver® installed at the Busco plant as well as many other sugar refineries worldwide allows these plants to ensure that a mastered quality product on both wet and dry sugars is delivered to their end customers. They are also able to track and record their complete production quality, which is very much appreciated by end clients.

Résumé

Les sucreries désirent améliorer l’équipement et l’instrumentation pour maintenir la consommation d'énergie et les frais de production aussi faibles que possible, tout en visant une qualité spécifique. La sucrerie Busco doit produire différentes qualités de sucre pour leurs clients. Ainsi, Busco a demandé à ITECA d’installer un Colobserver® et de gérer automatiquement le mélange du sucre. Différents schémas de mélange ont été développés en coopération avec l'usine pour produire les nombreuses qualités de sucre demandées. Nous avons particulièrement surveillé l'automatisation et ses alarmes afin d'assurer un fonctionnement parfait dans un mode entièrement automatique. Tous les paramètres peuvent être ajustés de façon indépendante. Aujourd'hui le Colobserver® installé à Busco, et dans d’autres raffineries dans le monde, fournit des outils qui permettent aux raffineries de se conformer à la qualité requise et d'optimiser la gestion des processus. Les raffineries sont également capables de suivre et d’enregistrer la qualité en production, ce qui est très appréciée par les clients.

EL USO DE COLOBSERVER® SISTEMA DE MEDICIÓN DE COLOR EN LÍNEA PARA AUTOMATIZAR UN PROCESO DE MEZCLADO DE AZÚCAR

Por

C. TRINTIGNAC y B. GAILLAC
Iteca Socadei, France
Coraline.trintignac@iteca.fr

PALABRAS CLAVE: En Línea, Color, Medición, Calidad, Colobserver®, Optimización de Proceso, Mezcla.

Resumen

Actualmente todos los ingenios azucareros necesitan mejorar su instrumentación y su equipo de proceso para mantener los costos de producción y el consumo energéticos tan bajos como sea posible, mientras se apunta a una calidad específica. El ingenio Busco debe producir y empaquetar diferentes calidades de azúcar acorde con las especificaciones de los clientes. Por esta razón Busco solicitó a ITECA la instalación de un Colobserver® y el manejo automático del proceso completo de mezclado. Se desarrollaron diferentes esquemas de mezcla en colaboración con la planta para cumplir con las numerosas calidades usadas por la producción. Se enfocó particularmente en el monitoreo automático y en sus alarmas operativas asociadas para asegurar una operación perfecta en un modo completamente automático. Todos los parámetros pueden ajustarse independientemente. Actualmente el Colobserver® instalado en la planta de Busco así como en muchas otras refinerías a nivel mundial suministra las herramientas apropiadas que permiten a las refinerías cumplir con la calidad requerida y para optimizar la gestión de proceso. Las refinerías son también capaces de registrar y seguir completamente su calidad de producción lo cual es muy apreciado por el cliente final.
CONTINUOUS VACUUM PAN – AN ATTEMPT FOR DUAL MASSECUITE BOILINGS WORKING

By

R. CHANDRAMOULI and B. CHANDRASEKAR
Ponni Sugars (Erode) Limited
rcm@ponnisugars.com

KEYWORDS: Continuous Vacuum Pan, Heating Surface Volume Ratio, Seed Rate, Ratio Controller, Conductivity Transmitter, Dyno Drive, Automation.

Abstract

The continuous vacuum pan is a boon to the sugar industry by nature of its high heating surface to volume ratio, constant steam demand, more exhaustibility of the massecuite, crystal growth, easy to automate, easy to operate, flexibility in capacity and so on. In Ponni Sugars, one continuous pan of 15 t/h capacity was installed five years ago. Taking advantage of its working pattern, an attempt was made to modify its design slightly to convert the pan from a single massecuite-boiling pan into a double massecuite-boiling pan. The practical experiences are shared in this article.

Introduction

Ponni Sugars (Erode) Limited underwent an expansion from 1250 tcd to 2500 tcd in 1994. This was done by installing limited and essential equipments, keeping the investment cost at minimal levels with no provision for additional built-in-capacity. As a result, Ponni lost the advantage for crushing higher than the rated capacity and could achieve no more than 2250 tcd crushing on an average during any season since the expansion.

The pan section was no exception to this and solids handling with the improved cane variety, and demand for sugar quality with higher crystal size from the market added fuel to the problems. So a decision was made to install a continuous vacuum pan (CVP) of 15 t/h capacity for boiling C massecuite which was subsequently erected and commissioned during 2004.

Continuous pan

The newly erected CVP was operated for C massecuite boiling right from its inception. For two years, the practice was followed. During the operation, it was found that the boiling rate was found so high such that the pan was working only about 10–12 hours a day, the rest of the time being kept idle. Starting and stopping the pan was posing a big problem to the operators. The operational data are enclosed in Appendix 1.

The pan was operated with part automation wherein the molasses feed was added to maintain the consistency of material inside the compartment and the seed was fed at a ratio to the molasses flow rate by using a ratio controller. The automation arrangements are shown in Figure 1.

Modifications made to the CVP

Since this continuous pan was operated in a discontinuous way i.e. the pan was operated for about 10–12 hours per day, several options were considered regarding the working of the pan. These included:

a. to reduce the number of compartments; and
b. to alter the design of the pan to suit working with two massecuites (i.e. B and C massecuites).

The second option was chosen because the existing continuous pan for B massecuite was also getting corroded badly and was incurring huge maintenance expenditure year after year.
Fig. 1—The three main control loops on the CVP prior to the modifications.

Since the design of the new CVP was suitable for the proposed modifications to boil two massecuites, the following modifications were made:

- The CVP was divided lengthwise into two on the vertical plane with respect to the compartment on either side of the top tube plate.
- Necessary changes to the flow path to ensure true plug flow of the massecuite in the different compartments.
- Feed liquor arrangements suitably rearranged to give better mixing of liquor and exhaustion of mother liquor in the CVP.
- Steam distribution divided into two to allow the use of vapour of different pressures for each massecuite.
- The compartment partition plate above the top tube plate was modified to avoid any short-circuiting.
- Plug flow of massecuite was achieved by rearranging the massecuite flow pattern.
- The existing condenser nozzle sizes were increased to suit the increased rate of evaporation.
- Existing partial automation was upgraded to complete automation.

The modifications are illustrated in Figures 2 and 3.

**Operation of the modified CVP**

After the modifications were completed but before the automation was completed, the CVP was recommissioned in 2006. Initially a lot of teething troubles were encountered as complete automation was not available. Since the CVP working efficiency depends wholly on the automation, efforts were concentrated on this aspect. Changes made to the automation system included:

- Existing sensors and transmitters were replaced by reliable and user-friendly equipment.
- VFD arrangements made for pumping B and C footing material.
- Control valves were replaced by proportionate type control valves for On/Off mode.
- Vapour valves were provided with proportionate type control valves.
- Jigger steam arrangements were provided to the bottom of the pan.
- Hot water addition on auto mode provided for further conditioning of molasses.

The logic of the automation is shown in Figure 4.
All the above improvements were made and the pan started working very well on fully automatic mode. The following benefits were noted:

- Throughput from the pan was increased without affecting the efficiency.
- The pan was utilised for the maximum hours of working.
- The flows of massecuites are uniform and centrifugal machines are continuously loaded.
- Improved evaporator performance due to constant steam demand.
- Since start up and stopping operations are avoided, deposits are avoided.
- Automation helps in flexibility to vary throughput according to crushing variations.
- The same logic can work very well for independent massecuite boiling also because of effective steam utilisation.

The data collected during the working of the pan with both massecuites are given in Appendix 2.

**Conclusion**

This novel concept of making the CVP as twin pan was conceived by the author Mr R. Chandamouli and successfully implemented in Ponni Sugars (Erode) Limited. Because of this modification work, not only was the pan utilised to its maximum capacity but also assisted to ease the solids handling on the pan floor. The total cost incurred for the modification works was around Rs. 4.00 lakhs.

It is well known that continuous pans work well only with full automation. Only with full automation did this pan succeed to work well for dual massecuite boiling. The rate of evaporation was found to be constant throughout the operational period. Whenever the pan had to be stopped for more than 4 hours, the contents were emptied, water boiled and again taken into service.

CUITE CONTINUE—UNE TENTATIVE POUR LE TRAITEMENT DE MASSECUITE DOUBLE

Par

R. CHANDRAMOULI et B. CHANDRASEKAR
Ponni Sugars (Erode) Limited
RCM@ponnisugars.com

Résumé
LA CUITE continue apporte beaucoup d’avantages pour l’industrie du sucre; par exemple le fort rapport de sa surface de chauffe au volume, une demande constante de vapeur, un fort épuisement de la mélasse, une bonne croissance cristalline, automatisation et travail faciles, flexibilité dans la capacité, et ainsi de suite. Une cuite continue a été installée à Ponni Sugars avec une capacité de 15 t/h, il y a cinq ans. Une tentative pour modifier sa conception légèrement afin de permettre le traitement de massecuite double a été faite. Les expériences pratiques sont partagées dans cet article.

TACHO CONTINUO—UN INTENTO PARA COCIMIENTO DUAL DE MASAS

Resumen
EL TACHO continuo es importante para la industria azucarera en razón de su alta relación de área de calentamiento a volumen, demanda constante de vapor, mayor agotabilidad de las masas, crecimiento de cristal, facilidad de automatización y operación, flexibilidad en capacidad y así sucesivamente En Ponni Sugars, un tacho continuo de 15 t/h de capacidad fue instalado hace 5 años. Aprovechando su esquema de funcionamiento, se intentó modificar ligeramente su diseño para convertirlo en un tacho para cocimiento de doble masa. En este artículo se comparten las experiencias.
ADVANCED COOLING TECHNOLOGY HELPS INGENIO TRES VALLES INCREASE CAPACITY

By

N. JORDISON¹ and A. URRUTIA²

KEYWORDS: Sugar Dryer, Sugar Cooler, Refined Sugar, Indirect Plate Cooler, Mass Flow.

Abstract

In 2006, Ingenio Tres Valles S.A. wanted to increase their plant production capacity and considered various ways in which this could be accomplished. Increasing the capacity in the drying and cooling sections was one of the requirements to ensure a top quality product. The challenges they faced were to select efficient technologies that would fit in the available space, utilise existing equipment where possible and offer the most cost effective solution. To increase the drying capacity of refined sugar, the decision was made to convert the existing rotary drum cooler to a rotary dryer. The next step was to add a stand-alone cooler. Tres Valles evaluated several options for the cooler; a fluid bed cooler, a rotary cooler and an indirect plate cooler. The indirect plate cooler operates on the principle of mass flow of sugar through a vertical bank of water cooled plates. After a thorough evaluation, Tres Valles selected an indirect plate cooler from Solex Thermal Science since the vertical configuration and small cross section fit easily into their existing facility. The indirect plate cooler also offered the most cost effective and energy efficient solution. The equipment was installed and commissioned in January 2008 in time for the seasonal operating campaign. The new drying/cooling configuration is now in the second operating campaign and has successfully played a role in increasing sugar production capacity at Ingenio Tres Valles. Quality objectives have been fully achieved and the equipment has met and exceeded the energy efficiency targets.

Introduction

The Ingenio Tres Valles S.A. plant in Veracruz, Mexico was operating with the conventional arrangement of two rotary dryer/cooler drums, each operating at the maximum capacity of 35 t/h. Tres Valles set plant objectives to increase capacity to a production rate of 75 t/h and improve product quality. From a quality perspective, they wanted to reduce ‘lumping’ of the product that was occurring due to moisture and temperature upsets which, in the 2006/2007 operating campaign, resulted in six quality claims against them from customers.

A technical and economic analysis was carried out to determine the best way to increase drying and cooling capacity as well as improve the quality and consistency of the product at the desired increased production rates.

With the deregulation of the sugar industry in Mexico, quality is becoming an increasingly important consideration with customers. Customers may require final product quality to be certified according to (among others):

- ISO 9001–2000;
- Hazard Analysis and Critical Control Point (HACCP);

...
• FDA (Federal Drug Administration);
• Kosher.

With this in mind, Ingenio Tres Valles required their production process to be able to meet these standards as this would help to differentiate them in the Mexican sugar market. In the short term, it was planned to ship some product in 1500 kg super sacks where there is an increased tendency for caking if the sugar is not fully dried and cooled.

**Tendency for caking**

The mechanism for sugar forming a ‘cake’ or ‘lump’ is caused by moisture migration through the sugar as illustrated in Figure 1. The moisture migration causes a ‘cement’ to form between adjacent crystals where they touch, forming a weak bond which leads to ‘lumping’. Moisture migration through the sugar is caused by the temperature gradient between the sugar and the ambient conditions. These conditions exist when sugar is stored or put in bags at too high a temperature. The requirement is to store the sugar close to ambient temperatures. Typically sugar is cooled to a temperature within 5ºC of ambient which minimises the risk of agglomeration.

![Figure 1—Micro crystal growth leads to caking.](image)

**Evaluation of available technologies**

The starting point of the study was to consider the possible alternatives. Following the study, three possible solutions were identified:

• Adding another rotary dryer;
• Changing to a fluidised bed cooler; and
• Converting the existing rotary cooler to a dryer and installing an indirect plate cooler to meet the cooling duty.

The first two options (rotary dryer and fluidised bed cooler) used equipment well known to the sugar industry in Mexico. The third option, using an indirect plate cooler, was not familiar to the Tres Valles engineers and had not been installed in any of the sugar factories in Mexico, although the technology had been extensively used in sugar factories in Europe.

**Description of the indirect plate cooler technology**

Plate heat exchanger technology has been applied to the bulk solids industry for approximately 20 years. The technology was first introduced in the fertiliser industry to cool bulk fertiliser and was quickly introduced to other bulk solid industries. Plate coolers have been used to cool crystalline sugar (beet and cane) for 10 years.

The idea behind the technology is simple: the bulk solid, in this case sugar crystals, flows slowly by gravity between water cooled plates as illustrated in Figure 2. The sugar crystals are cooled by conduction.
Fig. 2—Sugar crystals flow slowly between water cooled plates.

The heat exchanger plates are stainless steel and are of fully welded construction, with no gaskets; this design ensures very high mechanical integrity.

Water flows through the plates in counter-current flow with respect to the product flow, achieving high thermal efficiency. The plates are installed as a bank in a stainless steel casing.

**Uniform velocity**

The second requirement of an indirect plate cooler is that the sugar must flow at the same velocity over the full cross section of the heat exchanger to ensure an equal residence time which will result in uniform cooling as illustrated in Figure 3.

Uniform flow is achieved with a vibrating feeder discharge comprising overlapping shallow angled louvres. Product flow is proportional to the frequency of vibration and, when the feeder tray is stationary, there is no product flow due to the angle of repose of the sugar.

Fig. 3—Illustration of uniform velocity with full cross section vibrating feeder.
The advantages of indirect cooling

Indirect cooling with water results in several significant cost and quality advantages compared with direct cooling with air-sugar contact:

Air coolers require a large quantity of air for the cooling duty. This is inefficient, requiring a chiller and reheater, large fans and a dust collection system to prevent emissions to the atmosphere. This additional equipment adds to both installed capital and operating costs. In comparison an indirect plate cooler operates on a chilled water circuit.

- Direct cooling with air introduces the risk of contamination of the sugar crystals if there are micro-organisms present in the air.
- The slow gravity flow of the sugar through the indirect plate cooler is ‘gentle’ compared to a fluidised bed or rotary drum cooler. This gentle handling reduces degradation and breakage of the sugar crystals.
- The floor space required for the indirect plate cooler is small since cooling occurs in the vertical direction whereas, in a fluidised bed or rotary drum cooler, the product flow is horizontal, thus requiring a much larger floor space. This is a particular advantage in retrofit projects where floor space is usually very limited.

Water chillers use approximately 40% less energy than air chillers for the same heat load. This is explained by the fact that with an air chiller, the air must first be cooled to supersaturation, typically 10°C and 100% relative humidity and then reheated above the saturation point, typically 15°C and 70% relative humidity.

This requires energy to condense the moisture present in the air, plus the energy required for the reheat. With a chilled water system the only energy requirement is the sensible heat load to chill the water.

Technical and economic evaluation of alternative technologies

A comparison was made of the available technologies and summarised in Table 1.

Table 1—Technology and economic comparison.

<table>
<thead>
<tr>

</tbody>
</table>

The energy consumption for each option was also evaluated. The results are shown in Table 2. The power consumptions quoted for the rotary and fluidised bed cooler are for the fans and drives for the drum. Table 2 does not include the power requirement for the chillers in either the rotary dryer, fluidised bed or the indirect plate cooler.

Reference plants

The next step in the evaluation for the Tres Valles engineers was to visit reference plants in Europe where there were a number of plants using the indirect plate cooler technology. The objective of the visit was to see the installations and discuss operating experience, equipment reliability and maintenance issues with the plant technical and operating personnel. Table 3 lists the plants visited.

Results of technology evaluation

Each of the three methods of cooling was considered technically viable and mechanically reliable. After careful evaluation, the choice between the different technologies was made on two principal criteria:

- Ease of installation
- Energy savings

On this basis, the indirect plate cooling technology was selected for the plant upgrade. Tres Valles plant engineers chose the heat exchanger technology offered by Solex Thermal Science.

System design and process control

Tres Valles specified the following design conditions for the indirect plate cooler:

Capacity: 80 t/h
Product in: 60ºC
Product out: 35ºC
Water temperature in: 25ºC (from chiller)

To meet this duty, Solex configured the indirect plate cooler as a double bank design, with the water flow in series. A simple process flowsheet of the system is shown in Figure 5.

Fig. 5—Tres Valles process flowsheet.
Commissioning

Commissioning took place in November 2007 and the cooler was quickly on stream, meeting the required cooling performance. The Solex commissioning team was on site to assist with set up and calibration of the equipment and to observe the first few days of operation. In addition, on-site training was provided to the Tres Valles operations team.

Performance review 2007/2008 operating campaign

After operating the plate cooler through the 2007/2008 operating campaign, the following observations were made:

- Tres Valles was able to consistently maintain the product temperature to storage at the target temperature of 35°C
- The claims associated with lumping decreased from six in the 06/07 campaign to two in the 07/08 campaign. It has been identified that the two claims in the 07/08 campaign were the result of failures with the chilled water supply where they were unable to maintain the required cooling water temperature.
- The plant was also able to achieve the goal of increasing production capacity and did so in the 07/08 campaign by 20 000 tonnes from the previous campaign.

Conclusions

Ingenio Tres Valles needed to increase their sugar crystal cooling capacity to meet higher production targets and improve quality. They investigated alternative technologies including an additional rotary cooler, a fluidised bed and an indirect plate cooler for this duty. The indirect plate cooler had not previously been used in the Mexican sugar industry, so more in-depth study was required to understand both the advantages and disadvantages of the technology. They needed to ensure that this type of equipment could achieve reliable operation with a high on-stream factor and low maintenance cost.

Following the evaluation of the three possible technologies, the indirect plate cooler was selected since it most closely met the plant objectives.

The equipment was installed in the fall of 2007 in time for the 2007/2008 operating campaign. Operating experience through the first campaign proved the equipment fully met the objectives of the project. The equipment has now operated through the second season 2008/2009 and has again proven to achieve effective cooling and reliable operation.

Acknowledgements

We would like to acknowledge the support of the technical staff at Ingenio Tres Valles, it would have been impossible to prepare this poster without their help. Special thanks to Ingeniero Guillermo Mendoza Castillo, who was in charge of the project and the performance evaluation.

Une technologie avancée de refroidissement contribue à l’augmentation de capacité à Ingenio Tres Valles

Par

N. JORDISON1 et A. URRUTIA2

1Solex Thermal Science Inc., 2Ventura Process Equipment Company neville.jordison@solexthermal.com

MOTS-CLEFS : Sécheur, Refroidisseur, Sucre Raffiné, Refroidisseur a Plaques, Bilan Massique.

Résumé

En 2006, Ingenio Tres Valles S.A. voulait augmenter la capacité de sa production et a considéré différentes possibilités. On a trouvé nécessaire d’augmenter la capacité dans les sections de séchage et de refroidissement, afin de garantir un produit de qualité supérieure. Les problèmes rencontrés
ont été la sélection de technologies efficaces pour l’espace disponible, l’utilisation de l’équipement existant dans la mesure du possible et une solution efficace au point de vue du coût. Pour augmenter la capacité de séchage du sucre raffiné, on a converti le refroidisseur a tambour rotatif en sécheur rotatif. L’étape suivante a été l’addition d’un refroidisseur autonome. Tres Valles a évalué plusieurs options pour le refroidisseur; un refroidisseur a lit fluidisé, un refroidisseur rotatif et un refroidisseur a plaques. Dans le refroidisseur a plaques un débit massique de sucre passe a travers une bande verticale des plaques refroidies a l'eau froide. Après une évaluation approfondie, Tres Valles a sélectionné un refroidisseur a plaques de Solex Thermal Science qui s'intègre facilement dans leurs installations existantes. Le refroidisseur a plaques offre un coût et une demande d’énergie économiques. L'équipement a été installé et mis en service en janvier 2008, a temps pour la campagne. La nouvelle configuration de refroidissement/séchage est maintenant dans sa deuxième campagne d'exploitation et a permit une augmentation de la capacité de production du sucre à Ingenio Tres Valles. La qualité a été atteinte; l'équipement a atteint, et même dépassé, les objectifs d'efficacité énergétique.

TECNOLOGÍA DE ENFRIAMIENTO AVANZADA AYUDA AL INGENIO TRES VALLES A INCREMENTAR SU CAPACIDAD

PALABRAS CLAVE: Secadora de Azúcar, Enfriadora de Azúcar, Azúcar Raffinado, Enfriador Indirecto de Placa, Flujo Másico.

Resumen

EN EL 2006, Ingenio Tres Valles S.A. deseó incrementar su capacidad de producción y consideró varias rutas para lograrlo. El incremento de la capacidad en secado y enfriamiento de azúcar fue uno de los requerimientos para asegurar u producto de alta calidad. Los retos que ellos enfrentaron fueron la selección de tecnologías eficientes que pudieran acomodarse en el espacio disponible, el uso de equipo existente donde fuera posible y ofrecer la solución más costo-efectiva. Para incrementar la capacidad de secado de azúcar refinado, la decisión fue convertir el tambor rotatorio de enfriamiento existente en una secadora rotatoria. El siguiente paso fué adicionar una enfriadora independiente. Tres Valles evaluó varias opciones para la enfriadora: una de lecho fluidizado, una rotatoria, y una enfriadora indirecta de placas. La enfriadora indirecta de placas opera bajo el principio de flujo másico de azucar a través de un banco vertical de placas enfriadas por agua. Después de una evaluación exhaustiva, Tres Valles seleccionó una enfriadora indirecta de placas de Solex Thermal Science dado que la configuración vertical y la pequeña sección transversal se acomodaban al espacio disponible. Este equipo también ofrecía la solución más costo-efectiva y la mas eficiente energéticamente. El equipo fue instalado y puesto en marcha en Enero 2008 a punto para la zafra. La nueva configuración de secado/enfriado se encuentra ahora en su segunda zafra y ha desempeñado exitosamente un rol en el incremento de la capacidad de producción de azúcar en el Ingenio Tres Valles. Los objetivos de calidad han sido completamente alcanzados y el equipo ha cumplido y superado los objetivos de eficiencia energética.
A VEGETABLE CLARIFYING AGENT
FOR CANE JUICE CLARIFICATION

By

P. THANGAMUTHU and R.B. KHANDAGAVE
Karnataka Sugar Institute, Belgaum, India
thangamuthu_p@yahoo.co.in and drrbk1232@yahoo.com

KEYWORDS: Clarification, Flocculant, Settling, Mud, Clarity, Hibiscus lunarifolius.

Abstract
There is a continuous quest for biologically-derived flocculants to avoid chemically manufactured flocculants for cane juice clarification. Attempts were made to investigate vegetable-derived clarifying agents which are substitutes for the imported flocculants and cheaper. A comparative study was made with chemical flocculant used normally in sugar factories on settling characteristics, juice clarity and the compactness of mud. It was observed that the use of 3 ppm of Hibiscus lunarifolius extract provides a similar performance to 2 ppm of chemical flocculant. This plant extract has a peculiar property which helps in reducing the unwanted colours in the juice. The plant extract assumes a significant role as an alternative for chemical settling agents. The plant has wider adoptability in terms of its agro-climatic requirements and can be grown as a sole crop or as an intercrop in sugarcane having wide or paired row planting system. Thus an environmentally friendly plant extract is made useful to replace chemicals in the sugar industry.

Introduction
Most of the sugar mills are importing expensive settling aids for settling mud and to improve the clarity of the clear juice. The settling agents are added to the heated juice before entering the clarifiers.

To avoid these costly chemicals, it is preferable to introduce alternatives which can be environmentally friendly, less expensive and easily adopted.

In the manufacture of Khandasari and Gur sugars, the cane juice is clarified with plant extracts viz. 1. Hibiscus ficulneus (Deola), 2. Hibiscus esculentus (Bhindi), 3. Cadia celsina (Sukhlai), 4. Bombax malabarum (Semal Bark), 5. Grewia asiatica (Falsa), 6. Arachis hypogaea (Ground Nut), 7. Recinus communis (Castor Seed), 8. Aloe vera (Indian Aloe), 9. Moringa oleifera and Cordia myxa etc.

Based on these, it was postulated that the extract from such plants could be used in the process of clarification of cane juice for better flocculation and faster settling. In this paper, the details of the experiments conducted with Hibiscus lunarifolius and the results obtained are discussed.

Details of the plant
Hibiscus lunarifolius belongs to the Malvaceae family of the plant kingdom. It is herbaceous and 2–3 metres high. Physically, it resembles the Ladies Finger plant with the main difference being the length of the fruit which is 1/5 of the real Ladies Finger. The seeds are brown and minutely tubercled. The name of the plant in English is Van kapas.

The Van kapas plant is cultivated in the same way as Ladies Finger using seeds and can also be propagated by stem cuttings. Within 30 days after sowing, the plant will bear flowers and fruits. The leaves contain a sticky substance called mucilage which contains an albumin-like substance responsible for coagulating and bleaching characteristics.
The ideal time for picking the leaves to obtain the extract which can be used as a flocculant for cane juice clarification is before 30 days. Leaves will be broader before bearing of fruit bodies. If entire leaves are plucked, secondary leaves will develop within a few days. The plant can be irrigated once a week. It is a wild variety and can be grown in red and loamy or black and black loamy soil. Extracts can be obtained from the entire plant. The approximate crop duration is 3–4 months. The Van kapas plant can be found in tropical Africa, Australia, Sri Lanka and India.

### Experimental procedure

#### Extraction of plant material

Matured leaves of the plant were collected and washed with water. The leaves were soaked in water and squeezed to obtain the extract. The extract was then filtered through a cloth.

#### Preparation of solution

A 0.05% solution of *Hibiscus lunarifolius* extract was prepared by taking 0.5 g of the extract in a 100 mL volumetric flask. About 80 mL of distilled water was added. The flask was stopped and shaken well to dissolve the extract. The volume was then made to 100 mL using distilled water and further diluted ten times with distilled water to give 0.05% solution.

#### Use of the extract for clarification

Raw juice was obtained from processing sugarcane in a laboratory crusher. The juice was analysed for brix, pol, purity and pH and then heated to 70°C and limed to pH 7.2 and then heated to 100°C.

A series of 6 × 1 L measuring jars was prepared by adding the *Hibiscus lunarifolius* at 1 ppm, 2 ppm, 3 ppm, 4 ppm and 5 ppm, respectively. The sixth jar was empty as a blank.

One litre of the boiled juice was added to each jar. Each jar was stirred well and the contents allowed to settle. The settling rate was observed at regular intervals and recorded using a stop watch. The clarity of the clear supernatant liquid from all the measuring jars was measured using the Kopke turbidity meter (Meade and Chen, 1982) and recorded in Table 1.

#### Table 1—Use of *Hibiscus lunarifolius* extract in raw juice clarification.

Comparison of the extract with chemical flocculant

A 0.05% of solution of the chemical flocculant Magnafloc LT27, having a molecular weight of about 18 million, was prepared in a similar manner to the plant extract.

Tests on raw juice using chemical flocculant were conducted using the same method that was used for the plant extract so that the two could be compared. For these tests the settling rates were recorded in Table 3.

Comparative study

The juice obtained from the laboratory crusher was analysed for brix, pol, purity and pH. The juice was heated to 70°C. It was limed and the pH was adjusted to 7.2 by using sulfur dioxide gas and, to complete the reaction, the treated juice was heated to 100°C.

Three 1 L measuring jars were used. The first one was kept as a blank. In the second and third jars, 3 ppm of extract and 2 ppm of chemical flocculent respectively were added. The boiled
juice was poured into each of the three measuring jars and the volume was adjusted to 1 L mark. The contents of the measuring jars were stirred and the precipitate was allowed to settle. The data are recorded in Table 4.

Observations and discussion

From the analytical data, the optimum dosage of *Hibiscus lunarifolius* extract and chemical flocculant were found to be 3 ppm and 2 ppm respectively from Tables 1, 2 and 3. The results showed that the addition of *Hibiscus lunarifolius* resulted in faster mud settling rates and the mud volume was more or less equal in the case of chemical flocculant and the blank. The clarity analysis revealed that the supernatant juice obtained by the addition of *Hibiscus lunarifolius* extract was found to be similar to the juice obtained by the addition of LT27. The colour of clear juice obtained using LT27 at 2 ppm level was 11 000 IU, the same level as that obtained with the plant extract at 3 ppm. Due to the higher expenditure the colour analysis was not continued.

Table 4 reveals that the plant extract at 3 ppm gave a similar mud volume compared to the chemical flocculant at 2 ppm. Other parameters like brix, purity rise, pH, clarity and colour of the juice also showed similar results with these treatments.

Experiments are under way to analyse the constituents of *Hibiscus lunarifolius* extract that may be responsible for its flocculating characteristics and bleaching action. The effect of *Hibiscus lunarifolius* extract with the cane juice at different stages of processing will also be studied. Attempts are also made to crystallise *Hibiscus lunarifolius* extract to make it suitable for storage and marketing.

Conclusion

The comparative results of *Hibiscus lunarifolius* plant extract and the chemical flocculant reveal that 2 ppm of chemical agent produced similar results as 3 ppm of plant extract for settling of the mud in the juice. In addition, the formation of the floc is quicker and the flocs are larger with *Hibiscus lunarifolius*.

In view of these benefits, the extract assumes a significant role and is an ideal substitute for the traditional settling aid. The plant has a wide adaptability in terms of its agro-climatic
requirements and can be grown as a sole crop or as an intercrop in sugarcane having wide or paired row planting system. Even though the plant belongs to the same family of Malvaceae, unlike Ladies finger, it is not widely used. Rather, it is considered ornamental.

The plant extract is environmentally friendly. The cultivation of the plant may provide for an extra income for the farmers.

PALABRAS CLAVE: Clarificación, Floculante, Sedimentación, Lodo, Turbiedad, *Hibiscus lunarifolius*.

Resumen

Hay una continua búsqueda de floculantes biológicamente derivados para eliminar los obtenidos químicamente, usados en la clarificación de jugos de caña. Se han hecho esfuerzos para investigar agentes clarificantes de origen vegetal como sustitutos de floculantes importados y más baratos que estos. Se hizo un estudio comparativo con floculantes comerciales en cuanto a características de sedimentación, turbiedad y densidad de lodos. Se observó que el uso de 3 ppm de un extracto de *Hibiscus lunarifolius* proporcionó un desempeño similar a 2 ppm de un floculante químico. Este extracto tiene una propiedad peculiar que ayuda en la reducción de colores no deseados en el jugo. El extracto de la planta juega un rol significativo como una alternativa a los agentes sedimentadores químicos. La planta tiene una amplia adaptabilidad en términos de sus requerimientos agroclimáticos y puede cultivarse como único producto o como un cultivo asociado con la caña en un sistema de surco alternos. De esta manera un extracto de planta, ambientalmente amigable, es planteado como útil en el reemplazo de químicos en la industria azucarera.
REPORT ON THE SECOND ISSCT MANAGEMENT WORKSHOP, MAY 2008

Abstract

THE SECOND ISSCT Management Workshop held in Townsville, Australia in May 2008 attracted 41 delegates from 10 countries. The Management Commission and its workshops aim to enlarge the role of senior industry managers in the ISSCT, particularly to integrate management aspects into research and technological initiatives. The workshop format comprised presentations around a particular theme followed by interactive discussion where problems were contextualised and pragmatic solutions sought. A forum for CEOs and senior staff of research organisations followed the Workshop. Overall, the workshop was a success with helpful outcomes emanating from the four sessions: renewable energy, supply chains, research and development (R&D), and special projects. Suggested topics for future workshops include: (1) the R&D fraternity should identify three or four R&D priorities for the next 10 years; (2) experience and business strategies of large sugarcane-related companies should continue; (3) technology transfer and extension needs to be revisited; (4) human resource issues related to attracting and retaining talent in the organisation and change management tools; (5) investigating the use of ‘economic/commercial’ skills in the R&D context; (6) cane-payment approaches applicable to the renewable energy paradigm; and (7) environmental concerns.

Introduction

The second ISSCT Management Workshop held in Townsville, Australia in May 2008 attracted 41 delegates from 10 countries. The Management Commission and its workshops aim to enlarge the role of senior industry managers in the ISSCT, particularly to integrate management aspects into research and technological initiatives. In this regard, the workshop format of the first ISSCT Management Workshop held in Durban, South Africa in July 2006 was considered by the delegates then as appropriate, i.e. presentations around a particular theme followed by interactive discussion where problems were contextualised and pragmatic solutions sought. A similar format was adopted in Townsville where full scientific papers were not requested from presenters, only a PowerPoint presentation, the focus of the workshop being the interactive discussion. Although some delegates at the Durban Workshop suggested the inclusion of breakaway groups to address special interests with a plenary report back, this was not adopted at the Townsville Workshop because the plenary was of a size that (1) facilitated inclusive discussion and (2) diverse expertise and experience facilitated ‘fresh’ approaches to problem solving.
Following this workshop, Eoin Wallis (Chief Executive Officer, BSES Limited, Australia) coordinated a forum for CEOs and senior staff of research organisations to brainstorm common issues.

This paper gives a précis of the proceedings and the main lessons learned from the perspectives of both the organising committee (the authors of this paper) and the delegates (from a questionnaire).

**Field Trip**

The field trip involved a bus tour to the Burdekin District, 80 km south of Townsville, where the first stop was with the HCL Harvesting Group (120 000 t cane). Insights were shared on the group’s organisational structure and workforce complement, its equipment and operations, and its farming systems, including controlled traffic using GPS guidance, minimum tillage and break crops. A cane-planting operation was observed before leaving for BSES Burdekin near Ayr, where cane variety trials were explained and innovative cane-planting practices demonstrated. This was followed by a short visit to an independent grower’s farm where the challenges of cane farming were frankly explained in the context of aspiring to Australia’s acclaimed Sugar Yield Decline Joint Venture Program.

The delegation then returned to BSES Burdekin for lunch, followed by a visit to Pioneer Mill, which is owned by CSR (collectively across its seven mills, CSR produces approximately 40% of Australia’s sugar). The focus of the mill tour was its cogeneration capability (68 MW with 50 MW export capacity) and bagasse-handling facilities (> 110 000 t), as additional bagasse is sourced from nearby mills.

There was general consensus among the delegates that the field trip was appropriate despite the diverse backgrounds of delegates; i.e. the mixture of growing and milling, research activities and practical operations. Some delegates indicated that more attention needed to be given to areas such as cane breeding, farm related research, farm equipment suppliers and milling.

Most delegates appreciated the frank discussions regarding agronomic challenges, the insights into grower/miller relations, the hospitality of the hosts, and the expert commentary on the bus.

**Workshop Session 1—Renewable Energy**

Three presentations were made: ‘Dombe ethanol and cogeneration project in Mozambique’ by Graeme Bullock (Adjunct Professor and Consultant to Principle Energy, Australia), ‘The EID Parry experience with renewable energy’ by Ramesh Ponnuswami (Vice President: Refinery, EID Parry Ltd, India), and ‘Next generation technologies towards a sustainable biofuels future’ by Emile Van Zyl (Chair of Energy Research: Biofuels and Alternative Clean Fuels, South Africa). Questions raised in the subsequent discussion were:

1. What are the drivers of global renewable energy and why?
2. What are the renewable energy options from sugarcane, current and future, and what is their technology status?
3. Where does sugarcane fit into global renewable energy planning and how can this status be improved?
4. What fundamental changes are needed for sugarcane operations to sustainably embrace renewable energy?
5. What are some of the ‘gaps’ or ‘short comings’ in fast-tracking implementation programs?
6. What options are available to narrow these ‘gaps’ and ‘short comings’?, and
7. How can the change process or paradigm shift be fast tracked?
Some of the salient points emanating from the discussion and questionnaires received were:

- There are four fundamental global drivers of renewable energy that are not specific to sugarcane: (1) global warming and environmental factors; (2) national energy security in terms of a supply and demand imbalance; (3) national balance of payment concerns where the importation of energy is often a nation’s single biggest cost; and (4) job creation and socio-economic factors.

- Simplistically, ‘clean’ sugarcane currently delivered to a mill comprises water, fibre, sucrose and dissolved solids including sugars other than sucrose. Inherent energy sources are approximately 30% from sucrose, 13% from dissolved solids and 57% from fibre. Converting the sucrose and other dissolved sugars into energy is well established through fermentation and distillation. Efficient and economic conversion of fibre into energy remains a challenge. Research around the world is currently focused in the following ‘second generation’ energy from fibre areas: (1) combined cycle cogeneration to produce electricity; (2) gasification to produce multiple products in a bio-refinery; (3) pyrolysis to produce a crude bio-oil; and (4) hydrolysing the cellulose, hemi-cellulose and lignin into their constituent sugars for fermentation into ethanol (lignocellulosic ethanol). Commercial viability and role-out of some technologies are expected within 3–5 years.

- In terms of existing ‘first generation’ renewable energy harvests from sugarcane, cogeneration (the combustion of bagasse to produce high-pressure steam that in turn drives turbo-alternators to produce electricity) is the most prevalent; the production of ethanol from sugar streams is second. Generally, the viability of cogeneration depends on either an inherently high local electricity price, or a premium paid for its ‘renewable’ attributes that is facilitated through legislation.

- The ‘greenfields’ Dombe ethanol and cogeneration plant currently being established in Mozambique by Principle Energy demonstrates that the business model: (1) is economically viable and internationally cost competitive; (2) provides significant ‘spin-offs’, such as job creation and infrastructure development, benefit neighbouring communities; and (3) provides balance of payment advantages to the Mozambique nation as a whole.

- The success of EID Parry in India as a company is based on the following principles: (1) ensuring international competitiveness; (2) continuous improvement and innovation; (3) building a strong home base; (4) staying informed with best practice and latest trends; and (5) networking and collaborating in the global arena. Investing in the renewable energy sector is considered strategic. Their inventiveness in maintaining a credible cane supply from approximately 100 000 small-scale farmers in a difficult business environment is remarkable.

- It was affirmed that sugarcane is likely to be the commercial energy crop of the world in the not too distant future, but its momentum to-date has been constrained by: (1) the complex nature of the value chain and the quantum of change required; i.e. linking agriculture to agri-processors to petro-chemical companies or electricity distributors and to the consumer or public at large; (2) inappropriate government legislation and ill-informed politicians and government officials in terms of reviewing legislation; (3) indecision or ignorance on the part of sugarcane growers and millers in terms of which technology to invest their capital; and (4) unforeseen risks associated with new technology and immature markets. Sugar industries around the world should consider embarking on a marketing campaign to inform all stakeholders of renewable energy advantages of sugarcane.
• Little focus has been given to researching appropriate agronomic practices associated with ‘energy’ cane, their linkages with the processing facilities and associated institutional frameworks. For example, what are the soil-health impacts of delivering most of the biomass to the mill, how will the high bulk/density biomass be economically transported to the mill, how will the mill manage the initial volumes of biomass without compromising other products, and how will growers be paid for biomass?

Workshop Session 2 – Supply Chains

Five presentations were made: ‘Integrating the Mauritian supply chain’ by Kassiap Deepchand (MSIRI, Mauritius), ‘Legislative versus contractual miller/grower relationships in Australia’ by John Pollock (Mackay Sugar, Australia), ‘Harvesting and transport logistics in Thailand’ by Kanchana Sethanan (Khon Kaen University, Thailand), ‘Transport scheduling and related issues in South Africa’ by Peter Lyne (SASRI, South Africa), and ‘An holistic approach to new farming systems in Australia’ by Alan Garside (BSES, Australia). Questions raised in the subsequent discussion were:

(1) What is the role of government policy within sugarcane supply chains?
(2) How can incentives and relationships be aligned in the absence of legislation?
(3) What are the relative roles of legislation, contracts, trust and integration in terms of improving supply-chain efficiencies?
(4) How will renewable energy and other products impact supply-chain efficiencies?
(5) How can harvesting seasons be extended for the benefit of all stakeholders?, and
(6) How can incentives be given to sugarcane growers to deliver feedstock that optimises downstream value-adding activities?

Salient points emanating from the discussion and questionnaires received were:

The Mauritian experience demonstrates that a crisis is an excellent change agent! A 36% sugar price reduction in the EU was the catalyst to re-engineer the Mauritian sugar industry where all stakeholders were forced to make compromises in order to survive!

A re-engineering of the supply chain in the quest for efficiencies and optimisation requires a good understanding of the supply chain and its interrelationships. Effective logistics planning necessitates that ALL supply-chain components are integrated effectively.

The sugarcane supply chain was defined by the workshop as ‘on-farm sugarcane production, sugarcane harvesting and transport to the mill and sugarcane processing at the factory’. Most sugarcane supply chains are fragmented in terms of different segments having different decision-making authorities, causing a breakdown in communication among stakeholders. This fosters misunderstandings about common problems, resulting in little or no commitment to jointly address problems, which ultimately manifests itself in high costs and an inefficient supply chain. The fundamental element of any efficient supply chain is transparency of factual information derived from measurement and benchmarking. Sound information facilitates collective understanding of common problems and develops trust among stakeholders. Trust is the essential element needed for stakeholders to make meaningful commitments in addressing common problems.

EID Parry (India) and Mitr Pol (Thailand) are helpful case studies demonstrating that innovation happens in an environment where millers and growers constructively work together. In essence, a secure, viable and consistent cane supply is a critical success factor for any sugarcane-processing facility.

Distrust between millers and growers appears to be a global problem, which can partly be ascribed to the miller being a monopsony; i.e. the mirror image of a monopoly, where the miller is a
single buyer from many sellers (growers), who as individuals have little or no negotiation leverage with the miller in price setting. In recognition of this disproportionate economic ‘power’, governments have historically legislated local sugar industries. In Australia, abolished legislation was simply replaced with commercial agreements, achieving the same result. However, commercial agreements provide more flexibility; they are more easily changed to adapt to a dynamic market environment. Nevertheless, commercial agreements must provide a fair and robust conflict-resolution mechanism if such changes are to transpire in reality.

The concept of ‘best’ practice is a misnomer because different environments inherently require different management practices. This is particularly evident among countries, but also among on-farm fields. Effective supply chains make continuous incremental improvements in an effort to chase ‘better’ practice. In this regard, raising the performance of below average stakeholders can make significant improvements, i.e. by simply reducing performance variation.

Innovative technology, such as vehicle scheduling, GPS, etc, is available to streamline supply chains. However, difficulties associated with the effective implementation of technology are often underestimated; systems generally need to be adapted or even tailor-made for specific applications, as was the case with vehicle scheduling and logistics in Thailand and South Africa.

Technology adoption should preferably be guided by a supply-chain strategy because technology is the ‘accelerator/enhancer’ of business strategy. The question that arose was ‘who drives supply chain strategy?’. The answer that emerged was R&D! For example, BSES (Australia) questioned the sustainability of sugarcane agriculture in yesteryear, which led to the development of BSES’s new cropping system as the current foundation of the Australian sugarcane supply-chain strategy. In practice, R&D organisations need to work concurrently on business strategies and new technologies, but the first should provide a lead for the second, where at some point a consolidated ‘package’ is presented to industry for adoption (this could be ‘turn key’ or ‘iterative’ in nature).

The new BSES cropping system advocates: (1) green-cane harvesting and trash blanketing; (2) breaking the monoculture with increased fallow periods and/or legume break crops (given recent fertiliser prices, ‘free’ legume nitrogen has significant value); (3) controlled infield traffic; and (4) minimum tillage. If heavy infield machinery is used, it is unlikely that the full potential benefits of this system will be realised. Improvements in precision guidance technologies for harvesting and haul-out operations have accelerated/enhanced this strategy. The system is management intensive.

Supply-chain R&D should identify current and future challenges/opportunities, and then provide a suite of solutions to enable industry to meet/capture these challenges/opportunities. It was noted that ‘breakthrough’ R&D is uncommon, and meaningful progress is more often achieved through trial and error, so it is important to make a start! Actual implementation preferences are usually the sole preserve of industry itself.

This session was criticised as having too many diverse speakers that made it difficult to integrate the subsequent discussion. Two shorter sessions would have been more appropriate.

**Workshop Session 3—Research**

Three presentations were made: ‘Experiences from Mitr Phol, Thailand’ by Pipat Weerathaworn (Mitr Phol, Thailand), ‘Experiences from CTC, Brazil’ by Nilson Boeta (CTC, Brazil) and ‘Experiences from BSES, Australia’ by Eoin Wallis (BSES, Australia). Questions raised in the subsequent discussion were:

1. research organisations lead change but how do they ascertain the direction they take?
2. research is an investment not a cost; how can this message best be communicated to stakeholders?
3. human capital is ‘everything’ to a research organisation; how can this resource be optimised for best effect?
(4) how can researchers best influence the strategic intent of an organisation, or vice versa?

(5) research is worthless if results are not implemented; how can technology transfer be improved?

(6) is collaboration relevant in an environment of intellectual property protection?

Some of the salient points emanating from the discussion and questionnaires received were:

Mitr Phol (Thailand) and EID Parry (India) are both large, independent milling companies that own and operate sugarcane research facilities and that make substantial investments in the sustainability of sugarcane supply. This is necessary to maintain the viability of their milling operations because both milling companies are largely supplied by resource-poor small-scale farmers who have been unable to collectively establish effective sugarcane research and sustainability programs of their own.

Mitr Phol (Thailand) started as a single sugar factory and is now a multi-national (significant investments in China), multi-faceted (includes raw and refined sugar, cogeneration, ethanol, paper milling, logistics companies and others) conglomerate, including its Sugarcane Research Centre. The company’s Board of Directors largely dictates strategic direction for the Sugarcane Research Institute within the context of the larger conglomerate, driven by the mandate to maximise shareholders’ profit. The result is a focused and accountable Sugarcane Research Centre involving a wide range of research activities, such as agronomic practices, development of new cane varieties, processing properties associated with different varieties, processing of sugar and ethanol, production of cogeneration and biodegradable plastics, etc. Strategic focus and accountability is more difficult for research organisations that do not have a profit maximisation mandate and/or a relatively homogenous Board of Directors that mostly operate within the context of one organisation.

Research centres that have a governing body comprising individuals from diverse backgrounds with varied interests (e.g. independent miller and grower fraternities) often result in little or no strategic direction being agreed by the governing body and/or increasing reliance on the management team to guide strategy through the ranking and allocation of research funding, with the governing body having an oversight and approval role. However, management teams cannot formulate a strategic research direction effectively if they have to compete with other research organisations for limited funding from numerous funding agencies with different agendas. Strategic research direction can be absent or vague or unrelated to stakeholder profits that often remain confidential. In such an environment, fewer ‘industry’-funded research centres are expected to facilitate better strategic research direction. Without this, industry ‘needs’ are unlikely to be met, resulting in a ‘disconnect’ between industry and the research centres.

This ‘disconnect’, according to most delegates, is prevalent to some degree in most industries. Such ‘disconnects’ can be mitigated by: (1) researching economic value-adding industry ‘needs’; (2) eliminating research on uneconomic industry ‘wants’; and (3) quantifying the economic return of R&D outcomes (i.e. R&D is an investment and not a cost). This can be achieved by employing ‘economic/commercial’ skills at research centres that can better communicate in the ‘language’ of industry. Further mitigation measures include increased participation of stakeholders at strategic stages in the iterative R&D planning process.

Part of the Australian ‘disconnect’ arises from industry’s dissatisfaction with limited productivity improvements arising from R&D, where productivity is defined as tonnes cane per hectare. This is also true of other industries around the world. In this context, research centres need to reinvent their marketing/communication approaches because in the absence of R&D and its associated technology transfer, productivity would otherwise have been in decline, and productivity
benchmarks should be used in conjunction with economic related benchmarks to ensure that research centres speak the same language as industry. Economic benchmarks might be more meaningful, but are more elusive; they require a clear definition and explanation. A growing international trend is to replace historical productivity R&D objectives with a ‘vision of sustainability’, from a collective economic, environmental and social perspective. More attention needs to be given to this topic at future ISSCT Management Workshops.

CTC (Brazil) has a unique challenge in that its membership base and demand for its services is growing at an accelerating rate (CTC had 29 member mills in 2004 and 155 in 2008). Its principal response has been to decentralise its technology transfer operations to: (1) improve response times by reducing travel times (and associated travel costs); (2) improve relationships with local millers and growers; and (3) develop regional specialists to meet regional needs. The disadvantage with this approach is that regionalised technology transfer is isolated from centralised R&D, which CTC have countered by implementing a sophisticated web-based intranet that provides remote web-based training of staff, millers, growers and other stakeholders through e-learning programs and technical seminars. As a consequence, CTC has been able to partially outsource some technology-transfer functions.

Some of CTC’s key focus areas are to: (1) better identify and address sustainability needs of the industry; (2) hire, train and retain motivated staff; (3) foster partnerships and collaboration at all levels of the business; and (4) better market the value of CTC to existing and new potential members.

The effectiveness of technology transfer was raised as a concern in most industries. CTC’s web-based services are appropriate in the current ‘electronic era’, but more sociological research needs to be undertaken to increase the effectiveness of this approach as it is expected to be context specific. A global challenge for technology transfer is overcoming grower perceptions that extension advice is ‘quasi’ academic, having little bearing on the real challenges of growing sugarcane and, therefore, advice is discounted. Context specific web-based services might be helpful in this regard, because technology transfer becomes demand-led as opposed to supply-led!

Workshop Session 4 – Special Projects

Four presentations were made: ‘Biotech sugar crops and their market dynamics’ by Charley Richard (Sugar Processing Research Institute, USA), ‘A strategy to facilitate the commercialisation of GM sugarcane’ by Warren Males (Queensland Sugar Limited, Australia), ‘Managing multiple environmental challenges in Florida’ (Canegrowers Cooperative, USA) and ‘Accreditation for sustainability: proposals for international concern’ by Tim Wrigley (CANEGROWERS, Australia). Questions raised in the subsequent discussion were

1. what can be done to prepare the international sugar market for sugar production from GM sugarcane?
2. what role is there for international collaboration in promoting market access for sugar from GM sugarcane?
3. is ‘consumers are becoming increasingly aware of their environmental footprint,’ a valid statement?
4. what are some of the important environmental challenges facing sugar value chains? and
5. how can ‘better management practices’ be marketed in an effort to promote sugar?

Some of the salient points emanating from the discussion and questionnaires received were:

Potential sugar industry benefits through biotechnology include increased sugar and by-product revenue per tonne of cane, together with increased stability of production, and lower cost of
production per tonne of cane (e.g. weed, pest and disease resistance, drought tolerance, etc.).

Many markets across the globe are sceptical of biotechnology. As a consequence, a Sugar Industry Biotech Council (SIBC) has been established in North America, with its core leadership comprising the American Sugarbeet Growers Association, Beet Sugar Development Foundation and the National Sugar Cane Research Effort. Further representation comprises all North American sugarbeet growers’ associations, sugarbeet processors and marketers, sugarbeet seed companies, beet by-product marketers, sugarcane growers and processors, and technology providers. This entire group meets twice a year, but the leadership has conference calls every second week on issues related to strategic planning, issue management, information development and ‘sugar is the same’ (more about this later).

SIBC provides science-based information regarding technological advances in both sugar beet and sugarcane crops and communicates the broad range of environmental and consumer benefits of these advances. Part of this has included the commissioning of independent and accredited laboratories to scientifically test that there is no difference between sugar derived from GM sugarbeet or sugarcane, and (2) that there is no protein and/or DNA in sugar. The robust and conclusive results were affirmative, demonstrating that ‘sugar is the same’! Managing perceptions is critical.

The area planted to commercial biotech sugarbeet varieties in the US is increasing steadily. Despite the establishment of the International Consortium for Sugarcane Biotechnology (ICSB) in the early 1980s in association with the ISSCT, no commercial GM cane varieties are currently grown anywhere in the world, although South Africa, Brazil, Australia, Colombia, Argentina and the US have experimental plots. Guatemala, Mauritius, India and others are also working towards biotech varieties. A major constraint to the release of commercial biotech cane varieties is how trait providers can release a return from a vegetatively propagated crop. In the absence of commercial seed companies, industry itself needs to bear the commercialisation costs, including lawsuit insurances, countering anti-biotech campaigns and correcting market misinformation, particularly among existing and potential customers.

Commercialisation steps include: (1) obtaining regulatory acceptance in the home country; (2) building acceptance within the industry and developing market support; (3) influencing stakeholder perceptions (industry, consumer and public at large) using factual science-based information; (4) developing segregation and identity-preservation standards and procedures; and (5) facilitating commercial uptake and adoption at the local level. A helpful quote that was made in this context was ‘biotech crop varieties may provide a solution to rising food prices and increasing food scarcity and malnutrition as the world’s population continues to rise’.

With similar objectives as the SIBC in North America, the Australian industry has established the Sugarcane Gene Technology Group to specifically commercialise biotech sugarcane varieties (i.e. separate from the underlying R&D). As ‘sugar is the same’ and the challenges are common, the key to commercialising sugarcane biotech varieties is collaboration. Other industries are encouraged to engage in this process.

Environmental concerns and awareness is increasing in all sugarcane industries but the levels of concern and awareness differ. Such concerns and awareness are particularly acute in the south Florida (US) agricultural landscape where sugarcane contributes 73% of gross value. Current issues include: (1) water quantity and quality including high levels of phosphorus, nitrogen and pesticides; (2) air quality arising from cane burning, ash nuisance and perceived health concerns; (3) use of herbicides and pesticides and their effects on natural flora and fauna; and (4) habitat loss for indigenous species and the increase of exotic species.

The south Florida agricultural community, however, has an impressive history of proactively managing their environment. Various best management practices have been established
and coupled with a comprehensive suite of monitoring and performance evaluation systems. The result is that bird populations are larger, there are similar numbers of fish and more indigenous species of all taxa measured in agricultural fields than in non-agricultural areas. Invasive plant species are intensively controlled.

The Better Sugar Initiative (BSI), in association with World Wildlife Fund (WWF), has embarked upon a best-management-practice accreditation system for sugarcane agriculture internationally. The question was posed whether the ISSCT should be the lead agency in this regard. This was not supported because the nature of environmental concerns varies significantly among industries and within industries and, therefore, a single set of best management practices is not appropriate, and secondly, ISSCT is a voluntary, non-profit body that derives benefits for its members through collaborative activities that are of a non-binding nature. The BSI initiative has the potential for conflict, which might compromise the collaborative objectives of ISSCT. ISSCT, nevertheless, has a significant role to play in the sharing of information.

**Review and future of the ISSCT Management Workshop**

Qualitative and quantitative data were obtained from the workshop questionnaire, with 25 responses (61%) from 10 countries. Figure 1 indicates that all aspects of the workshop were well received.

![Figure 1](image-url)

**Fig. 1**—Impressions of delegates from the questionnaire.

Considerable qualitative data were also forthcoming, some of which was contradictory! The principal criticisms received include:

Presenters need to be encouraged to send their presentations to the organisers earlier so that all the print outs can be made available at the meeting.

The number of presentations should be limited to a maximum of three per session, or fewer, so that discussion time is not compromised and discussion remains topic-focused.

Chairing a discussion requires strong leadership. The chair needs to both challenge the presenters more and draw ‘quieter’ delegates into the discussion. As an aid to providing focus and structure to the discussions, the chair should refer more often to each session’s initial guideline questions, which should facilitate consensus outcomes.
The content of the discussions is valuable and, therefore, needs to be recorded better.

Despite these criticisms, delegates overall were complimentary (as supported by Figure 1) with special mention made regarding the venue, organisation and program including many delegates being complimentary of the session chairs and the outcomes achieved in the discussions. Suggested topics for future workshops include:

The R&D fraternity should drive the agenda in terms of identifying 3–4 R&D priorities for the next 10 years and expose the skills and resources that senior R&D management can use to increase the effectiveness and uptake of their R&D programs.

Sharing the experience and business strategies of large multi-national sugarcane-related companies (e.g. EID Parry and Mitr Phol, but there are many others), together with service providers such as Syngenta/Monsanto, Dedini/Praj, etc, is helpful, particularly with reference to the adoption and role-out of renewable energy (especially co-generation and ethanol). Non-sugarcane related experiences might also be helpful.

Technology transfer and extension need to be revisited, particularly with respect to the increasing trend of ‘traceability’ for compliance to an accredited set of better management practices; e.g. the Better Sugar Initiative (BSI). Determining success and failure factors through case-study analyses would also be helpful in facilitating new implementation/adoption strategies for novel technologies and/or measuring extension efficiency. Benchmarking initiatives also need to be considered.

A session related to human resources was suggested by some delegates and should address issues such as attracting and retaining talent in the organisation, understanding performance management of staff and identifying training needs and training opportunities. Aligned to this is embracing change management within R&D organisations and sugar industries that may need to adapt from sugar to energy industries.

The ‘disconnect’ between R&D organisations and their stakeholders appears to be relatively common and needs addressing. Investigating the use of ‘economic/commercial’ skills that use the ‘language’ of industry needs further investigation, together with increased participation of stakeholders at strategic stages in the iterative R&D planning process.

Alternative cane payments and other incentive mechanisms to optimise delivery of quality feedstock for processing require further investigation, particularly in the context of renewable energy.

Environmental concerns are expected to escalate and should remain on the agenda.
RAPPORT SUR LE SECOND ATELIER DE GESTION DE L’ISSCT – MAI 2008

Mots Clés: Gestion, Atelier de Travail, Recherche, Filière, Marchés, Energie Renouvelable.

Resume
Le second Atelier de Gestion de l’ISSCT s’est tenu à Townsville, Australie, en mai 2008 ; 41 délégués venant de 10 pays y participèrent. Le but des Ateliers de Gestion est d’intéresser les hauts cadres de l’Industrie Sucrière à l’ISSCT et particulièrement d’intégrer la gestion dans la recherche et les nouvelles technologies. L’atelier comprenait des présentations autour d’un thème particulier, suivi de discussions interactives où les problèmes étaient identifiés et les solutions pratiques proposées. Une réunion spéciale pour les Directeurs Exécutifs des organisations de Recherches ainsi que leurs hauts cadres suivit l’Atelier de Gestion. En général, l’atelier fut un succès avec les propositions intéressantes provenant des quatre thèmes : énergie renouvelable, filière, recherches et développement (R & D) et projets spécifiques. Les sujets suggérés pour les prochains ateliers incluent : (1) l’identification de 3 ou 4 projets de R & D pour les 10 prochaines années, (2) les innovations des grosses compagnies sucrières, (3) le transfert de technologie et la vulgarisation devra être redéfini, (4) les ressources humaines doivent être revues afin d’attirer et de retenir les bons éléments dans l’organisation et revoir le type de management, (5) évaluer les talents économiques et commerciaux dans le contexte du R & D, (6) le mode de paiement de la canne en relation avec l’énergie renouvelable, (7) les problèmes reliés à l’environnement.

REPORTE DEL SEGUNDO TALLER DE GERENCIA DE ISSCT, MAYO 2008

PALABRAS CLAVE: Gerencia, Taller, Investigación, Cadena de Abasto o Proveedores, Mercados, Energía Renovable.

Resumen
El segundo taller de Gerencia de la ISSCT que se llevó a cabo en Townsville, Australia en mayo de 2008, atrajo a 41 delegados de 10 países. La Comisión de Gerencia y sus talleres procuran que aumente el rol de la alta gerencia de la industria en la ISSCT, particularmente para que integren aspectos de gerencia en iniciativas tecnológicas y de investigación. El formato del taller comprendió presentaciones sobre un tema en particular, seguido por discusiones interactivas donde los problemas se contextualizaron para buscar soluciones pragmáticas. Después del taller se realizó un foro de CEOs y personal experto de organizaciones de investigación. En general, el taller fue un
éxito con diferentes contribuciones producto de las cuatro sesiones: energía renovable, cadenas de abasto o proveedores, investigación y desarrollo (I+D) y proyectos especiales. Algunos temas sugeridos para los próximos talleres fueron: (1) la fraternidad de I+D debe identificar tres o cuatro prioridades de I+D para los próximos 10 años; (2) la experiencia y estrategias de negocios para las grandes compañías relacionadas con la producción de azúcar deben continuar; (3) revisar las necesidades que existan en transferencia de tecnología y extensión; (4) temas de Recursos Humanos relacionados a atraer y retener talento en la organización y herramientas para el gerenciamiento/manejo del cambio; (5) investigar el uso de habilidades ‘económicas/comerciales’ en el contexto de I+D; (6) estrategias de pago de caña aplicables al paradigma de energía renovable; y (7) temas ambientales.
FUTURECANE—A MAJOR QUEENSLAND EXTENSION INITIATIVE THAT ACCELERATED THE ADOPTION OF IMPROVED FARMING SYSTEMS

KEYWORDS: FutureCane, Extension, Economics, Farming Systems, Yield Decline.

Abstract

In 2004, Queensland Department of Primary Industries and Fisheries (QDPI&F) collaborated with BSES Limited (BSES) to launch a major extension initiative called FutureCane. FutureCane was a three year State-wide extension program with the aims of promoting a sustainable and competitive cane growing sector, facilitating change in the sugar industry and assisting members of the cane growing sector to see a clearer picture of the future. State and regional steering and management committees were put in place to overview and implement the program. The main field focus was the accelerated adoption of new farming system components identified by the Yield Decline Joint Venture (YDJV), including various combinations of legume break crops, controlled traffic and reduced tillage, with an emphasis on profitability. QDPI&F provided the expertise on economics and the agronomy of break crops such as soybean, while BSES provided the expertise on cane growing. Extension methods employed included farm demonstrations, farm case studies and whole farm economic analysis. Baseline surveys were carried out to determine the current practice and progress was reviewed annually. Although uptake was relatively slow initially, the development of a Farm Economic Assessment Tool (FEAT) hastened adoption by emphasising the focus on improved profitability rather than productivity. By 2007, significant areas of cane were being grown under the new farming system throughout the Australian industry. The area using legume break crops increased by 4020 ha, controlled traffic increased by 20 133 ha and the area of reduced tillage plant cane increased by 17 071 ha. The program demonstrated the value of working collaboratively on an industry-wide basis to achieve results. This paper outlines the management structure of the FutureCane program focusing on the Farming Systems module and the practice change that occurred in the Australian sugarcane industry during the period 2004 to 2008.

Introduction

In 2004, the Australian Government unveiled a $444m sugar rescue package for the country’s struggling sugar industry (AAP, 2004). At the same time, the Queensland State Government passed the Sugar Industry Amendment Bill 2004 relating to major reforms for Queensland’s sugar industry, and the State’s sugar package was made available. The State’s package had three focus areas: Sugar Industry Change Management Program ($13 million); Sugar Industry Innovation Fund ($10 million); and a Farm Consolidation Loan Scheme ($10 million). Implementation of the package relied on partnerships between the Queensland Department of Primary Industries and Fisheries (QDPI&F), industry, the Queensland Department of State Development, Trade and Employment (QDSDTE), and BSES Limited. The QDPI&F contribution to the Sugar Industry Change Management Program was FutureCane, which was designed to
promote a sustainable and competitive cane growing sector. Within QDPI&F, FutureCane was regarded as an Adjustment Program likely to have a better longer-term impact than any short-term financial support.

The focus of FutureCane on a more sustainable and competitive cane growing sector was very topical in the Australian industry in 2004. The industry was reeling from the impact of low sugar prices and low sugarcane yields partly due to yield losses from the disease orange rust (Magarey et al., 2003).

Juffs et al. (2004) reported a general perception within the industry that the existing framework and direction of research, development and extension of results appeared not to be delivering best practice and innovation or achieving an acceptable rate of adoption. This led the CSR Company to engage management consultants, McKinseys, to guide the Cane Productivity Initiative, a major group extension project based on adult learning principles, in CSR mill areas.

Vanclay (2004) cited 12 legitimate reasons for non-adoption of new technology for natural resource management among Australian farmers: (1) Too complex; (2) Not easily divisible into manageable parts; (3) Not compatible with farm and personal objectives; (4) Not flexible enough; (5) Not profitable; (6) Capital outlay is too high; (7) Too much additional learning is required; (8) Risk and uncertainty is too great; (9) There is conflicting information; (10) Don’t see that there is a problem (lack of appreciation of the problem); (11) Lack of physical infrastructure; (12) Lack of social infrastructure.

Sundermeier et al. (2009) surveyed farmers in the Western Lake Erie Basin Watershed in Ohio, USA and found growers adopted conservation tillage because it saved time and fuel. Extension was made more effective by recognising economics and using the popular press when delivering findings.

Declining sugar yields in Australia had been recognised since the early 1990s, when the sugar industry became concerned that sugar yield per harvested hectare had reached a plateau and was declining. This prompted the formation of the Yield Decline Joint Venture (YDJV) in 1993 to identify causes of yield decline and develop solutions to it (Garside et al., 1997).

During the period 1970 to 1990, the sugarcane cropping system in Australia had become much more intensive with a general move to more ploughout-replant with frequent, aggressive tillage and less area fallowed (Willcox et al., 2000). The more intensive cropping system also coincided with the introduction of larger harvesting and haulout equipment, which normally had track widths wider than row spacing, thereby increasing soil compaction (Kidd et al., 2007).

Work during the first seven years of the YDJV showed that breaking the sugarcane monoculture using grain or green manure legume species (Garside and Bell, 2001), reducing compaction (Braunack et al., 2003a) and minimising the amount of tillage during the fallow and in-crop (Braunack and Magarey, 2002) can individually increase the productivity of the subsequent sugarcane crops, improve soil health and rainfall capture (Bell et al., 2001) and reduce production costs (Braunack et al., 2003b).

Perhaps more importantly, results were also suggesting the synergistic effects on productivity and profitability of successfully integrating these individual components into a new farming system (Bell et al., 2003; Garside et al., 2004). However, while confidence in the ability to design a more profitable and productive sugarcane cropping system was growing, adoption of the key components of the new farming system was very slow.

In October 2004, the YDJV held three regional workshops with extension officers and farmers throughout Queensland to update industry on their findings and to hear problems being encountered in the adoption of the new farming system (Agnew, 2004, Pers. Comm.). The YDJV workshops identified the 12 top issues that were knowledge gaps hampering the adoption of the new farming system as:
(1) Cane varieties to suit wider row widths;
(2) Economic comparison between controlled traffic systems and existing systems, including case studies of farms that have made the change;
(3) Canegrub management;
(4) Marketing and communication plans;
(5) Harvesting issues including effects on cane loss, extraneous matter and soil compaction;
(6) Extension officers’ agronomic knowledge of the break crops such as soybean;
(7) Weed control and herbicides applicable to the new farming system;
(8) Application of controlled traffic for furrow irrigation systems in the Burdekin;
(9) Dynamics of soil moisture;
(10) Precision billet planter;
(11) Maintaining soil health/microbes, including growers understanding of soil health;
(12) Compaction impacts over time in controlled traffic situations.

The establishment of FutureCane

The FutureCane extension project was established in 2004 as the Queensland Department of Primary Industries and Fisheries’ (QDPI&F) $5.2m contribution to the State Sugar Package, and was timely as it helped to initiate a major roll-out of the YDJV research findings.

The task of the FutureCane project was to bring together people with the skills to put together and implement a program of work to overcome the knowledge gaps identified by the YDJV workshops and provide the economic information to hasten the adoption of the improved farming system. The project team combined the expertise of farming systems agronomists, agricultural economists, and trade and business development officers to meet specific needs of Queensland sugarcane farmers. The FutureCane project was structured such that QDPI&F and BSES Limited staff members worked in partnership to deliver services, each providing their unique skills in a complementary manner to the sugar industry.

FutureCane was set up as a three year State-wide extension program with the aims of promoting a sustainable and competitive cane growing sector, facilitating change in the sugar industry and assisting members of the cane growing sector to see a clearer picture of the future. Outcomes envisaged were:

(1) Understanding within the delivery team of farming systems Best Management Practice for cane production in each of the four growing areas across the State;
(2) Raised awareness of the benefits of adopting a farming systems approach;
(3) Design and development of a workshop program to build understanding of benefits, costs and risks of moving to a farming systems approach;
(4) Growers with a better understanding of benefits, costs and risks of moving to a farming systems approach; Growers with the capacity to make necessary changes to their system;
(5) FutureCane services delivered in partnership with other service providers, and in conjunction with other sugar related programs.

The project was overviewed by a FutureCane Steering Committee chaired by the Executive Director Industry and Investment, QDPI&F. The Steering Committee had representatives from BSES Limited, Queensland Department of State Development and Innovation, CANEGROWERS,
Department of Natural Resources, Mines and Energy, Queensland Environmental Protection Agency, Sugar Research and Development Corporation (SRDC) and the Australian Sugar Milling Council. The FutureCane project leader and the FutureCane strategy coordinator were also members of the Steering Committee.

The FutureCane State Operational Plan had ten key Strategic Areas/Sub-Projects:

1. Program management;
2. Farming systems;
3. Establish Regional Delivery Service/Staff Training;
4. Communications Strategy;
5. Industry Liaison;
6. Business Planning;
7. Change Management;
8. Industry Structures/Business Alliances and Partnerships;
9. Industry Reform and Adjustment Support;
10. Trade and development/Marketing.

A FutureCane Management Committee was also established, principally to coordinate the activities of BSES Limited extension officers and QDPI&F agronomists in the Farming Systems Sub-Project. The Committee was chaired by the Adjustment Program Coordinator from QDPI&F, and consisted of QDPI&F and BSES FutureCane project leaders, representatives of the YDJV and the relevant research program leaders from both agencies.

Farming Systems focus

Hastening the adoption of the improved farming system identified by the YDJV was the principal focus of the FutureCane project. While the improved farming system had the potential to increase the productivity of the subsequent sugarcane crop, improve soil health and rainfall capture and reduce production costs, there was also opportunity to diversify farm incomes and improve farm profit by growing break crops such as soybean for grain in some districts (Garside and Bell, 2007).

The key Actions in the FutureCane State Operational Plan under the strategic area, Farming Systems, were:

- Inform key stakeholders and cane farmers about FutureCane (its services and benefits) and appropriately involve them in the local needs analysis assessment for FutureCane,
- Identify all activities and stakeholders involved in the same field of FutureCane activities in each regional delivery area e.g. CANEGROWERS, Millers, Central Agencies, SRDC, Productivity Boards,
- Provide clients with easy access to technical expertise,
- Provide, where appropriate, one-on-one support, particularly in new areas with ‘early adopters’.
- Develop a specific Farming Systems Educational module which was linked to existing and proposed business planning activities,
- Develop region specific economic models of farming systems,
- Develop a Sugar enterprise activity plan involving a change in the farming system,
- Document current knowledge relating to best farming systems practice in cane production for each growing area,
- Provide FutureCane staff with ongoing technical support from other units within QDPI&F (e.g. Plant Sciences, Bio-security),
- Provide access to technical expertise on complementary crops, including crop agronomy, marketing opportunities and gross margins etc.
- Provide cane farming clients with ongoing support through appropriate use of discussion groups/cell groups and/or other processes,
• In each region, identify or establish groups of growers, advisers, cane productivity companies and consultants to implement and assess proposed changes to sugarcane farming systems,

• Establish one on-farm commercial paddock in at least three of the Mill areas where all components of the new farming system (permanent beds established at spacings to enable controlled traffic adoption, fallow cropping, min./zero tillage planting of cane and legumes) were adopted,

• Initiate on-farm R&D programs to develop confidence in the practicality and benefits of systems change and facilitate adoption,

• Assist landowners with the growing of complementary crops outside their experience and assess their financial performance,

• Gross margins for complementary crops developed and incorporated with marketing information for publication,

• Conduct field days, workshops and bus tours as extension tools for rotational cropping and tillage practices,

• Promote farming systems at external field days,

• Develop a Newsletter to promote activities, YDJV results and ongoing extension activities or provide FC supplement to existing regional newsletters.

**Industry Liaison Officers**

The Queensland Government (Palaszczuk, 2004) recruited Industry Liaison Officers (ILO) as local ‘sugar industry champions’ in each district. ILOs had networks in their local sugar industry and worked with the FutureCane teams to promote FutureCane activities, gather local information on sugar industry needs. They also helped to identify opportunities for collaboration between different sectors in the industry and organised venues and resources for FutureCane activities.

**Local Management Groups**

Local Management Groups (LMG) were set up in each of the four cane growing areas: Far North; Herbert/Burdekin; Mackay; South East Queensland. Staff involved in the LMGs included Business Development Officers, QDPI&F agronomists, BSES extension officers, Industry Liaison Officers, Agricultural Economists, Financial Counselors and Trade and Market Officers. The LMGs developed work plans for each area in conjunction with local industry and overviewed their implementation.

**Results and discussion**

FutureCane officially commenced in July 2004, although many staff started in November 2004 and the last staff member did not commence until May 2005. While this late start meant there were missed opportunities during the first year, workshops were held throughout the State in conjunction with the YDJV team to promote a common understanding of the improved farming system. This saw a development of momentum for the project that encouraged farmers to look at new farming systems.

During the first year, there were some concerns that increasing the area fallowed may decrease overall production from a mill area and therefore threaten mill economic viability. These fears were largely allayed by developing a key message that ‘Profitability will be followed by Production’.

In the long run, improving the profitability of the cane growing enterprise by growing cash break crops in the fallow should make the cane growing business more sustainable and reduce the losses from land not growing cane.
These concerns expressed early in the project highlighted the need for the group to be able to clearly demonstrate the impact of changing farming systems on farm profitability. From a farmers viewpoint (Loeskow et al., 2006), the major impact of some of the components of the improved farming system was to reduce costs. Minimal tillage reduced fuel costs, legume break crops reduced nitrogen fertiliser usage and good fallow management reduced weed control costs for the sugarcane enterprise. To demonstrate the impact of these changes on farm gross margins and profitability, the Farm Economic Analysis Tool (FEAT) was developed by FutureCane economists (Stewart and Cameron, 2006).

FEAT was developed primarily to compare the economic performance of different cane farming systems. The tool does this by calculating several different economic performance indicators used in the agricultural sectors, e.g. gross margins, break-even yields and prices etc, and presents them in a whole-of-farm context. The focus of the tool is to look at Return on Investment when minor or major changes are made to the farming system.

FEAT was used to conduct a number of Case Studies (e.g. Halpin et al., 2008) and was also used extensively by FutureCane extension officers and agronomists. Copies were also made available directly to growers wishing to compare a number of farming system options using their own data. Much of the success of the FutureCane project was due to the widespread availability of FEAT, which allowed demonstrations of the savings that accrued from reduced tillage and the overall value of the increased income from grain legume break crops. This capacity was especially powerful when combined with ‘personalised’ data relating to farms within an individual growing area, or in many cases with data from the investigator’s own property.

Cane growers traditionally have made decisions based on production rather than profitability. When they saw little change in production as a result of the change in farming system, they tended to be reluctant to adopt it, not realising that the biggest impact was in profitability not production. FEAT overcame this problem.

Mid-term review

A mid-term review of the FutureCane project was commissioned to assess the performance of the project and outline areas for improvement and modification. The review was carried out in May 2006 and reported that ‘FutureCane is performing well, delivering benefits to the industry and challenging those who are listening. It would also be fair to say it is doing remarkably so, given its very short life.’

The reviewers also noted that ‘Its success is related to: (1) good leadership and management; (2) high quality staff; (3) a good working relationship between the participating agencies; (4) clear dovetailing of FutureCane with other industry programs; (5) a robust information base; (6) useful tools; (7) diverse and appropriate methods; (8) a main focus on industry progressives’.

The mid-term review suggested a number of changes to improve or modify the project, with the FutureCane Steering Committee endorsing a series of actions to facilitate change implementation. Specific recommendations were as follows -

- Improved consultation with all stakeholders at the levels of Steering Committee and regions.
- Facilitate reviews of the report by all regional groups so they may identify and commit to ways of improvement most suitable to their circumstances.
- Explore the feasibility and desirability of aggregation of the BSES part-time contributions into full-time commitment.
- Development of a strategic communications program to ensure all influencers are well aware of FutureCane, its bases and objectives, to widen awareness and encourage change by all growers, and record learnings of the project to date so that successors may be supported through them.
• Continue to support the first tier of innovators so they may implement the changes, and co-opt their support in reaching out to the growers who are sensitised but not yet changing.

• Consider establishment of, for example, awards for profitability and innovation, funded by industry or allied commercial interests.

• Continue to challenge growers by use of activities which take them out of their own circumstances, and expose them to relevant things outside their business, such as through bus tours to other areas and other industries.

• Look for and use all available ‘hooks’ to attract attention of growers, such as succession planning, the lifestyle benefits available from adoption of FutureCane recommendations, high fuel costs, water scarcity etc.

• Capitalise on interest in farm systems to introduce business analysis and management, and vice versa.

• Work with industry agencies to undertake an industry-wide benchmarking exercise to underpin and encourage ongoing beneficial change.

• Help build the capacity of all service providers so they may encourage and assist growers to change.

• Design and offer programs of activities for specific groups within the grower segment e.g. new and younger growers, women, large farms etc.

• Continue development and promotion of FEAT.

• Strengthen FutureCane’s attention to natural resource management and forge collaborative arrangements and activities with relevant agencies and groups.

• Undertake a risk analysis of the supply chains of the various complementary crops suitable as break crops, so to identify gaps and plan for their remediation.

• Review and redirect the activities of the ILOs to gain higher value through better matching of their skills to industry needs.

• Ensure all staff were fully familiar with the YDJV results as they continue to build through ongoing research, including FutureCane trials.

• Consider providing staff with the opportunity to enhance their capabilities in facilitation of change management and capacity building.

• Manage the risks associated with the identified threats to the project.

**Farming system change**

The level of adoption of new farming system principles in the various cane growing regions was monitored throughout the project. The area of fallow legumes, controlled traffic and zonal tillage in 2007–08 compared to 2003–04 is shown in Table 1.

The area of fallow legumes increased most markedly in southern Queensland, due largely to the development of soybean and peanuts as grain crops. This development was aided by the initiation of projects such as Grain in Cane (Bundaberg CANEGROWERS) and the involvement of local agribusinesses, as well as through the extension activities of FutureCane.

The negative result in the Burdekin was largely a seasonal effect due to wet weather and a late finish to crushing in 2007, which left little opportunity to establish break crops before the onset of the wet season.

The area of ‘controlled traffic’ was measured by quantifying the area planted to row widths of 1.8 m or greater, row spacings that effectively matched the wheel spacings of harvesters and haulouts.

While some of this area was established without the benefits of GPS guidance, most of it was and, during the period, a system of base stations necessary for differential GPS was set up in all areas.

The subsequent adoption of auto-steer using GPS guidance on planters, tractors, harvesters and haulouts is still continuing.

The area of zonal tillage (reduced tillage) increased in all areas. While central Queensland appears to be behind in terms of growth in zonal tillage, this changed significantly in 2008–09 with large areas planted using reduced tillage system.

**Arrival of sugarcane smut—a further catalyst for change**

The sugarcane smut disease was detected near Childers in June 2006 and by November 2006 had also been found in Mackay. The economic impact of sugarcane smut on the Queensland sugar industry was assessed and ways to facilitate economic recovery were identified in a report tabled in Parliament in February 2007 (Watson, 2007).

Recommendation 6 of this report stated that the FutureCane FEAT model should be made available to all growers and be backed by sufficient technical support to implement this decision tool effectively. The FEAT model was also able to assist in the broader on-farm agronomic decisions required to maintain economic viability as growers transitioned to resistant varieties.

The recommendations from the Watson Report saw the FutureCane project superseded by the Sugarcane Smut Economic Recovery Strategy in July 2007. Skills and resources developed as part of FutureCane were redirected to help growers prepare for and recover from the smut outbreak (Gillard, 2008). The Queensland Government committed $3 million over three years to:

- Support access to, and training in, economic decision-making tools such as FEAT to assist in complex decision making required to change over to smut-resistant varieties over the next few seasons
- Extension of the best farming systems practices to assist farmers in maximising soil health, minimising input costs and managing the transition to smut-resistant varieties.

**Reasons for FutureCane’s success**

The principal reasons for success of the FutureCane project were:

- Staff from the respective agencies working together to deliver quality advice on both the break crop and sugarcane components of the improved farming system. QDPI&F agronomists brought knowledge of break crops such as soybean and peanuts to the project and BSES Limited extension officers contributed knowledge of cane growing. Knowledge was shared at regular regional and State-wide meetings and through cooperation in the delivery of extension activities.
• The guidance of the YDJV team was also a key component in the correct interpretation of research results as they came to hand throughout the project. The inclusion of YDJV representatives on the FutureCane Management Committee was the key to the close working relationship that developed.

• The development of the FEAT computer program to demonstrate the impact of farming system changes on farm profitability. Many of the benefits of the improved farming system were cost savings with sometimes little overall increase in farm sugarcane production and were therefore difficult to demonstrate. FEAT gave extension officers and growers a tool to explore options.

• The inclusion of Industry Liaison Officers in local management groups gave the local industry more ownership of the project. The ILOs used their local networks to encourage more growers to attend FutureCane extension activities.

What could have been done better?

The mid-term review highlighted some areas where the project could have been better implemented, with the key areas involving relationships with local industry in the early stages of the project. For example, some local sugar industry groups felt that they had little input into the direction of the FutureCane program in their area.

Some millers felt that the emphasis on break crops meant there would be less sugarcane to crush. Some CANEGROWER groups felt that agencies external to the sugar industry (i.e. QDPI&F) were attempting to gain the kudos for work already commenced by the industry in some regions.

More involvement of local industry in the formative stages of the project would have given local industry a clearer view of the objectives of FutureCane and the project would have received local support much sooner. As it was, the support was earned through the successes of the project.

Résumé

En 2004, le Département des Industries Primaires et des Pêcheries du Queensland (QDPI & F) a collaboré avec le BSES Limited (BSES) pour lancer une initiative majeure de vulgarisation appelée FutureCane. FutureCane est un programme de vulgarisation de trois ans concernant tout le Queensland avec les objectifs de promouvoir une industrie sucrière durable et compétitive pour faciliter le changement et d'aider les planteurs de canne à avoir une meilleure vision de l'avenir. Des comités de direction et de gestion nationales et régionales ont été mis en place pour avoir une vue d'ensemble et mettre en œuvre le programme. L'objectif principal dans les champs était d’accélérer l'adoption des nouvelles pratiques culturales identifiées par le comité de Recherche sur la Baisse de Rendements (YDJV), incluant les différentes combinaisons de cultures de légumineuses, le contrôle du trafic et la réduction du travail du sol, en mettant l'accent sur la rentabilité. QDPI & F s’est occupée de l'économie et de l'agronomie des autres cultures telles que le soja, tandis que BSES a fourni l'expertise sur la culture de la canne à sucre. Les méthodes de vulgarisation employées comprenaient des démonstrations sur les fermes, des études de cas individuels et des analyses économiques globales. Des enquêtes de base ont été menées pour déterminer la pratique actuelle et le progrès a été revu chaque année. Bien que l’adoption du nouveau système a été relativement lente au départ, le développement d'un instrument d’évaluation économique pour les fermes (FEAT) a accéléré l’adoption en mettant l'accent sur une amélioration de la rentabilité plutôt que sur la productivité. En 2007, d'importantes superficies de canne à sucre ont été cultivées avec le nouveau système à travers toute l’industrie cannière australienne. La superficie sous culture de légumineuses en rotation a augmenté de 4020 ha, le contrôle du trafic a augmenté de 20 133 ha et la superficie replantée avec une réduction du travail du sol a augmenté de 17 071 ha. Le programme a démontré que le travail de collaboration entrepris sur une base à l'échelle industrielle a donné des bons résultats. Ce document décrit la structure de gestion du programme FutureCane en se concentrant sur le module des nouveaux systèmes agricoles et le changement qui s'est produit dans l'industrie australienne de la canne à sucre pendant la période 2004 à 2008.
FUTURECANE—UNA INICIATIVA DE EXTENSIÓN MAYOR EN QUEENSLAND QUE ACELERÓ LA ADOPCIÓN DE SISTEMAS DE MANEJO DE CULTIVO MEJORADOS

Resumen

En 2004, el Departamento de Industrias Primarias y de Pesca de Queensland (QDPI&F por sus siglas en inglés) colaboró con BSES Limited (BSES) para lanzar una iniciativa de gran extensión denominada FutureCane. FutureCane fue un programa de extensión estatal de tres años que se realizó con el objetivo de promover un creciente sector cañero que fuera sostenible y competitivo, facilitando el cambio en la industria azucarera y apoyando a los miembros de este pujante sector para que visualizaran una imagen más clara del futuro. Se establecieron comités estatales y regionales de dirección y manejo para dirigir la implementación del programa. El enfoque principal en campo fue la adopción acelerada de algunos componentes de los nuevos sistemas de cultivo identificados por el Esfuerzo Conjunto de Caida de la Productividad (Yield Decline Joint Venture, YDJV, en inglés) incluyendo varias combinaciones de cultivos de leguminosas de rotación o intermedios secuenciados entre cosechas, control de tráfico y prácticas culturales reducidas, con énfasis en la rentabilidad. QDPI&F proporcionó el expertaje en economía y agronomía de cultivos intermedios como la soya, mientras el BSES proporcionó su experiencia en el cultivo de la caña. Algunos de los métodos de extensión que se emplearon incluyeron: demostración en los campos, estudios de caso de fincas y análisis económicos completos de las mismas. Se realizaron encuestas de línea base, donde se determinaron las prácticas originales y se llevó un monitoreo del progreso anual. Aunque la respuesta fue muy lenta al principio, el desarrollo de una herramienta de monitoreo del campo (Farm Economic Assessment Tool, FEAT en inglés) apresuró la adopción al hacer énfasis en el enfoque de mejorar la rentabilidad en lugar de la productividad. Para 2007, se estaban cultivando áreas significativas de caña bajo el nuevo sistema de cultivo en toda la agroindustria australiana. El área con leguminosas se incrementó en 4020 ha, el control de tráfico se incrementó en 20133 ha y el área de prácticas culturales reducidas en caña se incrementó por 17071 ha. El programa demostró el valor de trabajar en colaboración a nivel de toda la industria para obtener los resultados. Este trabajo describe la estructura del manejo del programa FutureCane enfocándose en el módulo de Sistemas de Cultivo y el cambio de práctica que ocurrió en la agroindustria australiana en el período entre 2004 y 2008.
FUTURES BASED PRICING FOR AUSTRALIAN SUGARCANE GROWERS

By

BERNARD MILFORD and WARREN MALES

CANEGROWERS Australia and Queensland Sugar Limited
Bernard_Milford@canegrowers.com.au

KEYWORDS: Futures, Pricing, Growers, Restructure.

Abstract

AUSTRALIAN cane growers can now access futures based pricing for their sugarcane. Direct access to futures market pricing has long been available to growers of commodities such as grains, cattle, cotton and others. Some sugar processors have had access to these mechanisms but, in situations where cane growing and processing are separate, cane growers have traditionally been unable to hedge the price they receive for their product as unprocessed sugarcane is not deliverable against a futures contract. In Australia, many growers have recently commenced using futures based pricing mechanisms through new cane supply contracts with their sugar mills. Tonnages of sugar are apportioned to growers based on the cane price formula. Pricing contracts are ultimately closed through the pricing platform offered by the raw sugar marketing company. In this paper the range of price mechanisms available to cane growers in Australia are examined and the implications of these for industry sustainability are reviewed. These include a new, more commercial culture, longer-term cane supply contracts, growers’ ability to manage pricing decisions in light of their knowledge of growing costs and determine, to some degree, how much of the price risk they wish to manage and how much they wish to place in the hands of others.

Introduction

Contracts describing price, quantity, quality and delivery conditions are a common feature of most, if not all, sales agreements. The international commodity trade in raw sugar is no different. Some agreements include provision for fixed price sales. However, the majority of contracts include provision for futures based pricing.

In these contracts, the price has a futures based element, a component for a physical sale premium or discount and an adjustment for the pol of the sugar. Futures based pricing enables the buyers and sellers to independently manage their exposure to the world raw sugar price, using the raw sugar futures contract on the Intercontinental Exchange, known as the ICE #11.

Raw sugar sellers hedge their price exposure by taking short (sold) futures contracts and buyers by taking long (bought) futures contracts. At the time of physical sale, the buyers and sellers agree on a futures contract against which the price for the physical raw sugar will be settled and

1 The price clause of a raw sugar sales contract would typically be:
‘The price in U.S. Dollars per metric tonne net shipping weight in bulk basis 96 degrees shipping polarisation, Cost and Freight free out ex vessel’s holds at (Port), (Country), with all costs of discharge for the Buyer’s account shall be:
An AA transaction for (No. of pricing lots) lots versus the ICE #11 Futures Contract in the (Month) (Year) position, plus a premium of U.S. Dollars (amount) per metric tonne. The price to be converted to U.S. Dollars per metric tonne by multiplying by a factor of 22.046.’
agree on a mechanism to close their futures positions. In this transaction, the gain or loss made on the futures account when the contract is closed is offset against the sales price. The net price achieved by the buyer and seller is the price at which they hedged the raw sugar. Through this futures market pricing mechanism, the price achieved by the buyer can be very different to the price obtained by the seller.

The use of futures markets to manage price risk is a key feature of farmer activity in the grains, cotton and other agricultural industries. In these industries, farmers harvest a crop that can be delivered in settlement of their relevant futures contracts. In the sugar industry this is not the case. Sugarcane and sugar beet growers produce perishable agricultural products that need further processing into either raw or white sugar before commodity trade can occur. In most instances, the processor pays the farmer for the sugarcane or sugar beet received and arranges the sale of the sugar produced. Many countries regulate their sugar market, including the relationship between sugar prices and farm gate prices, which may reduce the need for farmers to manage their own price risk. However, where farmers are exposed to the world raw sugar price, regulatory structures can reduce farmers’ ability to use the futures market to match their price and production risk with their individual risk profile.

In Australia, commercial agreements, not government regulation, determine the relationship between cane growers and the raw sugar mill they supply. Although cane supply agreements vary, in all mill areas the price of sugarcane is a function of the raw sugar price. In recent years, Queensland Sugar Limited (QSL), the company that sells 95% of Australia’s raw sugar exports, has entered agreements with its mill supplier customers and developed a pricing platform that enables mill owners and, with new cane supply agreements, their cane suppliers, to independently manage the ICE #11 component of the price they receive for up to three years ahead.

Introduction of a new QSL pricing platform

In Australia, as in most other countries, cane growers sell the cane they produce to a sugar mill. Legal ownership of the cane changes hands from grower to miller at the ‘point of delivery’, generally a rail siding or road transport loading point close to the farm. From this point, the mill owner is responsible for the cane and owns all products from it.

The price the mill owner pays for the cane is a function of the price of sugar and the sucrose content of the sugarcane. In Australia, sucrose content is measured as the CCS. The cane price formula takes the following form:

\[ \text{Price cane} = \text{Price sugar} \times \text{fn(CCS)} \]

This formula means that, although the grower is not the owner of the sugar, he or she is still vitally interested in the price outcome achieved from the sale and marketing of the product.

The price of sugar used in this formula was traditionally the average net sales price realised by QSL from its pooled marketing activities. QSL actively managed the marketing and pricing of the entire crop, including the ICE #11 component based on a risk management strategy determined by the company’s board.

Mill owners all received the same price for sugar sold by QSL and this price was, in turn, used to calculate cane values. With sugar price risk managed by QSL, individual producers’ production decisions focused on cost minimisation and productivity improvement. Producers did not have a mechanism to effectively tailor management of their exposure to sugar prices to their individual risk profiles and, when the opportunity arose, to lock in long-term prices.

---

2 Often using ‘against actuals’ (AA) transactions where buyer and seller agree a price at which to close their respective futures positions.

3 Commercial Cane Sugar (CCS); an empirical measure of recoverable sugar in cane.

4 Average net price = \([\text{Gross sales revenues (ICE #11 + pol premium + physical sales premium)} - \text{QSL’s costs (marketing, storage and handling)}] ÷ \text{tonnes of sugar sold, expressed in AUD/tonne IPS.} \)
In 2005, the marketing of Queensland raw sugar was totally deregulated and all mill owners, with two exceptions, signed voluntary contracts to continue to sell all their export sugar through QSL. Building on past experience, taking advantage of the new raw sugar supply agreements that replaced the regulatory structures and relying on its sound financial structure and strong credit rating, QSL developed a new pricing platform, in conjunction with its supplier customers. Enabling the separation of price risk management from the physical marketing of raw sugar, this platform provides a mechanism that allows mill owners to manage a large part of their ICE #11 price exposure in both the current and future seasons. Most mills have made arrangements for their growers to access these facilities.

In order for mill owners and cane growers to use these pricing mechanisms, several risks have to be managed. The first is contractual; if parties are pricing into the future there must also be agreements for supply of the physical sugar over the same time period. This is achieved by supply contracts that extend at least as far as three years forward. Many cane supply contracts with mills are now ‘evergreen’, rolling agreements that remain in place for three years or more unless notice is given of their termination.

Production and financial risks must also be managed. If sugar has been priced into the future, that sugar must be physically available and the counterparty financially sound. QSL’s agreement with mills requires that, to take account of possible variations in the crop due to adverse weather events or disease, no more than 70% of the current season’s sugar be priced using its pricing mechanisms and a declining proportion of future expected crops be hedged. Mills, in turn, restrict growers’ access to pricing to no more than 60 to 70% of their crop for the current year and 30 to 50% for future years, with some variations put in place to allow for individual circumstances. The balance of production for the current year is supplied to QSL’s Seasonal Pool.

Lastly, exposure risk is to be managed. Raw sugar futures, trading on the InterContinental Exchange, sell in four main contracts; March, May, July and October^5. The Queensland sugar industry has made a significant investment in bulk raw sugar storage capacity to provide it with the ability to export sugar throughout the year. As shipping proceeds year-round, exposure to the four main ICE contracts can be managed year round.

Normal variability in crop production and sales patterns can lead to variability in the tonnage of sugar that is exposed to different ICE #11 futures contracts. QSL’s pricing platform is designed to quarantine its mill supplier customers from changes in this exposure. This is done by guaranteeing participants a fixed exposure pattern of 1:2:2:1 against the July, October, March and May contracts for the sugar they elect to price, a portion of their total production up to certain limits.

The balance of sugar is priced by QSL in the Seasonal Pool. All producers supply some of their sugar to this pool and QSL manages the exposure volatility arising from changes in production and sales patterns in this Seasonal Pool. In this way the pricing platform does not impact on QSL’s marketing activities.

The 1:2:2:1 pricing ratio means that pricing participants must have a minimum of six lots to trade. As the lot size on the ICE #11 contract is 50 short tons raw value, the minimum parcel that can be dealt with is 300 tonnes of sugar, equivalent to around 3000 tonnes of growers’ cane. As noted, mills impose limits on the pricing activities of their supplying cane growers, requiring that they contract no more than 60 to 70% of their crop for the current year and 30 to 50% for future years. This means that that, typically, a grower needs to produce over 10 000 tonnes of cane to participate on their own account, well above average production of 8184 tonnes of cane (Hooper, 2008). Mills have used the mechanisms available through the QSL pricing package to provide growers with a means of accessing the futures price risk management mechanisms.

^5 A January contract is also traded, but is not used extensively by the trade.
The QSL pricing platform offers a number of close out mechanisms to its mill supplier customers. Mills can price directly or through a bank that offers ‘over the counter’ products (OTCs) to provide access to the futures market and to credit. Where pricing is done directly participants face the possibility of margin calls (initial and variation); the requirement that money be lodged with the market operator to cover potential losses through price movements. In a period of rising prices, these can represent demands for considerable funds. In general, the pricing mechanisms offered to growers do not expose them to the requirement to fund margin calls. The margins are met by either the marketing company (QSL) or by banks who provide OTC pricing instruments and who, for a fee, assume the risk of margin calls.

In each case, mills close their futures position using the QSL pricing platform. Mill owners have likewise made available to growers a range of futures price risk management mechanisms. These can be generally classified as target price pools, call pools and grower managed pools.

Target price pools are the most popular. They allow growers to amalgamate their positions to bring trades up to minimum tonnages. Typically, mills offer growers the opportunity to price at a range of price targets set at increments of around USD 15 per tonne of sugar, expressed in AUD terms.

Growers nominate a quantity of sugar that they wish to commit at each level and, if there is sufficient sugar to meet the minimum tonnages set, the pricing order is placed. When and if the sugar price reaches this target, the contracts are priced and the sugar is hedged. Target pricing allows amalgamation of commitments so that problems with minimum tonnages can be overcome.

A ‘Call Pool’ is another mechanism some mills offer. Growers nominate a tonnage of sugar that corresponds to a multiple of the minimum number of contracts available for each contract month. They then undertake to notify the mill to price each of these contracts at a time of their choosing over the period within which these contracts are open. This allows the growers great flexibility in managing their price risks in relation to the market. This type of arrangement is subject to the minimum cane tonnages discussed above and therefore is available only to growers producing large quantities of cane.

Alternative Pools are offered by some mills. These provide growers with the opportunity to join a collective pool with a different pricing philosophy to that of the QSL Seasonal Pool. In some mill areas, growers have an opportunity to access QSL’s Aggressive Pool. Some groups have engaged independent brokers to undertake pricing on growers’ behalf, based on agreed pricing rules.

In other mill areas, representatives of growers set transparent targets relating to tonnage and price for a growers’ collective pool. A pool manager undertakes pricing when these targets are achieved. In these cases, target pricing is backed up by index pricing (pricing the same amount of sugar at regular intervals) over a defined period.

In Australia, payment for cane occurs progressively throughout the year, with up to 60% of the estimated final pay being made during the crushing season and the rest progressively over the following six months. Typically grower payment adjustments that result from pricing activity are included in the final ‘wash up’ payment made for that season.

Implications of the new arrangements

The new contracts were developed through commercial negotiation; normal commercial considerations provided the impetus. There was no external (government or regulatory) intervention.

The replacement of regulations with commercial contracts for the supply and delivery of raw sugar have enabled the development of QSL’s new pricing platform and new contracts between cane growers and mill owners for the supply of cane have improved commercial structures along the supply chain. A new, more commercial culture is emerging as producers exercise greater management of their profitability by taking greater control of both their revenue and cost flows.
Longer-term cane supply contracts have been developed. In the previous regulated environment, cane supply arrangements could change annually. As noted above, growers now contract to supply over periods from three to five years; many of these are ‘evergreen’, rolling contracts that require three year’s notice for their termination. As well as enabling forward pricing, the agreements put a contractual underpinning to district production, enabling both parties to plan ahead, knowing that cane is contracted for supply and the mill contracted to crush into the future. This provides an important basis for planning and development of infrastructure within a region. It has also allowed growers better access to finance; banks are more willing to lend for expansion if it can be demonstrated that a proportion of the farmer’s returns can be assured.

A further positive outcome of the availability of futures pricing for growers is the fundamental benefit of being able to manage their pricing decisions in light of their knowledge of growing costs. When prices are high, an understanding of the market fundamentals and drivers of future price movements will assist a grower in determining a suitable time to price their product. In times of intermediate prices, a grower’s understanding of his or her costs will inform profitable pricing decisions. Even if it were felt that the market may move higher, some might choose to cover a proportion of production at prices seen as remunerative, in case price movements were not as expected. In a low price environment, the use of the pricing mechanisms may help manage expected income levels, which may help capture profitable opportunities and ameliorate any losses.

Bringing an understanding of price drivers and possible future price movements to growers can be challenging, but represents an opportunity for service providers. In the previous regulated environment, pricing and marketing was carried out by a single statutory body; producers received a pool price and had little influence on price outcomes achieved. The new structures mean that producers are no longer interested bystanders, but active participants able to manage the majority of their price outcome. Producers are compelled to take direct interest in market drivers.

All price environments involve risk. The point of departure is how those risks are managed. In the previous environment, Queensland producers relied on QSL’s price risk management services and received a pooled price outcome. The new structures enable individuals to make their own pricing decisions. In doing so, they have an opportunity to balance their own attitude towards risk and assessment of market conditions with their cost structures to secure bottom line value.

Individual decision making brings with it potential for reward and the potential for loss. Individual growers can now determine, to some degree, how much of the price risk they wish to manage and how much they wish to place in the hands of others. QSL’s pool management options will continue to be a significant part of growers’ choice into the future. Because the volatility of production and sales patterns needs to be managed, all QSL suppliers will continue to have exposure to QSL’s Seasonal Pool.

Alternative crops have made inroads into traditional cane lands in some regions. Several mill owners are using the QSL pricing platform to provide pricing options to entice growers back into the industry. Figure 1 is an example of a newspaper advertisement in an area that is using futures pricing as an incentive to encourage increased planting of sugarcane. The ability to lock in a proportion of the crop’s value even prior to planting is seen by many as giving sugarcane growing a competitive advantage over alternative crops.

Data on uptake of grower pricing is not comprehensive. This, in itself, is a reflection of the fact that these arrangements are made between growers and mills directly and do not need outside interference to coordinate or codify. Privacy and commercial confidentiality limit the public availability of data. However, it is clear that grower uptake of the new schemes has been enthusiastic. Over 95% of growers have access to some pricing mechanism. Collective pools price all grower sugar in three mill areas and some sugar in three others. Target pool pricing is the most popular mechanism for pricing in those mill areas where it is available, with around 80% of growers participating. There are variations in uptake of pricing in these areas, reflecting a typical spread of
innovators, early adopters, early majority and so on. In one area, 80% of growers are reported as having taken a position in pricing; other areas report up to 60% of growers pricing typically 40% to 50% of their expected crop for the next season.

Fig. 1—Advertisement from CANEGROWERS Bundaberg newsletter (Anon., 2009).

**Conclusion**

The availability of futures pricing in the Australian sugar industry has coincided with strengthening prices on the futures market. In a sense, the introduction of grower pricing options could have not have come at a better time.

Many growers have, at the time of writing, secured at least a part of their returns for the 2010, 2011 and 2012 seasons.

The solid price foundation provides a stable base for these producers’ operations for at least this time period. The replacement of regulated structures with commercial agreements along the supply chain has enabled the development of these price mechanisms. The benefits of the new commercial structures are significant.

These include a new, more commercial culture, longer-term cane supply contracts, growers’ ability to manage pricing decisions in light of their knowledge of growing costs and to determine, to some degree, how much of the price risk they wish to manage and how much they wish to place in the hands of others. That the changes have occurred in a strong price environment is an added bonus.

MOTS-CLÉS: Prévisions, Prix, Planteurs, Restructuration.

Résumé

LES PLANTEURS de canne à sucre australiens peuvent désormais prévoir les prix qu’ils pourraient obtenir pour leur canne à sucre. Un accès direct à l'évaluation du marché à long terme est depuis longtemps disponible pour les producteurs de matières premières telles que les grains, la viande bovine, le coton et autres. Certains producteurs de sucre ont eu accès à ces mécanismes, mais, dans les situations où la production de canne et l’usinage sont séparés, les planteurs de canne n’ont jamais pu vendre en avance leur production car leur produit non transformé ne peut être considéré pour un futur contrat. Récemment, en Australie, de nombreux planteurs ont commencé avec l’aide des mécanismes de tarification à s’engager dans des nouveaux contrats de fourniture de canne à sucre avec leurs usines. Les tonnages de sucre sont répartis parmi les planteurs selon la formule établie du prix de la canne à sucre. Les contrats de tarification sont finalisés par l’intermédiaire de la société de marketing qui vend le sucre roux. Dans cette présentation sont examinés les différents mécanismes de prix disponibles aux planteurs de canne en Australie, et les implications de celles-ci pour la durabilité de l’industrie sont discutées. Cela inclut une nouvelle approche commerciale avec des contrats de fourniture de cannes à plus long terme, la capacité des planteurs à gérer les décisions tarifaires en connaissance des coûts, et à déterminer, dans une certaine mesure, combien de risque de prix qu'ils souhaitent gérer et combien ils souhaitent placer entre les mains des autres.
ESTABLECIMIENTO DE PRECIOS BASADOS EN FUTUROS PARA LOS PRODUCTORES DE CAÑA AUSTRALIANOS

Por

BERNARD MILFORD y WARREN MALES

CANEGROWERS Australia and Queensland Sugar Limited

PALABRAS CLAVE: Futuros, Precios, Productores, Reestructura.

Resumen

LOS PRODUCTORES de caña australianos pueden establecer ahora los precios de su azúcar basados en futuros. El acceso directo al mercado de precios de futuros ha estado disponible para los productores de materias primas como granos, ganado, algodón y otros. Algunos productores de azúcar habían tenido acceso a estos mecanismos, pero en situaciones donde la producción de caña y el procesamiento de la misma están separados, los productores, tradicionalmente, no tenían acceso a proteger el precio que recibían por su producto debido a que la caña sin procesar no se distribuye en contratos de futuros. En Australia, muchos productores han comenzado a usar mecanismos de precios basados en futuros a través de nuevos contratos para proveer caña en las fábricas. Las toneladas de azúcar son distribuidas proporcionalmente a los proveedores basados en la fórmula del precio de la caña. Los contratos de precios son cerrados a través de la plataforma de precios ofrecida por la compañía de mercadeo de azúcar crudo. En este trabajo se revisa el rango de mecanismos de precios disponible para los productores de caña de Australia y se revisan las implicaciones de éste en la sostenibilidad de la industria. Estas incluyen, una cultura nueva, más comercial, contratos con los proveedores a plazos más largos, habilidad de los productores para conducir sus decisiones de precios a la luz de su conocimiento de los costos de producción y determinar, hasta cierto grado, cuanto riesgo ellos desean manejar en el precio y cuánto desean poner en las manos de los otros.
REGIONAL SIMULATION APPROACH FOR EVALUATING A NEW SUGARCANE VARIETY USING SYSTEM DYNAMICS

By

Y. TARUMOTO

National Agricultural Research Organization

yusuke@affrc.go.jp

KEYWORDS: Simulation Model, System Dynamics, Strategy.

Abstract

The sugarcane industry is a complex system involving sugarcane growers and sugarcane mills. Technical evaluations whose purpose is the restructuring of sugarcane production must be based on a systematic methodology. The National Agricultural Research Centre for the Kyushu Region in Japan is trying to breed a new type of sugarcane which has early maturing and high ratoonability. Such a sugarcane variety would bring a trade-off between lower sugar content, an important quality of sugarcane, and a long-term increase in the sugarcane raw material supplied by sugarcane growers to mills. Against this backdrop, a simulation model was developed based on system dynamics that accounted for the area required to cultivate a new sugarcane variety and the first date on which the sugarcane mill operations would begin. This model regards sugarcane growers and the sugarcane mill located in a given area as a single entity. A crucial factor in this model is the pol value, which increases gradually in weekly increments until it reaches a peak mid-season and then declines. Furthermore, the simulation uses five ratoon cycles / years. The model consists of three units, each with ‘Cropping’, ‘Quota’, and ‘Evaluation’, where the output includes sugarcane production volumes, raw sugar volumes, and profitability (production costs per raw sugar unit). A scenario analysis showed a decrease in profitability during the first two years, but pointed to an increase in the third year. This suggests that the change would benefit both sugarcane growers and mills. Analysis of various scenarios will help in formulating strategies for the sugarcane industry by enabling mid- and long-term forecasts.

Introduction

Introducing new technologies that result in radical reforms in sugarcane production tends to be met with resistance, due to the complexity of the sugarcane industry, which makes it hard to grasp and evaluate the effects of new technologies. One such technology is the new type of sugarcane variety which has an early maturing capacity currently being pursued in Japan (Sugimoto et al., 2001; Irei et al., 2005).

Simulation analysis is suitable for assessing such complex systems. Among various simulation analysis methods, a system dynamics approach was used because it accounts for temporal factors and permits quantitative evaluations. System dynamics was developed in the 1950s to help corporate managers improve their understanding of industrial processes, and is currently being used throughout the public and private sector for policy analysis and design. This approach is ideal for evaluating various factors in complex systems such as the global computer model ‘World3’ for the Club of Rome (Donella et al., 2004). It is therefore considered an appropriate tool for analysing a complex system such as the sugarcane industry.
In the sugar industry, MAGI is one of the most advanced simulation systems currently available (Le Gal et al., 2003). MAGI has the following features: (1) It handles processes ranging from farming to milling; (2) the simulation is based on weekly increments; and (3) it emphasises distribution efficiency. MAGI is designed primarily to evaluate changes in sugarcane production, the reorganisation of mills to which sugarcane is supplied, changes in delivery rules, and changes in supply chain capacity. These characteristics make MAGI a useful tool for managing the complexities inherent in the sugarcane industry. MAGI has already seen use as part of management efforts to improve the sugarcane industry (Lejars et al., 2008; Le Gal et al., 2008). However, MAGI can simulate at most a period of one year. This is inadequate for modelling the effects of changes in sugarcane production over several years. Another simulation tool was needed to evaluate multiple ratoon cycles of sugarcane.

An alternative approach is to base the simulation on econometric methods, which pose their own drawbacks, including a limited capacity to accommodate structural changes resulting from the deployment of new technologies. For these reasons, a simulation model was developed using system dynamics. There are many system dynamics software programs such as ‘iThink/Stella’, ‘PowerSim’ and ‘Vensim’. Vensim is produced by Ventana Systems, which offers a free introductory version of its software, Vensim PLE, which can be downloaded from the web and was the software of choice in this study.

Characteristics of sugarcane production in Japan

In Japan, sugarcane is harvested from winter to spring. With declining sugarcane production volumes, the duration of operation of sugarcane mills has also declined. This has resulted in the concentration of harvesting tasks, the most time-consuming and labour intensive stage of sugarcane production.

Cultivation typically involves two principal operations: spring-planting, summer-planting, with ratooning taking place after both the harvest of spring-and-summer planted sugarcane. The summer-planting yields a crop every other year, offering consistent and high yielding but poor land use efficiency (Table 1). In response, current efforts focus on increasing the ratoon-based crop to boost sugarcane production volumes and income for growers. Spring-planted sugarcane has a lower yield but better land use efficiency.

Features of the new sugarcane variety

One of current Japanese breeding programs focuses on early-maturing sugarcane varieties and related cultivation methods. This approach achieves high and stable yield of new plantings based on a summer-planting operation and harvested in autumn (from October to November). This promotes sprouting in the ratoon cycle, since the weather is warmer at this time than during the ordinary harvest season. This leads to consistent ratooning and higher yields. However, sugarcane harvested at this time has lower pol values than crops harvested during the ordinary harvest season. Since sugarcane pricing is based on quality (i.e., pol value), higher pol values mean higher prices and more income for the grower. This factor has discouraged widespread cultivation of the new sugarcane variety. Sugarcane mills also prefer sugarcane with high pol values since raw sugar can be obtained more efficiently from such crops.

For this reason, earlier harvests offer no short-term incentives for either sugarcane growers or mills. We believe that this widespread and unquestioned acceptance of the idea that sugarcane must have high pol values is a major factor hampering the widespread adoption of early-maturing sugarcane varieties.

Overview of the model

Purpose of the simulation

A regional agricultural production model was designed based on an early-maturing sugarcane variety. A requirement was to formulate a scenario, despite the disadvantage in terms of pol value, offering long-term benefits not just to sugarcane growers but to sugarcane mills. A simulation explored in quantitative terms the likelihood of achieving this objective.

Features of the model

One of the features of the model is that it treats a sugarcane mill and sugarcane producers consisting of many growers as a single control constituent. Thus, the results of the simulation provide evaluation indices such as annual sugarcane production volumes for an entire area and aggregate sugar production costs per product.

In practice, the sugarcane variety and crop type selected by each grower vary widely. Dates for delivery of the sugarcane raw materials to the sugarcane mills are generally set based on grower requests. If rain prevents a harvest, the delivery schedule must be reviewed and adjusted. Among other factors, this complicates the process of delivering raw materials and the efficient operation of a sugarcane mill.

The model, however, assumes a special condition whereby sugarcane production and mill operations proceed rationally and efficiently.

The model is not designed to present a realistic situation. Instead, it produces a theoretical framework for region-specific models and provides guidelines for formulating future strategies.

Structure of the model

Changes in sugarcane production have effects that persist for several years. To account for sugarcane quality, we must also consider fluctuations in pol value from harvest to harvest. Thus, we performed a five-year simulation in weekly increments.

This model consists roughly of three sectors: the cropping sector, the quota sector, and the evaluation sector (Figure 1).
The structure of the model is discussed below, based on the parameters set for the hypothetical area (Tables 2, 3).

Source: Ministry of Agriculture, Forestry and Fisheries (2004)

**Cropping sector**

The spring-planting area is 300 ha, and ratooning is performed five times. The summer-planting area measures 300 ha and yields a crop every other year. The total available harvest area for sugarcane is 2400 ha.

For new planting, spring-planting on the 300 ha area takes precedence. The rest is planted in summer. The early-maturing sugarcane variety is planted instead of the normal summer-planting variety and is planted in the same quantities as for existing summer-plantings.

Additionally, ratooning of the early-maturing sugarcane variety is performed three times (Figure 2).
Fig. 2—Cropping model (built by Vensim).

The system dynamics model basically consists of two types of variables: ‘level’ variables that express conditions and ‘rate’ variables that express activities. In Figure 2, the area of each crop type is represented by a level variable, while each valve symbol indicates a rate variable. More specifically, Figure 2 shows that the valve opens once a year to move to the next crop stage.

**Quota sector**

The sugarcane production volume needed for the upcoming harvest is calculated by multiplying the harvest area for each crop type, which is obtained in the cropping sector, by the crop yield. The yield is 60 t/ha for spring-planting and its ratoons and 90 t/ha for both summer-planting and the early-maturing sugarcane variety. The crushing capacity of the sugarcane mill is 1500 t/day for a weekly quota of 10,500 t. As soon as sugar production begins, the volume of sugarcane raw materials needed each week is allocated in priority order.

Early-maturing sugarcane is granted highest priority. Next, ratooning of the early-maturing sugarcane variety is performed, followed by summer-planting, ratooning for spring-planting, and spring-planting, in that order. This produces a delivery schedule for sugarcane crop types.

**Evaluation sector**

The evaluation sector produces evaluation indices for sugarcane production volumes, raw sugar production volumes, and sugar production costs. Table 3 shows the parameters and relational expressions assumed.

Pol value is a factor that affects not just raw sugar production volumes, but the amount of money paid to growers. In this model, the pol value varies weekly for both the existing varieties and early-maturing variety. The early maturing variety is assumed to have a higher pol in autumn (Figure 3).
The recovery rate for sugarcane pol value was set to 86%, and the yield rate obtained by multiplying by pol and recovery rate was used to calculate raw sugar production volumes. Sugar production costs include a proportional cost, a fixed cost, and sugarcane purchase cost (Table 3). A proportional cost and a fixed cost were set based on data released by the Ministry of Agriculture, Forestry and Fisheries of Japan. Sugarcane purchase cost is calculated by relational expression using pol value. For fixed costs, we calculated total fixed costs based on total crop yields obtained in the simulation based on initial values.

Simulation results and discussion

We performed a simulation based on the introduction of an early-maturing sugarcane variety on a 200 ha area and an early start for sugar production in the first week of November. We compared the results of this simulation with the results of the simulation of the current system (early-maturing sugarcane variety not introduced and sugar production starts in the first week of January).

With regard to harvest area by crop type, the early-maturing sugarcane variety replaced summer-planting and was harvested from the second year (Figure 4).
Sugarcane production begins to increase from the third year, when the harvesting of the ratoons in early-maturing sugarcane variety begins (Figure 5). Note that actual raw sugar production volume drops from current levels in the first and second years. This is because sugar production starts earlier, but the early-maturing sugarcane variety has not reached its full potential.

Consequently, sugar production costs per raw sugar unit, a major index for sugarcane mills, rises for the first two years following the introduction of the early-maturing sugarcane variety. But from the third year, sugar production costs begin to fall (Figure 6). We compared the cost details between the current system and in the fifth year (Figure 7).

As the sugarcane and raw sugar increase, economies of scale effect to decrease average fixed cost. The decline of average fixed cost (fixed cost per raw sugar) contributes significantly to the reduction in sugar production cost per raw sugar.
Summary

A simulation model was developed and applied to sugarcane growers and sugarcane mills and simulations performed in which an early-maturing sugarcane variety was introduced. In the resulting scenarios, increased sugarcane production volumes reduced sugar production costs beginning in the third year following the introduction of early maturing varieties.

We believe introducing an early-maturing sugarcane variety will benefit a given region, and that the increased harvest area resulting from increased ratooning operations will improve income for growers. Introducing an early-maturing sugarcane variety offers potential benefits to both sugarcane growers and sugarcane mills.

Many factors affect the state of the sugarcane industry. Evaluating the potential advantages, disadvantages, or risks of any change in the status quo remains difficult. Nevertheless, system dynamics simulation makes it possible to forecast in quantitative terms the effects of such factors. The analysis presented in this paper focused on an early-maturing sugarcane variety, but the simulation method described can also be applied to other factors to help determine how to maximise the profitability of both growers and millers.

The simulation model created can help formulate strategies for the sugarcane industry by enabling mid- and long-term forecasts, which is the first step in the change management process. The second step, if these strategies are actually executed, is the implementation of efficient operational management practices. The MAGI modelling approach can help ensure the effective management of the actual implementation in the second step.

For agricultural business operators, we believe presenting analyses of various scenarios would not only allow them to select appropriate technologies and examine future countermeasures, but also help various parties build a consensus. This notion needs to be tested in the future.

Resumen

La industria azucarera es un sistema complejo que involucra a los productores de caña y a los ingenios azucareros. Las evaluaciones técnicas que se realicen con el propósito de reestructurar la producción de caña de azúcar deben basarse en una metodología sistemática. El Centro Nacional de Investigación Agrícola para la región de Kyushu en Japón está tratando de desarrollar una nueva variedad de caña de maduración temprana y buena habilidad de soqueo. Esta variedad permitirá obtener un equilibrio entre el bajo contenido de azúcar, una característica de calidad muy importante en la caña y el incremento a largo plazo de materia prima despachada por los proveedores hacia el ingenio. Contra este escenario, se desarrolló un modelo de simulación que se basa en la dinámica de sistemas que toma en cuenta el área que se requiere para cultivar la nueva variedad y la fecha en que empezará la molienda en el ingenio. Este modelo considera como una sola entidad a los proveedores y al ingenio que están localizados en el área de estudio. En este modelo, el valor de la pol es crucial, el cual se incrementa gradualmente por semana hasta que llega a un pico a la mitad del período de cosecha y luego declina. Además, la simulación utiliza cinco ciclos de soque/ años. El modelo consiste de tres unidades: ‘Cultivo’, ‘Cuota’ y ‘ Evaluación’, donde la salida incluye los volúmenes de producción de caña, volúmenes de azúcar crudo y capacidad de generar utilidades (costos de producción por unidad de azúcar crudo). Un análisis de escenarios demostró una reducción de la capacidad de generar ganancias durante los primeros dos años, pero apuntó a incrementarla en el tercer año. Esto sugiere, que el cambio beneficiaría tanto a los productores de caña como a las fábricas. El análisis de varios escenarios ayudará en la formulación de estrategias para la industria de la caña permitiendo realizar pronósticos de producción a mediano y largo plazo.
RE-SKILLING WORKERS WITHIN THE MAURITIUS
SUGAR INDUSTRY REFORM PROJECT

By

L.D. MAMET

Regional Training Centre, Réduit, Mauritius
ldmamet@intnet.mu

KEYWORDS: Human resources, Re-engineering,
Re-skilling, Re-training, Sugar.

Abstract
The African-Caribbean-Pacific (ACP) Sugar Protocol countries, of which Mauritius is a member, ceased to benefit from preferential prices for sugar exports to the European Union (EU) as from 2009. In anticipation of the changes, the Mauritian Government presented to the EU a Multi-Annual Adaptation Strategy (MAAS): 2006–2015 for the re-engineering of the sugar industry. The strategy aims to use a cluster-based model to provide efficiency and flexibility in production and marketing of outputs to enable Mauritius to remain a competitive supplier for the EU after the price reduction. The EU is playing a significant role in financing the MAAS through the EC Sugar Accompanying Measures over the period 2006–2014 and the first disbursement of funds (2006/2007) was linked to performance indicators in four areas, namely, de-rocking of lands of small holders; implementation of the centralisation of three factories; signature of contracts under the Voluntary Retirement Scheme 2 (VRS2); and provision of training for those that will make use of the VRS2. This paper concerns the fourth indicator. A profiling survey was carried out by the Regional Training Centre (RTC) in November 2006 on 3852 potential retirees to obtain information pertinent to the re-training of persons opting for the VRS2. The questionnaire covered biographic data, employment history, education, training and competencies, employee’s future plans and training needs. The results showed that 72% of the respondents were over 50 years of age and that the majority had more than 15 years experience in the sugar industry. The majority were field workers or overseers and 80% had no secondary education, 45% could not read but 72% were interested in re-skilling/training. Around 27 different courses were designed and implemented according to the retirees’ needs in areas such as gardening, vegetable production, plumbing, food production and driving. The performance indicator of 1500 retirees receiving training by 31 December 2007 was achieved.

Introduction

Sugar protocol
Mauritius has benefitted from preferential prices for its sugar exports for over 30 years. The ACP/EU Sugar Protocol (an emanation of the Lomé Convention) was signed in 1975 and provided for guaranteed access to the EU market for fixed quantities of ACP sugar at preferential prices over an indefinite period of time. Out of the 18 ACP Sugar Protocol countries, Mauritius had the largest allocation, which was 507 000 tonnes of sugar annually. This represented 94% of Mauritian sugar exports (and this corresponded to 25% of the EU’s sugar imports). In 2006, there was a review of the EU Sugar Regime as the EU restrictive trade practices did not comply with WTO rules on level market treatment. This led to the unilateral denunciation by the EU of the Sugar Protocol that will

**Multi-Annual Adaptation Strategy (MAAS)**

In expectation of these drastic changes the Mauritian Government presented to the EU a Multi-Annual Adaptation Strategy (MAAS): 2006–2015 for the re-engineering of the sugar industry. The sector had to be transformed into an integrated sugarcane industry that would optimise the production of higher-value sugars, increase electricity production from bagasse and develop ethanol production (Autrey and Tonta, 2005). The strategy aims to use a cluster-based model to provide efficiency and flexibility in production and marketing of outputs to enable Mauritius to remain a competitive supplier to the EU after the price reduction. The overall objective of the Adaptation Strategy is to ensure the commercial viability and sustainability of the sugar sector for it to continue fulfilling its multi-functional role in the Mauritian economy, but at a significant social cost. The strategy provides for a set of measures/projects aiming at increasing the country's revenue, optimising the use of by-products, maintaining the social welfare of low income groups of the sugar industry, while fully taking into account the social and environmental implications.

The Sugar Industry Efficiency (SIE) Act was amended in 2007 (GOM, 2007) in order to accommodate the MAAS strategies. The main focus was to reduce labour costs and create a more flexible workforce. This entailed the voluntary retirement of an estimated 6000 persons. The age of workers eligible for the VRS2 was brought down from 50 years to 45 for women and from 55 to 50 for men. Voluntarily retired workers were to be provided with a compensation package of a maximum 2 months salary per year of service and a plot of land with basic infrastructure. In addition, the new regulatory framework facilitated the use of seasonal labour which was previously not permitted. Moreover, prior to the voluntary retirement of an employee, he/she had to be provided re-skilling/training opportunities for eventual redeployment into other economic sectors or support for the setting up of a small enterprise within the agricultural or non-agricultural sector.

**Accompanying measures**

In order to support the adjustment process of ACP countries affected by the sugar reform, the EU is assisting these countries through a mechanism known as the European Commission (EC) Sugar Accompanying Measures (EC, 2005; EC, 2007). Funding is provided for country-specific strategies, which lead to sustainable adaptation and hence the MAAS was accepted by the EC as the basis for the restructuring of the Mauritian sugar sector. The disbursement of funds is linked to performance indicators in four areas:

- the de-rocking and preparation of 300 ha of land belonging to small planters;
- the closure of three sugar mills;
- signature of an initial number of contracts under the VRS2; and
- the provision of a social package, including re-training and re-skilling, to 1500 workers leaving the industry.

This paper is concerned with the fourth indicator, namely the re-training and re-skilling of 1500 workers leaving the industry.

**Profiling exercise**

In November 2006, in anticipation of the re-skilling project, the Regional Training Centre (formerly known as the Robert Antoine Sugar Industry Training Centre), in collaboration with the Mauritius Sugar Producers’ Association (MSPA), members of the Personnel and Industrial Relations Officers’ Committee of MSPA (PIROC) and trade union representatives, developed a profiling survey questionnaire to facilitate the matching of the training needs and levels of literacy
of the potential VRS2 beneficiaries with existing and novel training courses. The questionnaire covered biographic data, employment history, education, training and competencies, employee’s future plans and training needs. Training was then provided for all the Human Resource Managers / Personnel Officers of the sugar companies involved in the VRS2 who were to carry out the profiling exercise.

The profiling survey covered 3852 potential retirees from 24 different sugar companies. An individual analysis for each company and a combined analysis for all of the companies was conducted. The combined results showed that 72% of the respondents were over 50 years of age, and that 85% of the potential retirees were male. The age distribution is shown in Figure 1. There were, however 937 employees who were under 50 years of age.

![Age distribution of the potential VRS 2 beneficiaries.](image)

The majority of the respondents had more than 15 years’ experience in the sugar industry but many of them had over 30 or 40 years’ experience.

![Years of service in the sugar industry.](image)

The majority (80%) of the employees had only attended primary school. Only 102 employees reported having attended school up to Form V (see Figure 3).
The majority of the respondents were field workers or overseers and 80% had no secondary education. In Mauritius various languages are spoken. Literacy was reported by the potential retirees as shown in Table 1.

It can be inferred that around 45% of the potential beneficiaries could not read and 49% could not write, and this had implications for the design of appropriate re-skilling programs.

Table 1—Reported literacy in various languages (% of respondents).

Despite the low educational and literacy levels, 72% were interested in re-skilling/training. They were also questioned about other competencies that they believed they possessed and the most common responses were gardening/vegetable cultivation, masonry/bricklaying, plumbing, woodwork, electrician, painting, sewing, welding, fishing, mechanics and farming.

Training was designed to build upon these competencies as the ultimate objective was to facilitate eventual redeployment into other economic sectors and/or provide the basis for the setting up of small enterprises.

The potential beneficiaries were asked what plans they had for the future and 42% stated that they wanted new employment, 31% hoped to be self employed, while 14% wanted to retire from economic activities and 2% said that they wished to emigrate.

The percentage of retirees who were seeking employment after the VRS2 corresponded to the percentage who were interested in training. Concerning the new employment, the most popular responses are given in Table 2. The potential retirees were also asked to indicate what sort of training that they wanted to follow and Table 2 also shows these responses.

Implementation

An agreement was reached on 5 December 2007 between the MSPA and the Government of Mauritius on the industry reform process (MCA, 2008). This agreement successfully triggered the implementation of key reform measures and enabled disbursement of scheduled EU Accompanying Measures. Over 6500 employees of the sugar sector retired under the VRS2 and ERS schemes at the end of 2007. This is in addition to the 8000 people that left the industry in 2001 under the first VRS.

The Regional Training Centre was selected to be the coordinating body for the implementation of the re-skilling project. Around 27 different courses were designed (or selected from pre-existing courses) according to the retirees’ needs and level of literacy in areas such as: basic vegetable production, introduction to gardening, livestock production, plumbing and pipe-fitting, domestic electrical installation, food production techniques, housekeeping operations, basic arc welding, lorry driving, heavy goods vehicle driving, etc. All the courses were delivered in the local Creole language, used lots of visuals, and all were very practical in orientation. The course durations ranged from 27–84 hours. These courses were run at the Regional Training Centre and at various centres throughout the island in collaboration with the Industrial and Vocational Training Board of Mauritius and the Agricultural Research and Extension Unit of the Ministry of Agro-Industry, Food Production and Security.

According to the SIE Act (Amended) 2007, the training was to be provided while the beneficiary was still in employment. However, since the agreement between the MSPA and the Government of Mauritius was only reached on 5 December 2007 and the VRS2 had to be completed by 31 December 2007, it was logistically impossible to dispense all the training while the workers were still in service. It was therefore agreed that all transport costs and daily wages were to be refunded to the beneficiaries if they had to follow courses after their retirement.

Despite the time constraint, 1500 beneficiaries were enrolled on appropriate courses and were able to follow at least one training session prior to 31 December 2007 and the remaining sessions were completed in 2008. Evaluation questionnaires indicated that the retirees enjoyed the training programs and many mentioned that it was the first time that they had an opportunity to follow a course and that they were eager to put their new competencies to use.

Discussion

Had the deal between the MSPA and the Government of Mauritius been concluded earlier, the profiling data would have been used directly for the preparation of lists of trainees for each selected course. However, because of the 14 month delay, the data in the database was only partly true as, for example, the ages of respondents had changed, some people who were previously too young to obtain the VRS were now old enough to qualify, and some people changed their training...
choices, future plans, etc. Nevertheless, the profiling database was extremely useful for the planning of training courses, for the briefing of training providers about the target audience and for presentation purposes for the EC evaluators.

The feedback from the participants who followed the various training courses was positive but no data are available on how many beneficiaries are actually using their new competencies. Some of the overall objectives of the EU Accompanying Measures were to mitigate the social impact of the sugar industry adaptation strategies and to support ACP countries on their path to poverty reduction and sustainable development. In this context, the support for re-skilling was aimed at facilitating the transfer of employees from the sugar sector to other sectors of the economy. Available data show that around 13% of the beneficiaries were employed in other sectors in April 2008 but this is likely to be an under-estimate as many are self-employed. In addition, many retirees have been re-employed in the sugar sector as seasonal labour under new contracts of employment. The Government of Mauritius has set up a National Empowerment Foundation (NEF) whose aim is to broaden the circle of job opportunities for job seekers through training and placement facilities and help those whose jobs are affected by the global economic crisis. Thus VRS2 beneficiaries who are seeking jobs have been encouraged to enrol at the NEF.

The Regional Training Centre also provides training for those remaining in the industry. As the industry is being transformed into a modern integrated sugarcane industry, new skills are required. Courses and workshops have been designed to meet the new needs in areas such as new farming systems – the Australian model and the Mauritian adaptation, improving harvester performance and impact of extraneous matter on sugar and energy recovery, production of low colour raw sugar and refining technologies, as well as in management topics such as finance for non-finance managers, good corporate governance, negotiating skills, etc. The Mauritian sugarcane industry also has interests in the hotel, real estate and golf industries and therefore training in new areas such as landscape design, customer care, communication skills, sales techniques, and so on, are increasingly sought after.

Although much of the information in this paper is local in nature, it is possible that the processes used by Mauritius could be used as a model for other countries undertaking re-skilling programs in the context of sugar reforms. The European Union is obliged to assess utilisation of funds on an annual basis and reallocates them among protocol countries if the money is not spent as planned. Since the key performance indicator of 1500 retirees following training by 31 December 2007 was achieved to the satisfaction of the EC evaluators, disbursement was not impeded.

Résumé

LES PAYS signataires du Protocole Afrique-Caraïbes-Pacifique (ACP), dont Maurice est membre, a cessé de bénéficier de prix préférentiels pour les exportations de sucre vers l'Union européenne (UE) à partir de 2009. En prévision de ces changements, le Gouvernement mauricien a présenté à l'UE un «Multi-Annual Adaptation Strategy (MAAS): 2006-2015» pour la restructuration de l'industrie sucrière. La stratégie vise à utiliser un modèle de regroupement pour fournir l'efficacité et la flexibilité de la production et la commercialisation de produits permettant à Maurice de rester un fournisseur compétitif pour l'UE après la réduction de prix. L'UE joue un rôle significatif dans le financement de la MAAS, à travers des Mesures d'Accompagnement pour le sucre au cours de la période 2006–2014 et le premier décaissement des fonds (2006/2007) est lié aux indicateurs de performance dans quatre domaines, à savoir l’épierrage des terres des petits propriétaires, la mise en œuvre de la centralisation de trois usines, la signature de contrats dans le cadre du plan de retraite volontaire 2 (VRS2), ainsi que la prestation de formation pour ceux bénéficiant du VRS2. Ce document concerne le quatrième indicateur. Un sondage a été réalisé par le Regional Training Centre en Novembre 2006 sur 3852 retraités potentiels afin d'obtenir des informations pertinentes quant à la reconversion professionnelle des personnes optant pour le VRS2. Le questionnaire portait sur les données biographiques, historique de l'emploi, l'éducation, la formation et les compétences, les plans futurs des employés et leurs besoins en formation. Les résultats ont montré que 72% des bénéficiaires ont plus de 50 ans et que la majorité a plus de 15 ans d'expérience dans l'industrie sucrière. La majorité était des laboureurs ou des surveillants et 80% n'ont pas d'enseignement secondaire, 45% ne savent pas lire, mais 72% étaient intéressés à la reconversion et à la formation. Environ 27 cours différents ont été conçus et mis en œuvre en fonction des besoins des retraités dans des domaines tels que le jardinage, la production maraîchère, la plomberie, la production alimentaire et la conduite de divers véhicules. L'indicateur de performance de 1500 retraités, qui ont reçu une formation avant le 31 décembre 2007, a été atteint.
RE-CAPACITANDO A LOS TRABAJADORES EN LA INDUSTRIA AZUCARERA DE MAURICIO PROYECTO DE REFORMA

Resumen

LOS PAÍSES que conforman el Protocolo Azucarero África-Caribe-Pacifico (ACP), del cual Mauricio es un miembro, dejaron de beneficiarse de los precios preferenciales de la exportación de azúcar a la Unión Europea (UE) en 2009. Anticipándose a los cambios, el gobierno de Mauricio presentó a la UE una Estrategia de Adaptación Multi Anual 2006–2015 (MAAS por sus siglas en inglés) para efectuar la re-ingeniería de la industria azucarera. La estrategia promueve el uso de un modelo basado en un cluster para dar eficiencia y flexibilidad en la producción y mercadeo de los productos que le permitan a Mauricio permanecer como un proveedor competitivo para la UE después de la reducción de precios. La UE está jugando un papel muy importante en el financiamiento del MAAS a través de Medidas de Acompañamiento del Azúcar en el período 2006–2014 y el primer desembolso de fondos (2006–2007) estuvo ligado a los indicadores de desempeño en cuatro áreas: eliminación de rocas en tierras de los pequeños participantes, implementación de la centralización de tres fábricas, firma de contratos bajo el Esquema de Retiro Voluntario 2 (VRS2 por sus siglas en inglés), y provisión de entrenamiento para aquellos que harían uso del VRS2. En el presente trabajo se describen las actividades de este cuarto indicador. En noviembre de 2006, el Centro de Capacitación Regional realizó una encuesta de perfiles a 3852 candidatos potenciales a retiro para obtener información pertinente de la re-capacitación de personas que optaran al VRS2. El cuestionario incluía datos biográficos, historia de empleos, educación, entrenamiento y competencias, planes futuros de los empleados y necesidades de capacitación. Los resultados mostraron que el 72% de los encuestados, tenían más de 50 años y la mayoría tenía más de 15 años de experiencia en la industria azucarera. La mayoría eran trabajadores de campo o supervisores y el 80% no tenía educación secundaria, 45% no podían leer y 72% estaban interesados en ser re-capacitados/entrenados. Se diseñaron e implementaron alrededor de 27 cursos de acuerdo a las necesidades de las personas en el estudio, incluyendo áreas como jardinería, producción de vegetales, plomería, producción de alimentos y manejo. El indicador de desempeño de contar con 1500 candidatos a retiro recibiendo capacitación para diciembre de 2007 se cumplió.
USING COMPUTER SIMULATION MODELS TO AID REPLANT PLANNING AND HARVEST DECISIONS IN IRRIGATED SUGARCANE

KEYWORDS: Replant Planning, Information Technology, Simulation Modelling.

Abstract
LARGE commercial sugarcane operations face complex replant planning decisions. The replant operation is costly and limited resources must be employed where they are likely to produce the largest yield improvement. These decisions are complicated further by the need to evaluate the benefit across multiple cutting seasons. Typically, replant field selection is based on historical performance, and poorest yielding fields on poorer soils tend to be prioritised for replant. However, this approach might not maximise estate-wide productivity. The decision making process needs to consider: which fields should be selected for replant in which season; what varieties should they be replanted back to; and what long-term harvest sequence should be followed to minimise harvest age effects; to maximise sucrose production in current and future seasons. A replant planning decision support framework was developed in CanePro, a commercially available Agricultural Management System, to assist with this complex task. Field selection was made by benchmarking actual field cane yields against potential yields discounted for soil type and ratoon using a soil type/ratoon matrix. Climatic potential yields were estimated using a simplified version of the CANEGRO crop simulation model. Each field’s ideal replant ratoon age was estimated by maximising the total (across all fields) of the average (across all ratoons) expected yield of each field. Fields were assigned a replant date based on their ratio of current to ideal replant ratoon age within the estate’s replant capacity constraints. Replant variety selection was made by optimising overall sucrose performance in a season using variety-specific sucrose curves. The harvest sequence was adapted to maximise overall sucrose production. To evaluate the methodology, four seasons of historical field data were obtained from a commercial operation in Swaziland. Actual estate practice was compared with the replant recommendations made using the CanePro framework. The relative performance of the scenarios was evaluated by comparing the overall sucrose yield simulated for each scenario. A 0.6% improvement was attributed to the CanePro field selection algorithm and a further 0.6% to the harvest sequencing algorithm.

Introduction
Large irrigated commercial sugarcane operations form the backbone of many sugar industries in Africa, Latin America and Asia. Typically, these estates comprise one or more factories supported by miller-owned and managed nucleus estates. Often these agricultural operations are responsible for the bulk of mill supply and are used to ensure rateable delivery during the milling season. Estates range in size between 10 000 and 60 000 hectares but, on average, are between 10 000 and 20 000 hectares, typically made up of 1000–5000 fields. Management is usually well structured and competent, and required to meet strict production and budgetary targets.
The management of an operation this size is inherently complex, especially long-term replant decisions and variety selection following plough-out. Yield in successive ratoons tends to decline due to reductions in stalk population and mass, and an increase in stalk mortality (Chapman, 1988). The rate of yield decline depends on a range of factors, some inherent and others due to management practices employed (King et al. 1965). Inherent factors include sugarcane varietal characteristics and the crop’s growing environment including climate, soil structure and inherent fertility. Examples of management factors include soil compaction, nutrition, water management, disease management etc.

The decision to replant a field is principally an economic one. At some point, maintenance of a ratoon crop under a certain yield may not be profitable (Bakker, 1999). A number of methods have been proposed to establish an optimum replant ratoon age based on economic considerations (Chinloy and Shaw, 1973; Hoekstra, 1976; Keerthipala & Dharmawardene, 2001; Simms, 1982). However, these methods are difficult to integrate into a whole estate management plan and generally fail to acknowledge the limitations imposed by an estate’s capacity to replant in term of replant period(s) and capital constraints on plant and equipment. The replant decision on these estates changes from one of optimum replant age, to one of maximising estate-wide productivity given a limited replant capacity. Limited resources must be employed where they are most likely to produce the largest overall yield improvement. These decisions are further complicated by the need to consider their effect on current and future seasons.

**Estate practice**

Replant planning involves three primary decisions. Firstly, which fields to select for plough-out, secondly, what varieties to plant fields back to and, thirdly, an optimum harvest sequence to satisfy a plough-out calendar while maximising average harvest age and overall sucrose production.

Current estate practice tends to prioritise fields based on their absolute performance in isolation. Fields on inherently weaker soils tend to be replanted more frequently. This practice assumes that replanted fields attain a similar plant yield irrespective of inherent soil limitations. This is often not the case and more productive fields are often overlooked. Additional considerations confound field selection decisions. Probably the most important constraint to the replant operation is capital which restricts the area that can be replanted annually. Management also need to consider other issues including changes to field layout, irrigation system redesign priorities and estate variety composition which could take precedence over purely agronomic considerations.

Variety selection following plough-out appears to be well managed on these estates. Most estates have a clear understanding of how varieties perform during the season, have identified a long-term variety composition strategy and select varieties to satisfy seasonal differences and soil suitability within the constraints of an ideal variety plan.

Harvest planning tends to be confined to the current harvest season. Field sequencing is usually only finalised prior to the season start and the harvest age of plough-out fields is often sacrificed to ensure that harvest dates coincide with replant periods.

In an effort to address some of these limitations and improve the decision making process around replant planning, a decision support framework was developed in CanePro, a commercially available agricultural management information system (MIS) widely used in the industry.

**CanePro**

Decision support systems of this nature lend themselves to an MIS. An MIS can cope with the large amounts of historical data required to assess field performance and integrate the decision making process over a large area and multiple cutting seasons.

CanePro is a sugarcane-specific MIS developed by SQR Software, a software development company based in South Africa. CanePro has been adopted by a large number of commercial estates...
in Africa and Central America. The system provides general management functionality such as field and agronomic record keeping, resource utilisation and planning, labour control and payroll, but also more specific decision support tools including irrigation scheduling, harvest planning and field performance benchmarking functionality. These tools make use of components of CANEGRO, a crop simulation model developed in South Africa.

CANEGRO is a daily time-step model developed along the lines of the IBSNAT (International Benchmark Sites Network for Agrotechnology Transfer) models for maize, wheat and soybean (Inman-Bamber, 1991, 2001; O’Leary, 2000). CANEGRO has been incorporated into the latest DSSAT (Decision Support System for Agrotechnology Transfer) suite of crop simulation models and is being validated internationally (Singels et al., 2008). Models of this nature have developed to the point that they are becoming increasingly valuable in addressing strategic and technical issues in sugarcane agriculture (Inman-Bamber et al., 2001).

CANEGRO is principally climate driven. The daily inputs can be obtained from a standard meteorological station measuring rainfall, radiation (or sunhours), temperature, wind speed (or run), and a measure of vapour pressure deficit. Under irrigated conditions, potential sugarcane yields can be defined as the capacity of the crop to utilise radiation and temperature without bias (Liu and Kingston, 1995). This potential yield estimate provides a benchmark yield against which actual yield can be evaluated.

**Methodology**

**Potential and attainable yield benchmarks**

Individual field performance for a particular harvest season can be evaluated by comparing actual yield against potential yield simulated for the duration of that crop. This performance ratio can be used to compare field performance without the bias imposed by seasonal growing conditions, both within a season and between seasons. This is a useful benchmark, but fails to acknowledge the decline in yield with successive ratoons and the rate at which yield declines on poorer soils relative to more productive soils. Process-level models such as CANEGRO are calibrated and validated on well-managed small-plot experiments and are currently unable to simulate ratooning ability and some management effects which are unavoidable in a commercial operation. To cater for these effects, a soil/ratoon matrix was developed to discount potential yields based on soil type and ratoon number. Estate-specific matrices were calculated by comparing actual and potential yield by ratoon for fields within defined soil types. Potential yield, corrected for soil type and ratoon, provided a second benchmark, termed attainable yield potential, against which actual yields could be evaluated (example in Figure 1).

**Replant planning**

The ratio of actual to attainable yield was considered a useful tool when ranking fields to be considered for plough-out and replant, and is a key element of the replant planning framework implemented in CanePro. The average value of this ratio over the last five cycles has been adopted as an indicator of a field’s performance, and is assumed to continue to apply into the future, whether the field is replanted or not. The expected cane tonnage from a given field can then be estimated as the product of

- The field area;
- The field performance ratio;
- The relevant entry in the soil/ratoon matrix; and
- The potential yield

The potential yield is determined entirely by the meteorological conditions over the growing period. For longer-term decision making on replanting, we replace the potential yield by an annual
average value based on long-term mean meteorological data. Under this assumption, only the first three items in the list above are field-specific.

The first objective of the replant planning algorithm presented here is to assign a maximum ratoon age (i.e. ideal long-term ratoon age at which to replant) to each field such that

- The total (across all fields) average (across all ratoons) expected cane tonnage (as defined above) is maximised; and
- The average area replanted per annum does not exceed the limit for the estate.

The replant planning module of CanePro includes an algorithm to solve this optimisation problem. It accepts as inputs: the area and field performance ratio of each field; the maximum area that can be replanted per season and the soil/ratoon matrix. The output is the ideal maximum ratoon age of each field. As one might expect, fields whose entries in the soil/ratoon matrix show a slow decline in yield with increasing ratoon are typically assigned a high maximum ratoon age, corresponding to infrequent replanting. Fields whose performance ratios are below average also tend to be replanted less frequently because the lower performance ratios will still apply after plough-out and hence reduce the benefits of replanting.

The field selection algorithm implemented in CanePro sorts the fields in decreasing order of the ratio of actual ratoon age to ideal maximum ratoon age. The fields at the top of the list are assigned the first available planting season until the replant capacity is fully utilised. A field is overlooked only if its age at the required cut date makes it a poor choice. The algorithm then proceeds to the next season in the planning period.

**Variety selection following replant**

The algorithm used to assign cane varieties to ploughed-out fields aims to maximise total sucrose production subject to any constraints on the variety mix. The sucrose content of cane will typically show seasonal characteristics that depend on the cane variety. A polynomial curve was fitted to historical data on sucrose content by time-of-year for each cane variety. The polynomial curves are used to estimate the performance of each variety on each day of the cutting season, and thereby determine the optimal variety mix. This is reconciled against the variety mix of fields not being replanted, and the remainder used to determine which varieties should be introduced on ploughed-out fields so as to yield the greatest benefit in sucrose production.

In practice, decisions on variety selection are often constrained by external factors. The variety selection algorithm accommodates constraints on the minimum and maximum areas of each variety that can be planted in each planting period, and these can be used to limit the overall variety mix.

**Field harvest sequencing**

Once fields have been identified for replanting in future seasons, the cutting plans must be modified to ensure that fields to be ploughed-out are harvested in a timely manner and at acceptable cut ages. The CanePro replant planning module incorporates a harvest planning tool that determines an appropriate cutting sequence for each season in the period of interest.

Fields identified for replant are assigned fixed cut dates in the last season before plough-out, and their cut dates in intervening seasons are assigned using a constant cut age. Fields not selected for replanting are then added to the harvest plan in such a manner that the oldest cane is cut first. In this manner, a harvest sequence that is compatible with the replant plan can be determined for each season.

An attempt was made to optimise the harvest sequence so as to maximise total sucrose production within the constraints of the replant plan. The algorithm exploits the differences in the shape of the sucrose curves by exchanging fields in the sequence where it would increase the overall sucrose yield. Fields due for imminent replanting are constrained in terms of how far they
can depart from their assigned cut dates, but the cut sequence of the remaining fields is guided by the expected sucrose production. For each field, this is estimated using the cane yield from the CANEGRO model adjusted by each field’s performance ratio and the sucrose polynomial for that cane variety.

**Case study**

A case study was conducted using data from a commercial operation in Swaziland. The purpose of the study was to evaluate and compare a number of scenarios. All scenarios were based on the same (actual) data, but differed with respect to replant decisions. All scenarios were evaluated using the same technique, viz. by estimating cane yields as described earlier and using fitted sucrose curves for sucrose yield estimation. The relative merit of the replant decisions in each scenario was gauged from the simulated total sucrose production.

**Soil/ratoon matrix**

The soil/ratoon matrix was calculated using field history records between 1983 and 2008. Soils were grouped into soil classes as defined by Nixon (1986). Only fields comprised of >80% of a single soil class were included in the analysis. The average performance ratio (actual/potential yield) by season was plotted against ratoon and a linear regression fitted for each soil class (Table 1).

As expected for a commercial dataset of this nature, the scatter was relatively large as indicated by the low correlation coefficients ($R^2$) and the large root mean squared errors (RMSE). However, all five regression models were highly significant and described the relative productivity of the soil classes in line with commercial estate experience (Figure 1).

**Replant plan**

Four recent consecutive seasons of historical data were included in the study. No significant change in irrigation systems or field disposition had taken place during this time, and no fields had been ploughed out specifically to change their variety. Hence, all replant decisions during this time had been based on yield improvement.

A total of 1400 fields were included in the study and 538 of these (approximately one-third) had actually been replanted during this period. The replant periods within which planting took place (typically from July to November of each season) and the total areas replanted were determined from the historical data, and were used as a constraint on any alternative replant plan that was proposed. Similarly, the fallow periods following plough-out were typically between 8 and 11 weeks in duration, and were observed when determining dates of last harvest prior to planting.

Three scenarios were considered. The first was based on the actual replanting decisions during this period, and a second constructed using the plantings recommended by the field selection technique described earlier. A third scenario using no replanting was included for comparison purposes. In each scenario, a harvest plan was calculated for the four seasons of interest. The simulated tonnage of sucrose produced over the four seasons was then used as a measure of the relative benefit of each replant plan.
The harvest plans were calculated using actual mill crush rates, and the field harvest sequence was determined as described earlier. Fields were cut at the rate required to meet the demand for cane by the mill. The cane yield for each field was estimated as the product of its historical performance ratio and the attainable yield potential at the planned harvest date.

**Results**

The three scenarios were first evaluated using the same cane variety for all fields in all seasons. This was done to isolate the effect of the field selection by preventing small differences in the variety mix from influencing the results.

The outcomes are compared in the ‘field selection’ row of Table 2. The replant plan based on the field selection algorithm produced 0.6% more sucrose than the actual replant plan over the four seasons. However, both replant plans produced a benefit of less than two percent over the scenario having no planting. The results suggest that the field selection algorithm may be a reasonably good one, but that the scope for gains via field selection is rather limited.

A second set of simulations was conducted to test the effect of the modified field harvest sequence. These simulations made use of the full range of cane varieties. The harvest plan for each scenario was first calculated based on the ‘oldest first’ cutting sequence that is used by many estates. The scenarios were then re-evaluated using the harvest sequence optimised for sucrose production.

The results are shown in Table 2 in the ‘cutting sequence’ row. In each scenario, the modified cutting sequence produced an advantage over the standard sequence. The magnitude of the advantage depended partly on the degree to which the variety with the most distinctive sucrose curve had been incorporated in the replant plan. The plan recommended by the software considered
this a preferred cane variety, and the modified cutting sequence produced 0.6% more sucrose than the standard cutting sequence.

In each scenario, the migration of fields within the cutting sequence towards their preferred time of harvest was clearly evident when comparing the adjusted cutting sequence from one season to the next. The total sucrose produced in the first season was typically the same regardless of which cutting sequence was used. This is because the change in each field’s cutting sequence caused a departure from its ideal cut age, and this countered the benefit in sucrose yield. However, the advantage of the adjusted cut sequence increased with each season, as the cut age began to stabilise. By the fourth season, the total sucrose produced using the adjusted cutting sequence was one percent higher than when using the standard cut sequence, without any increase in cane production. These results applied equally to all three scenarios.

Table 2—Total sucrose production after four seasons estimated for the three scenarios evaluated in the case study.

| Sucrose produced with all varieties using modified cut sequence (t) | 1.166 m | 1.183 m | 1.193 m |
| Benefit of sequence optimisation (%)                                      | 0.5     | 0.7     | 0.6     |

Conclusions

Although relatively small, this potential increase in productivity was obtained with no increase in expenditure. The increase in productivity can be attributed entirely to better decision making. In addition, it is worth noting that this estate is technically well managed and has access to reliable field records through the CanePro MIS to aid decision making. Yield benefits may well be greater for estates with limited access to technical expertise and poorer information availability. Providing access to technical expertise is one of the advantages offered by an MIS such as CanePro. Technically complex concepts, often not readily available to commercial managers, can be harnessed in a user-friendly interface as part of an MIS to aid commercial decision making.

MOTS-CLES: Programme de Replantation, Technologie de l'Information,  
Modélisation de la Simulation.  

Résumé  

Le programme de replantation est complexe dans les grandes exploitations commerciales de canne à sucre. La replantation coûte chère et des ressources limitées doivent être utilisées pour améliorer au maximum les rendements. Ces décisions se compliquent davantage par la nécessité d'évaluer les bénéfices sur plusieurs saisons de coupe. En général, le choix du champ à être replanté est basé sur les performances passées et les champs à faibles rendements sur les sols pauvres ont tendance à figurer parmi les priorités pour la replantation. Toutefois, cette approche n’optimise pas la productivité globale de l’exploitation. La décision prise doit prendre en compte la saison dans laquelle certains champs doivent être replantés; les variétés qui devraient être replantées; et quelle séquence de récolte à long terme doit être suivie pour minimiser les effets de l’âge de la récolte et pour optimiser la production de sucre dans la saison actuelle et future. Un programme a été développé par CanePro, un système de gestion agricole disponible sur le marché, pour aider à la décision de replantation et faciliter cette tâche complexe. La sélection des champs a été faite par l'analyse comparative des rendements actuels et les rendements potentiels en prenant compte du type de sol et de la repousse. Les rendements potentiels dus au climat ont été estimés à l'aide d'une version simplifiée du modèle de simulation de culture CANEGRO. L’âge de replantation des repousses idéal de chaque champ a été estimé en maximisant (dans tous les champs) le rendement total moyen attendu (à travers toutes les repousses) de chaque champ. Les champs ont été assignés une date de replantation en fonction de leur rapport de l’âge actuel et idéal des repousses, en prenant compte des contraintes de capacité de replantation de l’exploitation. Les variétés sélectionnées pour la replantation ont été faites pour optimiser les performances globales de sucre dans une saison à l’aide de courbes pour des variétés spécifiques. La séquence de récolte a été adaptée pour optimiser la production globale de sucre. Pour évaluer la méthodologie, quatre saisons de données historiques ont été obtenues d'une exploitation commerciale au Swaziland. La pratique actuelle a été comparée avec les recommandations pour la replantation à l'aide du programme CanePro. Les performances relatives des différents scénarios ont été évaluées en comparant le rendement global de sucre simulé pour chaque scénario. Une amélioration de 0.6% a été attribuée à l'algorithme de sélection du champ fait par CanePro et une amélioration supplémentaire de 0.6% à l'algorithme de séquence de récolte.
USO DE MODELOS DE SIMULACIÓN PARA LA PLANEACION DE RE SIEMBRA Y LA TOMA DE DECISIONES DE COSECHA EN CAÑA DE AZUCAR CON RIEGO

Por

M.G. McGLINCHEY y M.P. DELL

Sugar Systems, PO Box 13048, Cascades, South Africa
markm@sqrsoftware.com

PALABRAS CLAVE: Planeación de Resiembra, Tecnología de la Información, Modelos de Simulación.

Resumen

Las operaciones comerciales a gran escala en las plantaciones de caña de azúcar enfrentan complejas decisiones de resiembra. La operación de resiembra es costosa y se deben utilizar recursos limitados donde se espera que produzcan una mejora significativa en la producción. Estas decisiones se complican aún más con la necesidad de evaluar el beneficio a través de múltiples cortes. Típicamente, la selección de un campo para resiembra se basa en el rendimiento histórico, y los campos con los rendimientos más bajos en los suelos más pobres son priorizados para la resiembra. Sin embargo, es posible que esta estrategia pueda no maximizar la productividad del estado o región. Este proceso de toma de decisión necesita considerar: qué campos deben ser seleccionados para resiembra en qué años, qué variedades se deben sembrar y que secuencia de corte se seguirá a largo plazo para minimizar los efectos de la edad de corte y para maximizar la producción de sacarosa en la época de corte actual y en las subsiguientes. Un marco para la toma de decisiones en resiembra se desarrolló con CanePro, un sistema de manejo agrícola comercial, para ayudar en esta tarea tan compleja. Se seleccionó el campo estudiando el rendimiento real del área contra rendimientos potenciales descontando los efectos del tipo de suelo y soca, usando una matriz tipo de suelo/soca. Rendimientos potenciales climáticos fueron estimados usando una versión simplificada del modelo agrícola CANEGRO. Se calculó la edad ideal de soca para la resiembra de cada lote, maximizando el total (a través de todos los lotes) del promedio (a través de todas las socas) del rendimiento esperado para cada lote. A cada lote se asignó una fecha de resiembra, basado en el radio de la edad actual a edad ideal de la soca para resiembra dentro de las limitantes de la capacidad de resiembra del estado. La selección de las variedades para la resiembra se hizo optimizando todo el desempeño varietal en una zafra, usando curvas de sacarosa específicas por variedad. La secuencia de corte se adaptó para maximizar la producción total de sacarosa para evaluar la metodología, se obtuvieron datos históricos de la operación comercial de 4 años para un área de Swazilandia. Las prácticas actuales se compararon con las recomendaciones de resiembra obtenidas con CanePro. El desempeño relativo de los escenarios se evaluó comparando la producción total de azúcar para cada escenario. Un 0.6% de mejora se atribuyó al algoritmo de selección de lotes de CanePro y otro 0.6% al algoritmo de secuencia de corte.
A DECISION SUPPORT APPROACH TO ADDRESS NEW SUGARCANE QUALITY-BASED PAYMENT SYSTEMS

By

C. LEJARS and S. AUZOUX
CIRAD, UR Systèmes des Cultures Annuelles, Montpellier, France

KEYWORDS: Quality Incentive, By-Products, Participatory Approach, Sugarcane, Payment Scheme.

Abstract
In sugar industries where growers and millers are independent economic entities, payment systems aim at sharing the annual sugar industry revenue. They have been designed to create incentives to improve milling performance, cane yields and quality. Like most revenue sharing agreements, they tend to be a contentious issue between growers and millers. In some industries, while modifying payment systems can be the key to increasing industry profitability, mistrust between growers and millers can hamper such improvements. The situation is now exacerbated by the development of sugarcane co-products, such as ethanol, electricity or by-products for niche markets, which can generate higher benefits than sugar, thus calling for a rethink of payment systems. This paper presents a decision support approach which aims to assess new cane payment systems while increasing revenue sharing transparency. It is based on a simulation tool called Pempa, which helps to assess the impact of new cane payment systems on growers’ revenue and on revenue sharing between stakeholders. Experiments have been carried out for 3200 growers supplying two mills on Réunion Island, to test the impact of implementing a new payment system based on a relative formula. Results showed that the simulation approach could facilitate understanding and implementation of a new payment formula, especially for multiple-purpose sugarcane.

Introduction
In sugar industries where growers and millers are independent economic entities, payment systems aim at sharing the annual sugar industry revenue resulting from the sales of sugar and all sugarcane by-products such as molasses and bagasse. They have been designed to create incentives to improve milling performance, cane quality and cane yields.

A review of sugarcane payment systems in the main sugarcane producing countries (LMC, 2002) showed that payment systems vary between, and sometimes within, countries depending on four main elements:

- Sugar and co-products price.
- Revenue sharing agreement between growers and millers. Revenue resulting from the sale of sugar is redistributed between growers and millers on a fixed basis (x% for the growers, (100-x) % for the factory) or on a variable basis (the price is defined for a standard level of quality and a fixed extraction capacity).
- A global payment formula. In all sugarcane industries, the tonnage delivered is used as a basis for payment. Tonnage can be combined with the mill average quality, a group average quality (especially for small-scale farmers) or an individual quality analysis.
• The definition of ‘sugarcane quality’ and the parameters used for quality payment. The indicator used to define sugarcane ‘quality’ differs between countries. It can be the sucrose content, an estimation of the recoverable sugar present in each tonne of cane or an estimation of the value of a tonne of cane in terms of marketable product. It can depend on elementary indicators, such as sucrose and fibre content, mill extracting capacities, materials and methods used for quality measurements, etc.

In practice, it is hard to design a ‘perfect’ payment system and guarantee that equity is always maintained while ensuring that incentives, for both growers and millers, are not distorted (Todd and Forber, 2005).

In most countries, payment systems are based on complex and sophisticated formulae. They have been built through successive historical negotiations, readjusted according to mill performance or growers' practice improvements and tend to be a contentious issue between growers and millers (Lejars, 2008).

Thus, in some industries, while modifying payment systems can be the key to increasing industry profitability (Kroes and Fadden, 2004; Higgins and Muchow, 2003; Le Gal et al., 2008; Lejars et al., 2008), mistrust between growers and millers and the fact that each of these stakeholders may not be able to clearly assess the impact of modifications in their own revenue can hamper such improvements.

The situation is now exacerbated by the development of sugarcane co-products, such as renewable energy from ethanol or electricity (Keating et al., 2002; Sutherland, 2002), fibre-based commodities (paper, packaging, etc.) or other niche products like furfural alcohol or lactic acid. Most payment systems currently aim at promoting the production of cane for sugar extraction. They encourage high sucrose content while penalising fibre rate, despite the fact that fibre can be used to produce by-products that have a higher value than sugar.

In some countries, part of the revenue from by-product sales can be allocated to growers depending on the tonnage of sugarcane delivered. However, by-product payments are independent of the quality parameters. Payment systems are generally adapted to a sector in which the main outlet is sugar. The development of multiple-purpose sugarcane, whether or not earmarked for sugar production, calls for a rethink of payment systems (Wynne, 2007; Higgins et al., 2007).

More generally for agro-industries, very few support systems have been developed to design payment systems. Some studies have been undertaken to design optimal quality price schemes (Zago, 2006), especially in wine industries (Touzard et al., 2001). Bouche and Attonaty (1999) conducted experiments on milk price elaboration to define quality standards.

As ‘milk quality’ has different meanings for different stakeholders, their objective was to build a typology to differentiate and define the different representations of quality. However, the implementation of new payment systems remains difficult and sometimes impossible when stakeholders are not involved in the decision process from the beginning and when they are not able to assess the impact of new payment systems on their own income.

This paper presents a decision support approach which aims to assess new cane payment systems while increasing revenue sharing transparency and quality incentives impacts on revenue. A software, called Pempa (Auzoux et al., 2008), has been developed in order to facilitate assessment of the impact of new cane payment systems on growers’ revenue and on revenue sharing between stakeholders.

Firstly, we focus on the method and the tool used to support payment system implementation. Then, we present an application tested in Réunion to achieve a more transparent alternative cane payment system based on a relative formula. Finally, we show how this method could be applied to alternative payment systems for multiple-purpose sugarcane in the near future.
The decision support approach

Objectives

The decision support approach aims to assess the impact of new cane payment systems on growers’ revenue and on revenue sharing between stakeholders. It is based on software called Pempa, which has been designed specifically for sugarcane industries.

The new payment formulae are developed by an expert or in partnership with stakeholders. Once stakeholders agree on the definition of sugarcane ‘quality’, the simulation tool assesses the impacts of new quality-based payment formulae on individual revenue. The purposes are to: (i) facilitate comprehension of the incentive effects of quality payment formulae, (ii) clarify the effects of new payment formulae on individual grower’s revenue, and (iii) increase transparency on value sharing between stakeholders.

Modelling structure and software

The software Pempa was developed with Microsoft Visual Basic.Net. This version does not require computer literacy and is available both in English and French. It is the subject of a data-processing patent filling and it is downloadable in free access on Internet on the website ‘www.agri-logistique.cirad.fr’. Payment scenarios can be imported from, or exported to, an Excel file. This facilitates data input and offers users considerable time savings for configuration of the payment system.

The model is based on a three level representation of stakeholders: farms, groups of farms and mills. Stakeholders’ links are represented through a pyramidal structure (Figure 1), including an elementary unit (EU), an EU group (Group) and the mill. An EU can be a farm, a part of a farm, a group of farms, etc. Each EU is characterised by their weekly deliveries and weekly quality indicators.

Cane ‘quality’ is defined through a synthetic indicator (QI), which depends on elementary indicators, such as fibre, sucrose content, or data relative to the mill process. Four quality elementary indicators and a synthetic indicator (QI) can be defined to estimate EU ‘quality’.

The payment model combines two sub-models: the first for quality parameters and the second for growers’ income (Figure 2). Through the first sub-model, the synthetic indicator is defined, and average indicators are calculated for each grower, group of growers and the mill. The quality used for payment (QP) and the global payment formula can also be determined by users. Through the second sub-model, a stakeholder’s revenue is calculated using tonnage and quality characteristics. Different sugar and co-product prices can be tested, such as different kinds of subsidies. Simulations are done on a weekly basis because the payment of growers is usually done using this time step.
Simulations of different payment systems

Users may define a large panel of payment schemes depending on:

- The synthetic indicator (QI)

  It can be modified using four elementary indicators, such as sucrose and fibre content. It can be an estimation of the sucrose content, the recoverable sugar present in each tonne of cane or the value of a tonne of cane in terms of marketable product. QI is chosen by the user and is a function of the elementary indicators (fibre, sucrose…). Various formulae for QI can be defined. This synthetic indicator can be defined on a weekly basis.

- The weekly paid quality

  The formula to calculate paid weekly quality is designed by the users and could be based on the expression of the predefined synthetic indicator, but also the mill annual average quality, the group annual average quality, the weekly mill average quality and the group weekly average quality.

- The weekly payment formula

  This synthetic indicator (QI) and the weekly paid quality (QP) can be used directly for payment or not. In a few countries, the quality paid is ‘relative’, i.e. representing the difference between the grower’s weekly results and the mill average. The formula to calculate the weekly payment can be a function of the weekly paid quality and the synthetic indicator. The formula is calculated for each EU or for each group.

- The revenue formula

  The parameters of the revenue formula (R) can integrate the three formulae before as members, but also the price of the sugar per tonne of cane, subsidies depending on tonnage or quality and the selling price of sugar or sugar by-products.
Simulation results

Pempa can be used to investigate the impacts of different payment schemes and quality incentives on growers' revenue, value sharing between growers and millers and value sharing among growers.

A wide range of issues may be addressed:

1. calculating growers’ revenue for different payment formulae, at an individual level and/or for a whole group of farmers
2. assessing the impact of modifying the parameters used in a payment formula such as sugar price, qualitative parameters, new subsidies
3. testing the impact of delivery allocation modification on growers’ income for a given payment formula
4. By comparing the results of the different scenarios, it is possible to calculate the value sharing between growers and miller and among growers. The results obtained can be analysed according to farm type or any other feature.

The tool calculates a stakeholder’s revenue on a weekly and annual time step, according to given quality delivery characteristics and payment rules. The simulation results are represented at the three levels of the mill area structure: EU, PU, and mill.

Experiments conducted in Réunion

An experiment was carried out with two mills on Réunion Island. Two different payment systems have been tested: the current one and a payment system based on a relative formula.

Scenarios

In the current system, a synthetic indicator, called ‘richesse’, is used to estimate the amount of sugar that could be extracted from cane. It depends on the sucrose content (S), juice purity (p), bagasse (b) and fibre (f) rates (Figure 3).

Growers are paid according to their weekly results QI

\[ QI = Rich = f(S, b, f, p) \]

As the ‘richesse’ (Rich) reaches a peak in the middle of the season, with this kind of payment, growers are understandably reluctant to deliver cane before or after this peak. Some growers tend to over-estimate their production at the beginning of the season, so as to have a higher weekly allocation and be able to deliver more cane in the middle of the season. Consequently, millers foresee a longer season length and do not work at their full crushing capacity at the beginning and end of the season. The extension of the milling season tends to reduce the season average sucrose content (Moor and Wynne, 2001) because the additional milling takes place at the beginning and end of the season, when the sucrose content is low.

Thus, we assessed the impact of switching from the current system to a relative one. The relative payment was designed to regulate deliveries when payment is done on a quality basis (Buchanan, 1974). In a relative payment system, growers are paid according to the difference between their quality and the weekly average of the mill. The \( Richrel_{i,k} \) indicator used for payment is:

\[ Richrel_{i,w} = (Rich_{i,w} - \overline{Rich}_w) + \overline{Rich} \]

Where

\( Rich_{i,w} \): Sugar content of grower i for week w
\( \overline{Rich}_w \): Average sugar content for week w
\( Rich \): Mill average sugar content for the whole season
The impact of modifying the payment formula was simulated for the 3278 growers indexed in the Inter-professional Centre of the Cane and Sugar (CTICS) database. Simulations were performed for four different years using data for the seasons from 2001 to 2005.

With Subs1: subsidies depending on tonnage
Subs 2: subsidies depending on EU

Results

The analysis showed that switching from one payment to another (Figure 4):

- Did not modify the division of proceeds between millers and growers.
- Slightly modified large-scale growers’ revenue.
- Could modify small-scale growers’ income by around 20%.

Fig. 3—From the current system to a relative payment.
We then identify and characterise the growers who were highly affected by the payment modifications. We showed that:

- For most of them, losses were offset from one year to another. Only 8% of the growers lost part of their revenue every year.
- Growers who lost more than 10% of their income were those who systematically delivered more sugarcane at the middle of the season.

As expected, the simulations showed that the relative payment system would encourage growers to deliver cane regularly throughout the season. These results were discussed among stakeholders.

The discussion process highlighted the necessity to investigate a new scenario based on regular deliveries. We thus simulated a modification in the tonnage delivered each week by these 10% of growers who systematically delivered more sugarcane at the middle of the season.

We showed (Figure 5) that, if they delivered regularly, milling capacity utilisation could be improved.

The season length could be reduced by one or two weeks. A reduction of two weeks could increase the total sugar production and total revenue by 4%, without any additional investment for millers or growers.

When the simulations were run on an inter-annual basis, we showed that a relative payment system and a season reduced by two weeks increased the revenue of all the growers (We supposed that logistics costs are not modified).
Consequently, simulations showed that the relative payment system would encourage growers to deliver cane regularly throughout the season, resulting in improved utilisation of milling capacity and a potential 2-week reduction in the season length.

**Discussion**

Pempa should be used in collaboration with stakeholders involved in sugarcane payment system elaboration and outsiders such as researchers or consultants.

Scenarios should be designed with a steering committee that at least includes growers’ and millers’ representatives, as this sort of issue requires participation and agreement of every stakeholder’s group.

Once stakeholders have agreed on the payment system to be studied or modified, scenarios are configured and can be simulated using the software. The scenario outputs are compared mainly on the basis of individual revenue and value sharing.

The simulation tool promotes discussion between grower and miller representatives on potential changes in payment systems. It provides information that enhances and facilitates the negotiation process between stakeholders.

The purpose of the tool was to better formalise payment systems and value sharing among stakeholders. The simulations and the stakeholders’ participation provided greater insight into both the nature of relative cane payment and opportunities for improving industry efficiency by adopting such a system.
Conclusions and prospects

The division of proceeds between growers and processors may lead to conflicts between the two groups. Modelling and simulation could considerably increase transparency and facilitate the implementation of new payment schemes, with the support of professionals and researchers, providing a quick and reliable way for assessing and comparing alternative scenarios.

Pempa makes it possible to evaluate new payment formulae, designed and developed in partnership with sugar industry stakeholders. This tool enables their evaluation and facilitates their comprehension while clarifying their individual effects.

Pempa could be used to support implementation of new payment scheme designed for multiple purpose cane (sugar, electricity, ethanol, etc.). At this stage, we do not have an example of a quality-based payment system for multi-purpose sugarcane. However, once a formula or a set of potential formulae are designed, PEMPA could be used to support implementation of a new payment scheme designed for multi-purpose sugarcane.

Profits and their distribution between the stakeholders can be calculated for each use. However, this step must be accompanied by an analysis of parameters that should be considered to evaluate the ‘quality’ of cane for products other than sugar.

Moreover, this tool could be further extended by including other parties involved in production and processing within the supply chain, particularly hauliers and independent workers, who are paid on a tonnage basis whereas their work has an impact on the product quality. The current software is designed to include these other parties, which could be paid through a different payment formula.

MOTS CLÉS: Incitation, Qualité, Sous Produits, Approche Participative, Canne à Sucre, Méthode de Paiement.

Résumé

Dans les industries sucrières où les planteurs et les usiniers sont des entités économiques indépendantes, les systèmes de paiement visent à partager les revenus annuels de ces industries. Ils ont été conçus pour créer des incitations afin d’améliorer les performances d’usinage, les rendements et la qualité des cannes. Comme la plupart des accords pour le partage des revenus, ces systèmes causent parfois des litiges entre planteurs et usiniers. Dans certains secteurs, le changement des systèmes de paiement peut être la clé pour accroître la rentabilité de l’industrie mais la méfiance entre planteurs et usiniers peut entraver ces améliorations. La situation s’est aggravée aujourd’hui avec le développement des coproduits de la canne à sucre, comme l’éthanol, l’électricité ou les sous-produits pour des marchés ciblés, qui peuvent générer des bénéfices plus élevés que le sucre, ce qui amène à revoir les systèmes de paiement. Les auteurs présentent une approche d’aide à la décision pour évaluer les nouveaux systèmes de paiement de canne à sucre avec plus de transparence dans le partage des revenus. Il est basé sur un outil de simulation appelé Pempa, qui aide à évaluer l’impact des nouveaux systèmes de paiement de canne sur les revenus des planteurs et du partage des revenus entre les parties concernées. Des expériences ont été effectuées à la Réunion pour les 3200 planteurs fournissant des cannes à deux usines pour tester l’effet de la mise en œuvre d’un nouveau système de paiement basé sur une formule relative. Les résultats ont démontré que l’approche de simulation pourrait faciliter la compréhension et la mise en œuvre d’une nouvelle formule de paiement, en particulier pour les multiples produits de la canne.
UN ENFOQUE DE SOPORTE DE DECISIONES PARA TRATAR SISTEMAS DE PAGO BASADOS EN CALIDAD

PALABRAS CLAVE: Incentivo de Calidad, Co-Productos, Estrategia de Participación, Caña de Azúcar, Esquema de Pago.

Resumen
EN LAS industrias azucareras donde los productores de azúcar y los productores de caña son entidades económicas independientes, los sistemas de pago están encaminados a compartir el retorno anual de la industria. Estas se han diseñado para crear incentivos para mejorar el desempeño de la molienda, la productividad en campo y la calidad. Tal como sucede en la mayoría de convenios donde se comparten ganancias, se crea rivalidad entre los productores y los ingenios. En algunas industrias, mientras la modificación de los sistemas de pago ha sido la clave para mejorar la rentabilidad de la industria, la desconfianza entre los productores y los ingenios puede ensombrecer las mejoras. La situación está ahora agravada por el desarrollo de co-productos de azúcar, como el etanol y la electricidad o los otros productos para nichos de mercado específicos, que pueden generar beneficios más altos que los del azúcar, lo que llama a replantear los sistemas de pago. Este trabajo presenta una estrategia para la toma de decisiones que promueve la búsqueda de nuevos sistemas de pago mientras se incrementa la transparencia en la distribución de ganancias. Está basada en una herramienta de simulación llamada Pempa, que ayuda a evaluar el impacto de nuevos sistemas de pago en las ganancias de los productores y en la distribución de retornos entre las partes interesadas. Se llevaron a cabo experimentos para 3200 productores de caña que proveen materia prima a dos ingenios de la Isla Reunión, para evaluar el impacto de la implementación de un nuevo sistema de pago basado en una fórmula relativa. Los resultados mostraron que la estrategia de simulación podía facilitar el entendimiento y la implementación de una nueva fórmula de pago, especialmente cuando la materia prima se usa para diferentes propósitos.
THE CARBON FOOTPRINT OF SUGAR

By

KEYWORDS: Carbon Footprint, Energy, Sugarcane, Sugar, Ethanol.

Abstract

Climate change is rapidly becoming a serious issue and one which will increasingly demand the attention of sugar producers. Estimation of the greenhouse gas emissions in the production of sugar, otherwise known as the carbon footprint, is an essential part of any sustainability study. A method of estimating net energy usage and greenhouse gas emissions has been developed, based initially on work done on biofuels. The calculation routine was developed for use in the Better Sugarcane Initiative standards, which focus on the sustainability of the sugarcane industry. This estimation procedure estimates primary energy requirements including both direct effects, mainly energy usage, and indirect effects, which include energy used in the production of fuels, fertilisers and chemicals. Allowance is also made for the inclusion of direct land use change effects. The estimation procedure allows for the production of molasses and/or ethanol, and for the export of power. Attention is given to the potential errors and problems in arriving at these estimates. The main problems are uncertainties in emissions from fertiliser use and the way in which emissions are allocated to co-products. The results show that the carbon footprint is most affected by sugarcane yield, sugar recovery, fertiliser usage, irrigation, cane burning and power export. A factory set up efficiently for maximum power generation can show a negative carbon footprint and, in this respect, maximum export of electric power can deliver a lower carbon footprint than maximum ethanol production. The calculation routine estimates the greenhouse gas emissions from field to factory gate and can be used for an existing operation or in the design of a new project to assist in making good sustainability choices.

Introduction

The issue of climate change has promoted an interest in the greenhouse gas (GHG) emissions, otherwise referred to as the carbon footprint, associated with a variety of products. The main focus has been on the production of biofuels, which has spurred the development of systems to estimate GHG emissions. Pressure is coming from the market place, through consumer expectations, and from responsible producers, to measure, control and minimise the carbon footprint of their products.

The carbon footprint of cane sugar is favourably impacted by the use of the natural fibre in sugarcane, which provides the fuel source for its production. The development of a system of calculating emissions that has wide acceptance is an important step in being able to measure and then control emissions.

It is impossible to control emissions until they are first measured. This becomes a powerful tool in the hands of producers, enabling them to assess how changes in the way they produce sugar can influence GHG emissions and one that serves as a basis for sound decision-making by business, consumers and other stakeholders.
Emissions are an important aspect of the broader subject of sustainable production. This paper focuses on the method used to estimate emissions in the production of raw sugar, and was developed as part of the sustainability standards of the Better Sugarcane Initiative.

**Status of efforts to calculate carbon emissions**

The major impetus for the calculation of carbon emissions has been the production of biofuels and the conditions which the EU and other importers wish to attach to imported biofuels, largely in an attempt to ensure that they are produced in a sustainable way. Sugarcane is the source of a great deal of ethanol produced, mainly in Brazil, and increasingly to a larger extent in other cane producing countries.

Thus, a number of studies have been done to estimate the net energy ratios and carbon emissions associated with bioethanol production. Different estimates of GHG emission savings relative to fossil fuels are obtained if different assumptions are made in the calculation procedure.

Wang *et al.* (2008) estimate a reduction of 78% for ethanol transported to the US from Brazil; they estimate this will increase by up to 9 percentage points if cane burning is phased out. Data produced in Brazil indicates that bioethanol produced and used in Brazil shows GHG emissions savings of 89% compared with petrol (BNDES, 2008).

The EU has compiled a Renewable Energy Directive (RED) which sets out how the emissions should be calculated for the production of a biofuel from any particular feedstock. In addition, some GHG emission saving default values, assuming no land use change, are given to be used in the absence of primary data required for its calculation.

Ethanol produced from sugarcane has the best default value of 71% emission saving relative to fossil fuels; emission savings using corn, wheat or sugar beet are significantly lower, varying between 16 and 52% depending on the feedstock and the process used.

The carbon footprint of sugar has received less attention. PAS 2050:2008 is a Publicly Available Specification, developed in the UK in conjunction with the Carbon Trust (BSI, 2008).

Recently, both British Sugar Corporation and Tate & Lyle have used this carbon footprint and labelling initiative to evaluate the carbon footprint of sugar, using a life cycle analysis approach. Renouf and Wegener (2007) have calculated the carbon footprint for raw sugar production under three different Queensland scenarios.

In the US, there has been controversy surrounding the net energy ratio and the GHG emissions for ethanol for use as automobile fuel produced from corn, relative to gasoline. The results of a number of studies have illustrated clearly how the input assumptions can radically affect the estimated quantities.

Various studies on the net energy value of ethanol from corn have been compared by Farrell and co-workers at UC Berkeley (Farrell *et al.*, 2006). Their EBAMM (ERG Biofuels Analysis Meta-Model) spreadsheets are available on the internet and are used as the basis for the computations here.

A number of other carbon calculators are available on the internet, mostly designed for the production of biofuels, which also take into account the distribution and use of the biofuels. The Renewable Fuels Agency in the UK provides an on-line calculator, as does the GREET (Greenhouse Gases, Regulated Emissions and Energy Use in Transport) model produced by the Argonne National Laboratory in the US (Wang *et al.*, 2008). This list is not exhaustive and various other calculators are available from specialist consultants.

**System boundary**

In conducting life cycle analyses, it is important to define the boundary of the system under investigation. The scope of the system being investigated has a substantial effect on the computations. In the case of sugarcane, the best approach considers the system to contain each individual mill and its growers as a unit, rather than a company owning and operating more than
one mill. In the case of IPPs (Independent Power Producers) providing steam and power to a mill from bagasse that has been provided by the mill, the IPP should be considered together with the mill concerned. All the activities of a plant on one site should be considered, to reflect the sustainability of the total system producing food, fuel, energy and chemicals.

The system boundary includes growing and processing of sugarcane, but also includes embedded energy inputs. It starts with the manufacture of fertiliser and chemicals. Farming operations include chemicals application, irrigation, tillage and harvesting.

The cane is processed to sugar and molasses or ethanol, and may include export of electric power or bagasse. No allowance for transport of products from the factory is allowed for. The system is illustrated in Figure 1.

![System boundary assumed for GHG emissions calculation.](image)

There are two commonly used descriptions for life cycle analyses, Business-to-Business (B2B) and Business-to-Consumer (B2C). The former accounts for the provision of inputs, including products, to a third party that is not the end user (cradle-to-gate); the latter accounts for the provision of inputs, including products, to the end user (cradle-to-grave), thus including the packaging and transport of products to the retailer/consumer, as well as the recycling and disposal of packaging waste.

This analysis represents a B2B analysis, considering the operation of a cane sugar processing facility, producing raw sugar and/or ethanol at the factory gate.

**Direct and indirect effects**

The energy and GHG calculations are associated with direct energy inputs and at a second level by indirect inputs.

Direct inputs are mainly fuel and power inputs, expressed in terms of the primary energy value (taking into account e.g. the efficiency of conversion of fuel to power, and the energy in producing gasoline and diesel). Indirect inputs include, in addition, the energy required for the production of chemicals, fertilisers and other materials used.

In some cases the indirect inputs also include the additional energy necessary for the manufacture and construction of farm, transport and industrial equipment and buildings. There is as yet no uniformity in different approaches.

PAS 2050 (BSI, 2008) dictates that the GHG emissions arising from the production of capital goods used in the life cycle of the product should be excluded from the assessment of the GHG emissions of the life cycle of the product. This is also the approach taken by Concawe (2007), the RTFO in the UK and the EU RED. American approaches tend to include this energy; in this analysis, it is excluded.
Land use change

It has been suggested that land use changes due to large scale sugarcane expansion could lead to significant changes in the soil carbon. This could result in additional emissions by sacrificing carbon storage and sequestration as land is diverted from its existing uses. These changes can be separated into direct and indirect components:

- **Direct** land change refers to a change from the original state of the land to use for sugarcane production. Depending on the previous use of the land in question, it is surmised that the land use change can unlock some of the carbon in the existing soil and vegetation.

- **Indirect** land use change concerns secondary effects induced by large scale expansion. This displaces existing crops, leading to expansion of crop land elsewhere, either in the same country or in other parts of the world. The effects of these changes are very difficult to estimate, and have generally been neglected in any analyses, largely because of the uncertainty in modelling the effects.

Searchinger et al. (2008) postulated that taking account of both direct and indirect land use change will make most biofuel ventures GHG positive, rather than reducing GHG emissions. This is based on the assumption that, as biofuel crops displace other crops, commodity prices rise and new land is put to crop cultivation in various countries, particularly Brazil, China, India and the US. Their results have been disputed by a number of people; for example, Kim et al. (2009) suggest that sustainable crop management practices significantly reduce the direct land use effect, while indirect land usage estimates are too uncertain to have any validity, depending substantially on what assumptions are made.

The Gallagher report prepared for the UK government released in 2008 concludes that GHG emission estimates must include the effects of indirect land use change and also avoided land use from co-products. The report recommends that biofuel production should target only idle and marginal land and make more use of wastes and residues. It also calls for sustainability standards to be extended beyond biofuels to all agricultural production.

The EU RED allows for a substantial credit of 29 g CO$_2$eq/MJ for a period of 10 years if severely degraded or contaminated land is used for biofuel crop purposes. Klenk and Kunz (2008) have shown that, in the case of ethanol production from sugar beet and wheat, the co-products replace other feedstuffs which would have required additional land, and so actually free up land for other crop production. In some developing nations, the land can actually be improved by diligent farming.

Because the methods and data requirements for calculating emissions from indirect land use change are not fully developed, the assessment of emissions arising from indirect land use change is not included in any current estimation procedures, but this is likely to change in the future.

In general it is accepted that direct land use change after a cut-off date must be taken into account. The PAS 2050 standard proposes a cut-off date of 1 January 1990, but the EU RED suggests 1 January 2008. In the absence of better information, the table of IPCC default land use change values for selected countries published in the PAS 2050 can be used (BSI, 2008). For perennial cropland, the default values are of the order of 15 to 25 t CO$_2$eq/(ha.y) for conversion of forest land and 1.5 to 7 t CO$_2$eq/(ha.y) for grassland. The values for forest land conversion are punitive and sufficient to derail development of new cane estates.

**Handling of co-products and multiple products**

A co-product is any one of two or more products, where one cannot be produced without the other being produced. An example is molasses, which is not produced unless sugar is produced at the same time. Sugar and ethanol produced in a mill would be regarded as multiple products. Waste products are defined by the IPCC as having no economic value, and will have zero allocation of energy and emissions.
Different methods of handling co-product credit have been suggested. The Concawe report (Concawe, 2007) as well as ISO 14044 lifecycle assessment standards favour the ‘substitution’ or ‘displacement’ method, which attempts to model reality by tracking the likely fate of by-products. Each co-product generates an energy and emission credit equal to the energy and emissions saved by not producing the material that the co-product is most likely to displace. Other studies have used ‘allocation’ methods whereby energy and emissions from a process are allocated to the various products according to mass or energy content or monetary value. These allocation methods are attractive because they are simpler to use, but they have little logical or physical basis, and allocation on monetary value varies by region and over time. In the event that substitution is not feasible, ISO 14044 standards recommend allocation by economic value. Although the prices may change over time, the relative market prices between joint products may be less subject to variation than absolute prices.

The displacement method has been favoured in the US in determining the credit to be applied to co-products, particularly DDGS (Farrell et al., 2006; Gabroski, 2002). In the case of corn ethanol, sensitivity analysis has shown that co-product allocation has the greatest individual effect on calculations.

In the case of sugarcane processing, a factory exporting power or bagasse can apply a credit in terms of energy and emissions saved. Thus, the use of the term ‘GHG emissions’ actually refers to ‘net GHG emissions’ after applying a credit for energy exports. Wang et al. (2008) assume that electricity exported by the mill displaces electricity generated with natural-gas electric power plants. This is contrary to PAS 2050 which dictates displacement of energy with the country’s average generation mix.

In terms of efficiency, cogeneration is intrinsically superior to conventional power generation. Conventional technologies convert into useful power about 30% – and in extreme conditions up to 50% – of the energy in the fuel. Cogeneration systems, by directing otherwise wasted heat to meet thermal needs of the process, achieve efficiencies exploiting 85% of the fuel’s efficiency (BNDES, 2008). Potentially, using 50% of the cane tops and leaves, generating steam at 105 bar and 525°C, should enable the year-round export of 158 kWh/t cane processed. A process for gasification could increase power generation to yield above 180 kWh/t cane processed.

Where a factory produces only sugar and molasses, the allocation in proportion to market value is most easily adopted; in most cases, the allocation to molasses is less than 10% of the total and the products it displaces (e.g. animal feed components) may be difficult to identify in different countries.

In the case of a factory producing more or less equivalent quantities of sugar and ethanol, the split of energy input and GHG emissions between the two products becomes a more difficult issue. The EU RED requires that allocation should be by energy content of the products. Sugar has a calorific value of 16 500 MJ/t and ethanol 21 MJ/L; on the basis that 600 L of ethanol are produced from one tonne of sucrose, this implies an ethanol equivalent value of 16 500/600 = 27.5 MJ/L for sucrose. On this basis, 57% of the emissions should be allocated to sugar and 43% to ethanol.

In the case of an autonomous distillery, where the only product is ethanol, the problem disappears, and energy use and emissions are related to litres of ethanol produced.

Assumptions and methodologies involved

Components contributing to emissions

CO₂ from sugarcane emitted in combustion and in ethanol fermentation is considered zero CO₂ emission to the air, because this is the carbon taken in from the air during sugarcane growth. CO and VOCs emitted in combustion are assumed to be converted to CO₂ fairly rapidly, but methane and nitrous oxide (N₂O) from burning bagasse must be accounted for in GHG emissions.
CO₂ emissions arising from biogenic carbon sources are excluded from the calculation of GHG emissions from the life cycle of products, except where the CO₂ arises from direct land use change.

The greenhouse gases covered in the Kyoto protocol are CO₂, N₂O, CH₄, SF₆, methylene chloride, certain ethers, perfluorinated compounds and hydrofluorocarbons. Only the first three are relevant here. Methane and N₂O have global warming potentials 25 and 298 times that of CO₂ respectively (IPCC, 2007). The carbon equivalent value is calculated by multiplying the mass of one of these gases by its global warming potential. This is added to the CO₂ evolved and expressed as CO₂ equivalent (CO₂eq).

Methane produced in anaerobic digesters that is used as fuel in boilers is not considered to produce GHG emissions. Methane produced by anaerobic processes from wastes but not captured has to be taken into account in calculating emissions. Where methane is combusted without the generation of useful energy (i.e. flaring), no GHG emissions shall be incurred where the methane being combusted is derived from the biogenic component of the waste.

**Default and secondary data**

In some cases, secondary data (obtained from sources other than direct measurement) may be used to calculate emissions in preference to primary data to enable consistency and, where possible, comparability. Generally used secondary data used here are:

- Global warming potential of greenhouse gases
- Electricity emissions (in kg CO₂eq/kWh) from various energy sources
- Energy content of fertilisers per kg
- Energy use of pesticides and herbicides per kg
- Embedded energy and emissions for process chemicals
- Fuel emissions per litre
- Waste emissions per kg
- N₂O and CH₄ emissions from burning bagasse
- N₂O and CH₄ emissions from burning cane
- Direct land use change
- Agriculture emissions from soils

Default values used have been collected from a number of sources and are given in the Appendix. The EU RED suggests a more detailed treatment of default values which can give more accurate results where the particular type of nitrogenous fertiliser is specified.

**Calculation method**

The calculation approach adopted in this study is similar to that used in the EBAMM model, which itself is similar to the GREET model. These models have been used mainly to model the production of biofuels from corn, and they have had to be modified for sugarcane to incorporate additional issues as follows:

1. Modifications to incorporate sugar manufacture as the major activity. This includes power, fuels and lubricants.
2. Emissions due to cane burning. This is based on IPCC emission factors for burning biomass of 0.07 kg N₂O/t dry matter and 2.7 kg CH₄/t dry matter.
3. Allowance for N₂O emissions from filter cake, vinasse and cane residue left in the field. This assumes 1.225% of N in the residue is converted to N in N₂O (Macedo et al., 2008).
4. Emissions of CH₄ and N₂O in burning bagasse in sugar mill boilers; values of 30 and 4 g/1000 MJ energy in bagasse respectively are used (Wang et al., 2008).
5. Energy value of process chemicals.
6. A credit for molasses (where produced) based on its economic value relative to that of sugar.

7. Emissions from anaerobic treatment of effluent in the case that methane is not captured and used as a fuel. IPCC guidelines suggest 0.21 t CH₄ produced per t COD removed.

8. Allowance for any imports of molasses, bagasse and/or other biomass.

Difficulties associated with agricultural chemicals

The GHG balance is particularly uncertain because of nitrous oxide emissions. N₂O emissions can vary by more than two orders of magnitude, depending on a complex combination of soil composition, climate, crop and farming practices.

The use of nitrogen fertilisers results in GHG emissions in two stages: fertiliser manufacture (primarily CO₂ emissions from energy used) and fertiliser application (primarily N₂O emissions from nitrification and denitrification processes in the soil).

The assumption is made that 1.325% of N in nitrogen fertiliser is converted to N in N₂O through nitrification and denitrification, following the IPCC recommendations.

Various studies in Australia have focussed on GHG emissions, and how they are affected by soil type, moisture conditions and trash blanketing (Allen et al., 2008; Denmead et al., 2008; Denmead et al., 2005).

These studies estimated that N₂O emissions from Australian sugarcane soils may be higher and more variable than the emission factor of 1.325% recommended by the IPCC. Wang et al. (2008), however, showed that, for conditions approximating average conditions in Queensland, the emissions factor is close to the IPCC value.

Agricultural lime application results in GHG emissions from both production energy use and in-soil reactions that release CO₂. These latter emissions are poorly understood and are a source of uncertainty. The EBAMM model uses the IPCC factor of 0.44 kg CO₂eq/kg lime, which assumes that all C in lime becomes CO₂. This is the upper limit; it is possible in weakly acidic soils that limestone results in a net sink of CO₂.

Calculation results

A typical sugar mill has been modelled, based on processing 500 tonnes cane/hour and producing only sugar and molasses. The average values for the base case considered are shown in Table 1.

This assumes a conventional mill producing only sugar and molasses, processing 50% burnt cane, with some power imported for use in irrigation and some exported.

The results are summarised in Table 2. Net energy use in the agricultural operation is 206 MJ/tC (MJ/tonne cane) and in cane transport 26 MJ/tC. The combined number of 232 MJ/tC is slightly higher than the comparable value calculated for Brazil centre-south conditions of 210 MJ/tC.

The total energy usage of 278 MJ/tC is reduced by the export of power, to give a net energy usage of 98 MJ/tC. This is a substantial reduction, largely due to the multiplier for exported power of 2.5 to convert the exported power to its primary energy value, based on an average conversion efficiency of primary energy to power of 40%.

An average emissions factor of 150 g CO₂eq/MJ for electricity production is assumed; in practice, the value relevant to the country considered would need to be used.

The total GHG emissions are 0.43 g/g sugar, but when the credit for molasses production and power export is applied, this drops to 0.31 g CO₂eq/g sugar. In this instance, with the relative prices for sugar and molasses used, 7% of the GHG emissions are allocated to molasses. The emissions associated with molasses are < 0.1 g CO₂eq/g molasses.

A breakdown of the energy usage and GHG emissions is illustrated in Figures 2 and 3.

*per tonne molasses
Emissions from the use of nitrogen fertilisers and lime in the fields account for almost half the emissions from the agricultural operations. The uncertainty introduced by the use of these fertilisers has a significant bearing on the reliability of the emissions estimates. Burning of cane in the fields also has a significant effect, comprising 10 to 15% of agricultural emissions when the total crop is burnt.

These values assume that all sugarcane lands were established before the cut-off date, thus excluding direct land change effects. The effect of direct land use change is very significant. If it is assumed that all cane land is established from grassland, use of the average of IPCC default values of 4 t CO₂eq/(ha.y) leads to doubling of the carbon footprint, before any credits, to 0.86 g CO₂eq/g sugar.

After credits for molasses and power, the footprint at 0.73 g CO₂eq/g sugar is more than double that of the base case. If it is forest land that is converted, the penalty in terms of GHG emissions is too large to bear.
Sensitivity to input parameters

A sensitivity analysis was carried out to show the effect of changes in the assumptions that have the greatest effect on the calculated values. This is a simplified analysis, since it assumes that changing one variable at a time does not affect any other variables. Impacts of the most important variables are shown in Table 3. It is apparent that the yield of cane per ha and the recovery of sugar in the mill (cane/sugar ratio) both have a substantial effect. The cane transport has a less significant effect on GHG emissions. The quantities of N fertiliser and lime added also have a considerable influence. The effect of emissions in the field is known to be uncertain and variable and so could be responsible for considerable uncertainty in the values obtained. The extent of cane burning is also very significant; it leads to significant amounts of CH₄ and N₂O emissions, with a high global warming potential. Cane residues left to rot in the fields lead to much lower GHG emissions.

The major influence on energy and GHG emissions is the extent of power export. The base case assumes that 10 MW is exported on average during the crushing season, representing 20 kWh/tC in this case. Reducing this to zero increases the net GHG emissions by about one third. Conversely, if the export is increased to over 80 kWh/tC, the GHG emissions actually become negative. This does not mean that the system is actually abstracting CO₂ from the atmosphere, but rather that the effect of power replaced gives a negative balance. A negative net energy use is also obtained.

The use of sulfitation, with a high dosage of 500 g S/tC, has a small effect, only increasing the emissions figure by 0.02 g CO₂eq/g sugar.

If the energy embedded in capital plant and equipment is included, as some schemes propose, the overall effect is small. The net energy usage increases by about 50 kW/tC, but the GHG emissions increase by only 0.02 g CO₂eq/g sugar.
If the blackstrap molasses produced is all converted to ethanol (18.2 ML/y), the GHG emissions are little changed. If they are allocated to sugar and ethanol according to the energy value of the products, the emissions factor for sugar reduces to 0.29 g CO$_2$eq/g sugar, and the emissions for ethanol are 388 g CO$_2$eq/L or 18.3 g CO$_2$eq/MJ.

If ethanol only is produced, the net energy used increases to 118 kW/tc or 1.5 MJ/L ethanol. Carbon emissions are 488 g CO$_2$eq/L ethanol or 23.0 g CO$_2$eq/MJ. This compares with estimates for the Brazilian centre south region of 417 and 436 kg CO$_2$eq / m$^3$ of ethanol for hydrous and anhydrous ethanol respectively, or 20 g CO$_2$eq/MJ (Macedo et al., 2008).

Results of other studies

Tate & Lyle report a figure for white cane sugar of 0.38 g CO$_2$eq / g sugar in a 1 kg consumer pack. Previously, they had reported a value of 0.5 g CO$_2$eq / g sugar, taking into account refining, packing and transport, and recycling and disposing of packaging waste (Houghton-Dodd, 2008).

The growing and milling activities are responsible for 0.19 g CO$_2$eq / g sugar. The figure reported by Tate & Lyle for beet sugar in the same study is almost 1 g CO$_2$eq / g sugar.

Renouf and Wegener (2007) report much higher values in the range of 0.5 to 0.8 g CO$_2$eq / g sugar. These values are inflated by higher estimates of nitrogen emissions from fertiliser, by irrigation and emissions from energy embedded in agricultural capital equipment.

Florida Crystals market ‘carbon-free’ sugar, achieved through the cogeneration and sale of electric power. Their power generation facility can produce 80 MW from 103 bar steam, using the mill bagasse as well as 900 000 tonnes of wood waste/year diverted from landfills as the fuel source.

British Sugar used the procedure of PAS 2050 to arrive at a figure of 0.6 g CO$_2$eq / g sugar. This is the B2B figure, as provided to the industrial user. About 60% of the emissions are due to fuel use at the factory (pers. comm. P. Watson 2009).

Use of cogeneration in the manufacture of ethanol from wheat particularly in combination with a gas-fired turbine can significantly improve energy and emission improvements relative to gasoline (Concawe, 2007). This strategy is put to good use in British Sugar’s operations.

Strategies to reduce carbon emissions

Any strategy to reduce overall energy use, minimise the use of raw materials and other inputs, and reduce waste will lead to a reduction in the carbon footprint. It seems, therefore, that a low carbon footprint will generally be a consequence of an efficient operation.

In the sugarcane industry, particular improvements can be achieved by focussing on the following, in roughly the following order of importance:

- Cogenerate and export power to the maximum extent possible
- Maximise cane yield and factory recovery
- Reduce the amount of fertiliser and chemical inputs, particularly N fertiliser
- Reduce the extent of cane burning to zero
- Reduce the quantities of any supplementary fuels purchased.
- Minimise irrigation power input.
- Reduce cane transport distances
- Recycle water to reduce water intake.

Other avenues to explore could involve the generation of biogas from wastes. Vinasse from 1 m$^3$ of ethanol treated anaerobically produces 115 m$^3$ of biogas, which in turn can generate 169 kWh of power, after deducting the power used in the process (BNDES, 2008). This can help to augment the amount of power available for export.
Conclusions

It is anticipated that, in the future, the carbon footprint associated with the production of sugar in any cane growing area of the world will have to be declared. This paper provides a way to do this, using currently accepted practices. It is an objective of the Better Sugarcane Initiative to get agreement on a standardised system of estimation both within the sugar industry and the international consumer markets.

The carbon footprint of sugar at the factory gate is expected to be about 0.3 g CO$_2$eq/g sugar on average. In a country where the average per capita consumption is 30 kg sugar per annum, the emissions from the consumption of sugar will be 10 kg CO$_2$ per capita per year. In the UK, the average individual carbon footprint is about 11 t/year – clearly sugar consumption plays a minuscule part in an individual’s carbon footprint.

The carbon footprint of sugar is low by comparison with other products, particularly when full use is made of energy production in conjunction with sugar. This can be used to promote the use of sugar, particularly by comparison with other sweeteners.

L’EMPREINTE CARBONE DU SUCRE

Par

P.W. REIN

*Louisiana State University,*
*Consultant to Better Sugarcane Initiative, United Kingdom*

peterein@gmail.com

MOTS-CLES: Empreinte Carbone, Énergie, Canne à Sucre, Sucre, Éthanol.

Résumé

Le changement climatique est à devenir rapidement un problème grave qui exigera de plus en plus l’attention des producteurs de sucre. Estimer les émissions de gaz à effet de serre dans la production de sucre, aussi connu comme l’empreinte carbone, est une partie essentielle de toute étude de durabilité. Une méthode d’estimation de l’utilisation net d’énergie et des émissions de gaz à effet de serre a été développée, basée sur les travaux effectués sur les biocarburants. Le calcul habituel a été développé pour être utilisé dans les normes de la Meilleure Initiative de la Canne à Sucre, qui mettent l’accent sur la durabilité de l’industrie sucrière. Ce calcul estime les besoins en énergie primaire y compris les effets directs, principalement la consommation de l’énergie, et les effets indirects, qui comprennent l’énergie utilisée dans la production de combustibles, d’engrais et de produits chimiques. Il prévoit également les effets sur le changement d’utilisation des terres. La méthode d’estimation comprend la production de mélasse et/ou d’éthanol et l’exportation de l’énergie. Les erreurs potentielles et les problèmes rencontrés pour arriver à ces estimations sont pris en compte. Les principaux problèmes sont les incertitudes liées aux émissions de l’utilisation d’engrais et la façon dont les émissions sont allouées pour les coproduits. Les résultats démontrent que l’empreinte carbone est plus affectée par le rendement de canne, la récupération du sucre, l’utilisation des engrais, l’irrigation, le brûlis de la canne et l’exportation de l’énergie. Une usine efficiente, configuré pour un maximum de production d’énergie, peut montrer une empreinte carbone négative et, à cet égard, l’exportation d’énergie électrique maximale peut montrer une empreinte carbone inférieure à la production d’éthanol maximale. Le calcul habituel des émissions de gaz à effet de serre des champs à l’usine peut être utilisé pour une unité existante ou dans la conception d’un nouveau projet pour aider à faire les bons choix durables.
LA HUELLA DE CARBÓN DEL AZÚCAR

Por

P.W. REIN

Louisiana State University
Consultant to Better Sugarcane Initiative, United Kingdom
peterein@gmail.com

PALABRAS CLAVE: Huella de Carbón, Energía, Caña de Azúcar, Azúcar, Etanol.

Resumen

El cambio climático se ha convertido en un tema muy serio y requerirá cada vez más de la atención de los productores de azúcar. Estimar las emisiones de gases del efecto invernadero en la producción de azúcar, conocida también como la huella de carbono, es una parte esencial de cualquier estudio de sostenibilidad. Se ha desarrollado un método para estimar el uso neto de energía y las emisiones de gases de invernadero, basado inicialmente en trabajos anteriores realizados en bio combustibles. La rutina de cálculo fue desarrollada para ser usada en los estándares de la Iniciativa para Mejor Azúcar (Better Sugarcane Initiative, Reino Unido, en inglés) la cual se enfoca en la sostenibilidad de la industria de la caña de azúcar. Este procedimiento de cálculo estima los requerimientos de energía primarios, incluyendo tanto los efectos directos como el uso de energía y los indirectos como la energía empleada en la producción de combustibles, fertilizantes y productos químicos. También se pueden incluir los efectos de los cambios provocados por el uso directo de la tierra. Este procedimiento de cálculo también incluye la producción de melazas y/o etanol y la exportación de energía. Se ha prestado atención a los errores potenciales y a los problemas que se deriven de llegar a estos estimados. Los principales problemas son las incertidumbres de las emisiones derivadas del uso de fertilizantes y la forma en que las emisiones son adjudicadas a los co-productos. Los resultados muestran que la huella de carbón está afectada en mayor proporción por el rendimiento de azúcar, la recuperación de azúcar, el uso de fertilizantes, el riego, la quema y la exportación de energía. Una fábrica planificada para obtener máxima eficiencia en la generación de energía puede mostrar una huella de carbón negativa y a este respecto, la mayor exportación de energía puede derivar en una huella de carbón más baja que la producción de alcohol más eficiente. La rutina de cálculo estima las emisiones de gases del efecto invernadero desde el campo hasta las puertas de la fábrica y puede ser usada para una operación existente o en el diseño de un proyecto nuevo para la adecuada toma de decisiones que garanticen la sostenibilidad del mismo.
RADICAL NEW RESEARCH STRATEGY AT THE SMRI: SOME LEARNINGS FROM THE PREPEX PROJECT

By

S.B. DAVIS, G.T. SMITH and J. DEWAR

Sugar Milling Research Institute, Durban, South Africa

sdavis@smri.org, gsmith@smri.org

KEYWORDS: Prepex, Research, Commercialisation, Patenting.

Abstract

In 2006, the Sugar Milling Research Institute (SMRI) embarked upon an ambitious new research strategy to develop technologies capable of creating step-change opportunities for the South African sugarcane processing industry. In doing this, the SMRI has moved away from incremental improvements to much more innovative research with potentially greater commercial rewards for its members. The first major project to be identified under this new strategy was the ‘Prepex’ project, which aims to replace the conventional cane preparation equipment with non-wearing components in order to minimise downtime for knife and hammer replacement. Laboratory and small-scale pilot plant research was undertaken, a detailed economic model was developed, and market assessment was conducted to assess the technical and commercial viability of the process. The technology was proven and a patent was lodged. The learnings outlined in this paper include intellectual property management and the role of economic modelling in driving research and development direction and paving the way for commercialisation.

Introduction

The Sugar Milling Research Institute (SMRI) is a research organisation funded primarily by the southern African sugarcane processing industry and the research arm of the Institute is almost wholly funded from this source. In 2005, the SMRI identified the need to revise its research strategy, in light of a highly competitive marketplace, both domestically and internationally, and the pressure placed on the South African sugarcane industry from diverse factors. The South African sugarcane processing industry already operates at high levels of efficiency and relatively low costs of production by international standards, leaving little scope for using existing technologies to make substantial improvements in efficiencies and costs.

This led the SMRI to embark upon an ambitious new research strategy in 2006 to develop technologies and new products capable of creating step-change opportunities, fully aligned with the strategic objectives and needs of the industry (Dewar and Davis, 2007). In doing this, the SMRI moved away from incremental to much more innovative, high-impact research with potentially greater commercial rewards for its members.

SMRI researchers were encouraged to think laterally and to investigate other industries for technologies that could be used in sugarcane processing, and which could result in significant cost savings or recovery increases.

Cane preparation had been identified as a high cost area of the process, because of the labour and maintenance costs associated with wear of knives and shredder hammers. The first major project to be identified within this new research strategy was to find a way to replace conventional cane preparation equipment with a process that has minimal wearing parts, which it was postulated would reduce maintenance costs and reduce the regular shunts for maintenance.
The nature of this project brought with it a number of challenges which needed to be worked through including, but not limited to, intellectual property (IP) management, economic modelling, and scenario identification and modelling around the potential market for the technology. The development of the process and the learnings that have come with it are discussed in this paper.

The Prepex idea

The Prepex process was born from a demonstration of high-pressure water jetting, and the idea that it might be used to shred sugarcane. A quick test with suitable portable equipment showed that high-pressure water could indeed shred cane very finely. It was clear that this innovative approach could eliminate the maintenance and labour costs associated with regular replacement and hard-facing of the wearing parts in conventional cane preparation equipment, and could reduce the frequency of factory stops required for this replacement. It was envisaged that as a consequence of its ability to shred the cane finely, the water jetting process could not only replace conventional preparation equipment, but it could perhaps combine preparation and extraction into one unit operation (Figure 1), with obvious cost savings. Hence the name ‘Prepex’ (Preparation/Extraction) was coined.

![Fig. 1—Outline of Prepex process.](image)

From an early stage it was realised that two of the key factors that would determine the commercial feasibility of Prepex were the amount of water required to shred the cane, and the energy required to do so. The first factor not only influences the energy required directly, but any more water used for the preparation and extraction in excess of current imbibition added would bring an additional energy penalty for evaporation. Hence, it was necessary to develop a test rig to determine the water and energy requirements.

Need for confidentiality

It was obvious that, should the Prepex technology prove successful, it would need to be exploited appropriately, and that the SMRI members should get the benefit of having funded the development. Thus, protection of the idea and know-how at an early stage was critical to ensure that a formal IP protection route could be followed if deemed appropriate. Confidentiality around the new idea had to be assured. This entailed consideration of:

- **In-house confidentiality.** Scientific researchers are taught to publish their results in journals and at conferences and are keen to share their experiences with other experts in the same field. When working on new, possibly ground-breaking, technologies, this is not always the desired behaviour. It may be necessary to keep the invention, design, project, and the scientific work confidential until the IP has been properly protected. For Prepex, this required a change of behaviour on the part of the researchers, and also required that measures above and beyond the standard Confidentiality Agreements required by the company were put in place. This included frequent reinforcement of the need for confidentiality with employees, not solely the researchers, but every member of staff who assisted with research, documentation, analysis, and any other work to do with the project.
• **Collaborator/Partner/Supplier/Service provider confidentiality.** During the Prepex project, the SMRI team required particular information (for example, the specifications and costs of very high pressure pumps with particular materials). Before revealing any of the process know-how or even the Prepex concept to potential collaborators, suppliers, or service providers, it was necessary to ensure that there was a comprehensive Non-Disclosure Agreement (NDA) in place to protect the potential IP. This led to delays in the research as these NDAs were negotiated and signed. The terms of the NDAs included the requirement that the other party also had agreements in place with their employees to ensure that the NDA was adhered to across the company.

• **Distribution of reports.** The SMRI’s Advisory Research Committee (ARC), which comprises industry, scientific and academic representatives, meets twice yearly to guide research direction and to oversee progress of current research areas and to ensure that the SMRI Research Program remains relevant to the industry’s needs. In order to keep SMRI member factories, and more specifically the ARC, informed of progress and to retain their support to continue work on Prepex, it was necessary to provide regular progress reports. There was thus a play-off between maintaining confidentiality and providing information each time a report was issued. To reduce the risk of premature leakage of IP, the SMRI was forced to produce reports that contained indications of success, as well as any problems that needed to be overcome, without revealing the intricate details of the IP. It was also necessary to differentiate what information was distributed to the ARC, and what was disclosed to the general membership via monthly reports. Raising awareness with the ARC of the need for confidentiality of the information shared with them was also a new requirement of the SMRI’s new research strategy.

**Techno-economic modelling**

It is well-appreciated at the SMRI that, in order for research to be considered successful, it must be directed towards achieving outcomes, namely the commercial implementation of technologies, processes and products derived from the research. Hence, evaluation of the merits of a research project must be done on the basis of both technical and commercial risks and potential rewards, to both the SMRI and its members.

Consequently, it is necessary at an early stage in the project to develop a techno-economic model that can provide insight into these areas. The detail and accuracy of the information contained in the economic model will likely increase as the project progresses.

Where a technology will replace an existing process, as with Prepex, this allows one to know what the boundaries are relating to costs. For Prepex, rough estimates of costs were used initially, but as the project progressed, the numbers in the model were refined as information was gathered.

Regular updates of the model allowed the research team and the ARC to make informed decisions on the viability of Prepex, as well as decisions on how the perceived costs, or risks, weighed against the perceived rewards should the technology be implemented. An important aspect of such a model is that it should include sensitivity analyses to direct research towards the key elements that have the greatest influence on the economic feasibility of the technology.

The model used for the Prepex technology compared the existing technology costs with those of the Prepex process, and included costs such as:

- Annualised capital costs. These were based on major items, such as knives, shredders, diffusers and mills, with percentages applied for ancillary items.
- Annual maintenance costs;
- Annual labour costs, where savings could be made;
- Energy costs.
Although the first three costs sound simple to determine, it was difficult to get accurate values for existing preparation and extraction installations. Of the three, capital costs should be the most accurate, as data from projects involving new factories, or capacity increases, are fairly readily available. Companies are, however, often reticent to divulge these numbers. Accurate maintenance and labour costs for particular areas of the factory were even more difficult to come by for a number of reasons. This area is one where sugar companies can compete on production costs and, as such, they are often unwilling to divulge information that may assist a competitor. Secondly, factories do not always maintain accurate records of maintenance and/or labour costs for each section of the factory. It was therefore necessary to estimate these costs for the project economic reviews.

At the early stage of development of Prepex there was poor technical definition of the size and nature of the equipment required. As the project progressed, it was possible to refine these costs only slightly as the plant design could not be finalised. Maintenance costs depend on the reliability of equipment and maintenance cycles required. In the case of new technologies, these may need to be estimated for the entire project life cycle, until a demonstration plant is in operation. In the case of Prepex, suppliers of the major equipment could not provide any reliable data on the maintenance or replacement frequency of the equipment, such as nozzles and high pressure pumps and, consequently, estimates had to be used. Conservative ‘worst-case’ estimates are often used, which could affect the viability of the new technology detrimentally, but for Prepex the research team and its industry-appointed advisors used their engineering judgement to estimate realistic values.

Technical development

Laboratory experimental work

A small rig (Figure 2) was constructed at the SMRI for testing of the principles and to gain an understanding of the key factors affecting the efficiency of the Prepex process. This rig was capable of processing only a few stalks of cane at a time and for short durations only (2–10 seconds). Nevertheless, it enabled several different types and configurations of nozzles to be tested, and allowed the project team to get an idea of what was possible and what wouldn’t work. However, although the rig enabled the team to shred cane completely and rapidly (Figure 3), it was clear that it would be difficult to optimise the energy and water consumption because of edge and start-stop effects associated with the small rig. At this stage, it was realised that a larger rig would be required, which would be able to generate sufficient shredded cane for initial extraction trials to progress, and a request for such a rig was taken to the ARC for support.
However, because of the radical nature of the technology and the conservativeness of the world sugar industry, the ARC guided the SMRI research to focus initially on preparation only, rather than develop the combined Preparation/Extraction technology. This was not entirely in line with the project team’s thinking, as the maximum benefit was believed to come from the combination of preparation and a simplified extraction process. Nevertheless, the ARC approved the budget to construct a larger rig that was capable of handling up to 60 kg of cane at a time.

![Cane shredded with Prepex.](image)

This larger rig was built (Figure 4) and testing commenced. One of the factors that was believed to limit the efficiency achieved with the first rig was the pressure of the water. The new rig was designed to handle a higher pressure, but the cost of a pump to supply the pressure and flow-rate was prohibitive, so a suitable pump for testing was borrowed from a commercial high pressure cleaning company. However, the limited availability of the pump meant that an extensive experimental program could not be carried out, and unavoidably delayed the rate of progress.

![Larger Prepex rig.](image)

The trials that were performed showed that the technology certainly had great potential, and that energy requirements were in line with those of current preparation equipment. Some concern was again expressed about the amount of water required, and how this would impact on the extraction achieved in the following step. It was postulated that a way around this would be to use juice instead of water for the shredding. The major problem that was encountered was sourcing
pumps that could pump sugar juice at the flow rates and pressures required. Most pump manufacturers contacted were unwilling to commit to quoting for a unit for this duty, and one pump that was considered suitable was extremely and unrealistically costly because of the uncertainty about the effects of the high pressure juice on the pump internals. This information was fed back into the economic model, and somewhat changed the outlook for the viability of the technology.

**Upscaling the technology for commercialisation**

In order to get more certainty about the energy and water consumption, and to better define the technical details with a view towards commercialisation, the next stage was to design and build a pilot plant at a factory. The SMRI realised that for the technology to become a success and to be transferred to the marketplace where commercial outcomes could be realised, it was appropriate to engage with a company that would be able to assist the SMRI to scale-up the technology through to commercialisation. It became clear that a simple ‘arm’s length’ transaction with a party was not going to be appropriate, and a partnership would be required. A potential partner would want to be assured of the technical and commercial potential of the technology and share in the subsequent commercial returns from the technology.

The appropriate time to bring a partner on board requires some thought, considering the balance between the increased likelihood of commercial success and the share of the eventual returns. Detailed agreements on IP sharing are required, i.e. what background IP each of the parties possess and how foreground IP developed during the partnership will be shared.

The process to decide on an appropriate partner for Prepex required considerable debate, in that some of the obvious candidates were already involved as SMRI members or were direct competitors in technology development. Thus it became necessary to develop and agree on a set of evaluation criteria that could be used objectively to rate each candidate’s suitability, and an expression of interest was called for from the short-listed candidates. In the end, a suitable partner was selected but, by this stage, the time was rapidly approaching for the national patenting applications, and there were still some technical and commercial hurdles to be addressed.

A brainstorming session was held with the chosen partner to agree on the way forward and the appropriate way of developing the technology. The technical success of the technology was recognised, but some peripheral technical hurdles could only be addressed by further expenditure on a pilot plant. However, the cost of pumps to pump juice appeared to be a major factor in the economics, and there was insufficient information available to reduce the uncertainty and risk associated with these costs. It was agreed that, given the current information available to the parties, the commercial risk did not warrant investment in a pilot plant and further work at this stage.

**IP protection**

**Early considerations**

In parallel with the technical development, formal protection of the IP was considered. The first decision to be taken was whether to patent at all. Just because an idea is patentable does not necessarily mean that it should be patented. Issues that need to be considered are the costs of patenting, the chances of being able to exploit the patent, the willingness of the organisation and its stakeholders to protect, enforce and defend the patent, and how the patent would be linked with the technology exploitation plan.

Once it has been decided to patent, the decision as to when to patent must then be made. It is generally advisable to delay the formal IP protection process until sufficient information has been obtained to decide on the likelihood of technical and commercial success, but the decision as to when to patent is not always easy. There is a need to balance the risk of the idea being leaked and thus entering the public domain, which will jeopardise the granting of protection by the relevant authorities, with the risk of someone else developing the idea in parallel and lodging proprietary protection in advance.

Although most countries abide by the ‘first to protect’ principle, some countries, notably the USA, abide by the ‘first to invent’ principle. In such cases it may be possible to challenge IP
protection based on dated records kept of meetings, brainstorming sessions, research work, or any other associated ideas. Similarly, such detailed records are important with regards to NDAs signed with collaborators, service providers and the like in terms of establishing background IP. Although it is accepted practice for scientists to document work in a laboratory workbook, it is less common for engineers to do this as engineers tend to be more interested in solving the problems than in recording how. Keeping of detailed dated records of modifications made and new ideas that were tried was a necessary behavioural change that the Prepex research engineers had to embrace.

**Provisional patent protection**

With regards to the Prepex technology, the SMRI lodged a South African provisional patent in February 2006. This started the clock ticking for development of the technology to the point where a strong and well-defined full patent application could be submitted. However, delays in sourcing and installing some of the equipment meant that time was running out on the provisional patent, and insufficient results were available to be sure of the viability of the technology. One option was to allow the first provisional patent to lapse and to apply for a new one. This carried the risk that anyone who had developed the same technology in parallel and had applied for a provisional patent before the second Prepex provisional patent was taken out would get priority. However, the risk associated with this was considered very small, and the decision was made to buy the extra time with this option, with the follow-up provisional patent being lodged in February 2007.

As work on the project proceeded, the ARC agreed that there was sufficient commercial potential in the technology to apply for a Patent Co-operation Treaty (PCT) provisional patent. Writing this application required considerable debate about what should be included. Considerations included:

- Should the patent cover the process (i.e. the use of high pressure liquid to shred cane) or the product (the details of the equipment to achieve this)?
- Should the patent cover preparation only, or be extended to cover extraction as well?
- Should the patent cover applications beyond preparation of sugarcane to produce sugar to include ethanol as well?
- What are the key elements of the technology that are patentable and protectable?
- What competing technologies were in the public domain, including other patents?

In the end, these questions were resolved, but it was clear that the level of knowledge required to answer them went beyond the experience of the technical project team who had started the project. Other team members with more experience in IP and commercialisation were brought in to assist with these issues. Finally, a PCT patent application was submitted in February 2008 (Loubser and Gooch, 2008). Feedback from the International Preliminary Examination Authority was that all claims were found to be both novel and inventive.

**National phase patenting**

When considering the appropriate strategy for national phase patenting, several issues come into the picture. It is necessary to identify in what countries the protection is to be sought, as each country requires a separate application, with resultant costs. These costs include legal fees for compiling the patent filings, translation costs where required in non-English speaking countries, the actual filing costs and annual fees for maintaining the patents. Potential costs for enforcing patents also need to be considered.

Identification of the countries in which to patent requires knowledge of the potential markets in order to determine whether the potential returns would cover the protection costs. These could include countries where the technology may be installed, manufactured for use in other countries or further developed. In the case of sugar factory applications, the market size is probably the easiest to ascertain. The number of factories world-wide, and by country, is readily available. More difficult is an estimation of market penetration. Points that need to be considered include:
• Would the technology only be installed in new installations?
• Would the technology be installed to replace worn-out or obsolete equipment?
• Would the technology be installed to replace functional existing equipment?
• Would the technology be installed for capacity increases?

Factors which affect the above decisions are mainly the capital and operating costs and the return on this investment. If the returns are significantly higher than for existing technologies, then there is a case for replacing equipment and reaping the rewards as soon as possible. If the benefits are lower, then the technology may only be used for some of the other scenarios.

Another factor for consideration in the scenario analysis is the industry itself. What barriers to entry exist in the industry with regards to new technologies? The sugar industry has shown itself to be fairly conservative, with the uptake of new technologies (e.g. wholestick shredders and diffusers) to be fairly slow, despite the apparent advantages. This consideration could have a significant effect on the market penetration of a new technology, and should be borne in mind for IP management. Patents have a finite lifespan, and the likely number of installations completed in this time is of significance.

While taking account of the assessed commercial risk when national phase patenting decisions had to be made, the SMRI Board was appreciative of the potential impact of the technology which may be realised should some of the existing constraints change or an opportunity arise to exploit the Prepex technology (for example, together with a simplified extraction technology). The Board therefore approved that the technology be patented in South Africa, being the home country, and in Brazil, being the country of greatest growth and expansions and where suitable applications were most likely to arise.

**Conclusions and key learnings**

The Prepex project has been the first major project for the SMRI since the implementation of its ambitious new research strategy. As such, the learning curve has been extremely steep. Irrespective of the outcome of this particular project, the information gathered will stand the Institute in good stead going forward in its quest for radical new technologies that will revolutionise the sugar industry. The key lessons learnt are summarised:

• R&D needs to be aligned with industry strategic objectives – i.e. it must be relevant.
• Assess the techno-economic potential of various projects as early as possible and invest in those where there is a higher chance of successful outcomes.
• There is more to a commercial outcome/success than a good idea and a technically proven technology. Commercial issues may be more difficult than the technical ones.
• It is important to develop an economic model early and update it frequently.
  o Include sensitivity analyses.
  o Identify key hurdles and direct R&D efforts to resolve them.
• Understand the importance of collaboration – different skills feature strongly at different phases of the innovation process.
• Realise the importance of good IP management.
  o IP awareness among all stakeholders – researchers, support staff, members/sponsors, collaborators, suppliers – is critical.
  o Need to look at ways of keeping interest/support of members/sponsors without divulging key details (risk of IP leakage).
  o Ensure that membership rights are reserved.
  o Don’t waste time innovating in areas where you are already locked out by prior patents/public domain issues – keep abreast of the state-of-the-art.
  o NDAs must be in place before discussions with outside parties and this can slow down the development process.
o It is critical to maintain a detailed paper trail of developments and discussions.

• Patenting decisions are complex.
  o Whether to patent – just because the technology is patentable does not mean that one should patent the technology.
  o When to patent – there is a trade-off between needing sufficient knowledge about the technology to lodge a strong patent and the risk of IP leakage or being piped at the post by a competitor.
  o Where to protect – this is driven by the exploitation strategy, cost: benefit assessment, potential take-up of the technology, conservativeness of the industry, and so on.

• Learn from your mistakes and successes, and use the lessons the next time.
• If failure seems likely, fail quickly – otherwise it can be VERY expensive.
• Decision-making is required at each stage to upscale the technology.
  o The more certainty required, the more it tends to cost.
  o When the certainty is not there, the decisions tend to come down to the potential of the technology (Prepex: potential = MASSIVE) versus the technical/commercial risks and the investment required.

• Above all, if you do not try, you will never succeed!

NOUVELLE STRATEGIE RADICALE DE RECHERCHE AU SMRI: QUELQUES RESULTATS DU PROJET PREPEX

Par
S.B. DAVIS, G.T. SMITH et J. DEWAR

Sugar Milling Research Institute, Durban, Afrique du Sud

Mots clés: Prepex, Recherche, Commercialisation, Brevet.

Résumé

EN 2006, le Sugar Milling Research Institute (SMRI) a entrepris une nouvelle stratégie de recherche ambitieuse pour développer des technologies capables de créer des opportunités de changement radical pour la transformation dans l’industrie de la canne à sucre sud-africaine. Ce faisant, le SMRI a réduit les projets de moindre importance pour des recherches novatrices, avec un potentiel de gains commerciaux plus importants pour ses membres. Le premier projet majeur à être identifié dans le cadre de cette nouvelle stratégie a été le projet ‘Prepex’, qui vise à remplacer le matériel de préparation de canne à sucre traditionnelle avec des composants qui résistent à l'usure afin de minimiser les arrêts pour le remplacement des couteaux et des marteaux. Des essais à petite échelle et en laboratoire furent entrepris, et un modèle économique détaillé a été développé afin d'évaluer la viabilité technique et commerciale du projet. La technologie a été prouvée et un brevet a été déposé. Les résultats présentés dans ce document incluent la gestion de la propriété intellectuelle et le rôle de la modélisation économique de la recherche et du développement ouvrant la voie à la commercialisation.

NUEVA ESTRATEGIA RADICAL DE INVESTIGACIÓN EN EL SMRI: ALGUNOS APRENDIZAJES DEL PROYECTO PREPEX

Por
S.B. DAVIS, G.T. SMITH and J. DEWAR

Sugar Milling Research Institute, Durban, South Africa

PALABRAS CLAVE: Prepex, Investigacion, Comercialización, Patente.

Resumen

EN 2006, el Instituto de Investigación de Molienda de Caña (SMRI) se embarcó en una nueva y ambiciosa estrategia de investigación para desarrollar tecnologías capaces de crear oportunidades de ‘cambio de nivel’ para la industria procesadora de caña de Sudáfrica. Al hacer esto, el SMRI pasó de realizar mejoras incrementales a una investigación más innovadora con mayores beneficios potenciales para sus miembros. El primer gran proyecto de esta nueva estrategia fue el proyecto ‘Prepex’, que busca el reemplazo de los equipos convencionales utilizados para la preparación de caña por equipos con componentes que no se gastan, con el propósito de minimizar el tiempo de reemplazo de éstos. Se realizó investigación a pequeña escala en laboratorio y planta piloto, se desarrolló un modelo económico detallado y se realizó un estudio de mercado para determinar la viabilidad técnica y comercial del proceso. La tecnología fue comprobada y patentada. Los conocimientos descritos en este trabajo incluyen el manejo de la propiedad intelectual y el rol del modelamiento económico para conducir la investigación y el desarrollo y construir el camino hacia la comercialización.
THE PREPARATION OF HUMAN RESOURCES FOR SUGARCANE IN MEXICO

By

N. MILANÉS-RAMOS¹, A. CASTILLO-MORÁN²,

KEYWORDS: Sugarcane, Human Resources.

Abstract

The University of Veracruz (U.V.) is a public institution that has historically been recognised, both nationally and internationally, for its work in the fields of art and literature. However, U.V. is located in the Mexican State with the highest sugar production of the country and, therefore, in recent times has focused on social, cultural and technological aspects of the local community within which U.V. finds itself, particularly in this significant agro-industry of Mexico. The Institute for the Improvement of Sugar Production (IMPA), founded in 1949, was the institution that sponsored research in this area, but this entity closed in 1990. This was the main catalyst that led the University of Veracruz, jointly with other centres, to initiate a program to prepare students for a career in the sugarcane sector in Mexico. A total of 57 sugar mills operate in Mexico, which are distributed throughout 15 states and produce over 5.5 million tonnes of sugar. The State of Veracruz contributes 41% of the national production. Eleven of its factories are located in the region of Cordoba, where the MSc program ‘Sugar Cane Cultivation and its Impact on the Environment and Social-Economic Factors’ has been implemented. Based on the previous 40 MSc students of ‘Management and Use of Sugar Cane Agricultural Systems’, 8 students have qualified and the remaining are expected to qualify at the end of 2010. Currently, nine graduates are working in sugar mills within the Cordoba region. The paper shows all the characteristics of the MSc program and its relationships to the agro-industry of Mexico, through the research project and technological improvement, and offers several results of the finalised research. The preparation of highly trained human resources for the sugar cane industry is the essential goal of this program.

Introduction

In México, 57 sugar mills, distributed throughout 15 states of the Republic, are operating and grow over 650 thousand hectares of sugarcane, within 4 agro-climatic regions along west and east coasts of the Pacific Ocean and the Gulf of Mexico-Caribbean Sea at 19º latitude, (Marín, 1998; Flores, 2001). Production amounts to more than 49 million tonnes of cane and five million tonnes of sugar, with cane yields ranging in recent years between 64 and 72 tonnes/ha and factory recovery (commercial cane sugar) around 11% (Manual Azucarero Mexicano, 2008). That the industry supports, directly or indirectly, more than three million Mexicans. Veracruz comprises approximately 41% of the national production with 22 sugar mills, of which 11 are in the Cordoba Region, where the University of Veracruz (U.V.) is situated.

This University is a public institution with significant national and international stature. Being in the heart of the Mexican sugar industry, the U.V. has been associated with the sugar industry in social, cultural and technological fields. Consequently, when the former Institute for the Improvement of Sugar Production (IMPA) closed in 1990, the U.V., in collaboration with the
National Program of Research in Sugarcane Science and Technology and with the Latin America and Caribbean sugar exporting countries group, initiated a specialised sugarcane related program in 1993, which came to fruition in June 1995. This experience fostered a strategic alliance between the organisations and enabled the establishment of the Masters degree of ‘Management and Use of Sugarcane Agro systems’ in December of 1996.

The objective of this course was to provide the local sugar industry with highly qualified personnel, with 56% of the teaching staff having a Ph.D. degree. This high level teaching experience comprises staff having qualified at the University of Veracruz (U.V.) including its Library and Information Services Unit (USBI), the Autonomous University of Chapingo (ACH), the National Chamber of Sugar and Alcohol Industries (CNIAA), DGETA, the Veracruz, Oaxaca and Puebla sugar mills, and the Orizaba High Tech Lab (LATO-U.V.), all from Mexico, and internationally: the National Sugarcane Research Institute (INICA) of the Ministry of Sugar (MINAZ) of Cuba, the Havana Agricultural University (UNAH), CENGICAN, the University of San Carlos and Pantaleon Sugar Mill of Guatemala, the Luis de Queiros Higher Agriculture School of the University of Sao Paulo (ESALQ) of Brazil, and the Sugarcane Research and Extension Division (DIECA) of Costa Rica.

Program goals

The program goals are to prepare human resources, which may contribute to the development of a competitive, diversified and sustainable sugarcane agro-industry, able to design, lead and conduct programs of applied research, training and technological innovation in sugarcane, linked to the agro-industry and to the environment.

General characteristics of the program

The general characteristics of the program are as follows:

- Two years of postgraduate study (four semesters), including a dissertation or thesis work, except certain cases in which the research project requires a longer period, which must be certified by the tutor of the thesis and which cannot be more than one year.
- The student must submit a thesis title, at the beginning of the study program, which, once approved by the tutor, can be submitted to the Masters coordinator from which time the student has a two year period to finish his (her) thesis or to timely apply for an extension.
- The Study Plan is composed of 19 subjects, comprising three main groups; viz Methodological Training, General Agricultural Training and Specific Sugarcane Training. 14 of the subjects are compulsory and one elective subject needs to be selected from the remaining five. Furthermore, the program includes two activities as program requirements: the writing of a dissertation or thesis and an exam. This comprises a total of 1125 hours, of which 585 hours are of theoretical preparation and 540 of practical training. Tables 1 and 2 highlight the work hours and academic credits associated with the course as well as the broad curriculum structure.
- Students must also obtain Level II English and/or French Language as well as demonstrate computer use proficiency that may be acquired from institutions accredited by the Ministry of Public Education before the degree is awarded.

Applied research lines of the program

The dissertation or thesis projects of the students generally focus on the current research needs within the local sugar industry at that time but are confined to the broad areas of:

- Sugarcane breeding and selection.
- Sugarcane agricultural technology.
- Sugarcane byproducts, biotechnology and the environment.
- Sugarcane plant protection.

Academic results

Admissions and exits

During the period 1997 to 2008, ninety-seven (97) students registered, of whom 40 have graduated, amounting to 41% of the total number of registered students (Table 3). The masters graduated are, in large majority, working in various sugar mill plantations and other agro-industrial enterprises of the country, with excellent production and social achievements.

Training for growers and field technicians of the sugar mills

Since 2002, the Masters Degree program has also been conducting training courses for growers and field technicians in the following subjects: Sugarcane Pest, Disease and Weed Management, Varieties and Seed cane, Nutrition and Fertilisation, Field Management, Sugarcane Quality, Sugarcane By-products and Crop Harvesting. Until December 2008, twenty courses have been made available, with 614 students from 57 sugar mills attending, and 22 postgraduate professors have delivered classes. Relationships with other national and international institutions and enterprises

Practical tours arranged by the professors for the students have been arranged with the support and collaboration of the following institutions and countries:

• To the National Sugarcane Research Institute (INICA) Cuba, during years 2002,
• To CENGICAÑA, Pantaleon Sugar Mill and the University of San Carlos, Guatemala, in years 2001, 2002, 2004 and 2006.
• To ESALQ and CENA of the University of Sao Paulo, Brazil, in years 2005, 2008 and to CINCAE of Ecuador in 2005.
• To DIECA, Costa Rica, in year 2007.

Furthermore, support has been received to fulfil student's project tasks by the following sugar mills: Central Motzorongo, San Miguelito, Central Progreso, San José de Abajo, El Potrero, La Providencia, Constancia, La Margarita, Tres Valles, Adolfo López Mateo, El Modelo, Calipam and Huixtla.

Main research results attained

• Characterisation of the main commercial, promising and traditional sugarcane varieties of Mexico. Through various student dissertation (thesis) projects and the available information, the botanical and agro-industrial characterisation of the most important sugarcane varieties of the country, including photos and ripening curves, was carried out, including the following varieties: Mex. 69-290, CP 72-2086, Mex 79-431, Mex 57-473, Co 997, Q 96, SP 70-1284, RD 75-11, My 5514, ITV 92-1424, PR 66-2231, CMex 93-45, CMex 93-49, MotzMex 91-207, AteMex 96-40, C86-12, NCo 310, L 60-14, POJ 2878, B 4362 and Co. 421 (Hernández, 2004; Patiño, 2005).

• Characterisation and control of the main weeds of sugarcane in the region ‘Central Veracruz’, Mexico. Through various student dissertation (thesis) projects and the available information, the descriptive characterisation, distribution, propagation and integrated control of the 50 most important weeds, by their level of hazard to sugarcane, which include the following number of weeds by families: Poaceae, 17; Cyperaceae, 2; Amaranthaceae, 4; Compositae, 8; Commelinácea, 1; Portulacaceae, 2; Solanácea, 1; Papaveraceae, 1; Malvaceae, 2; Leguminosae, 3; Convolvulácea, 1; Acanthaceae, 1; Cucurbitaceae, 1; Euphorbiaceae, 3; Fabaceae, 1; Araceae, 1 and Boraginaceae, 1. (Ordóñez, 2002; Vilaboa, 2003; Illescas, 2004; García, 2008).

• Nitrogen fertilisation of sugarcane in San José de Abajo and San Miguelito Sugar Mills, Veracruz, showed no response in the plant cane cycle, nor to split application of this nutrient, under the prevailing rainfed conditions, in San José de Abajo Sugar Mill, both in cane yield or in sugar recovery. In the second ratoon cycle, under rainfed conditions, in San Miguelito Sugar Mill, nitrogen fertilisation positively influenced cane yield, and through this the pol or sucrose yield per hectare (Table 4), but not in a split application. An optimum rate of 140 kg/ha was found (Figure 1) (Escarola, 2003; Norato, 2004).

• Sugarcane potassium fertilisation on Cambisol soils, of San Miguelito Sugar Mill, Córdoba, Veracruz, México. At planting of trials, due to inadequate monoculture and crop agronomic management, losses of soil nitrogen (0.11%), organic matter (1.55%) and potassium (16.5 K₂O/100 g) had taken place, producing changes in the category of these components (Tables 5 and 6). Treatments of 150 and 225 kg of potassium per hectare and fixed levels of 167 and 0 kg/ha of nitrogen and phosphorus, respectively, resulted in significantly higher tonnes cane/ha/month, percentage of pol/cane and tonnes sugar/ha/month in plant cane while, in first ratoon, only the treatment of 225 kg potassium per hectare was higher (Tables 7 and 8). (Arreola, 2002; Niño, 2007; Colorado, 2008).

• Influence of sugarcane harvest residue management on cane yield at El Potrero Sugar Mill, Veracruz. When evaluating the following harvest managements: 1) Cane pre-harvest and post-harvest residue burnings (PHRB), 2) Cane pre-harvest burning, without post-harvest residue burning (WPHRB), 3) Green cane harvesting, without pre-harvest and without post-harvest residue burning (GCWPHRB) and 4) Green cane harvesting, without pre-harvest but with post-harvest residue burning (GCPHRB), it was concluded that the best treatment was No. 3: Green cane harvesting, without pre-harvest and without post-harvest residue burning, which produced 24.25 tons of cane more than burnt cane, while the lowest yield was in the green cane harvest and subsequent residue burning (Table 9), as reported by Molina (2004).

Conclusions

Programs for training of human resources as presented in this paper can contribute to improve human capital for the sugarcane agro-industry. The programs require collective support of neighbouring countries for maximum effect. Many of the subjects included in the program are available as distance learning subjects, which assists in the admission of students in their own countries and the participation of professors from various countries of the world. Education and research is an important element for ensuring the sustainability of sugar industries around the world. This particular program has made an important impact in the Mexican sugar industry.

Résumé

L'UNIVERSITE de Veracruz (U.V.) est une institution publique qui a été historiquement reconnue, tant au niveau national qu'international, pour son travail dans les domaines de l'art et de la littérature. Toutefois, cette université se trouve dans l'état mexicain où la production de sucre est la plus élevée du pays et, par conséquent, elle s’est concentrée ces derniers temps sur les aspects sociaux, culturels et techniques de la communauté locale au sein de laquelle elle se trouve, en particulier dans cette importante région agro-industrielle du Mexique. L'Institut pour l'Amélioration de la Production de Sucre (IMPA), fondée en 1949, a entrepris la recherche dans ce domaine, mais cette entité a fermé ses portes en 1990. Cela a été la principale raison qui a conduit l'Université de Veracruz, conjointement avec d’autres centres, à lancer un programme afin de former les étudiants pour une carrière dans le secteur de la canne à sucre au Mexique. Un total de 57 usines sucrières fonctionnent au Mexique, réparties dans 15 Etats et produisant plus de 5.5 millions de tonnes de
sucre. L'état de Veracruz contribue à 41% de la production nationale. Onze de ses usines sont situées dans la région de Cordoba, où le programme pour l’obtention d’une maîtrise en Culture de la Canne à Sucre et son Impact sur l'Environnement et les Facteurs Sociaux-Economiques a été mis en œuvre. Parmi les précédents 40 étudiants de Maîtrise en Gestion et Utilisation des Pratiques Culturales de Canne à Sucre, 8 étudiants se sont qualifiés et les autres le seront à la fin de 2010. Actuellement, 9 diplômés travaillent dans les usines sucrières au sein de la région de Cordoba. La présentation montre toutes les caractéristiques du programme de Maîtrise et ses relations avec l'agro-industrie du Mexique, à travers le projet de recherche et l'amélioration technologique et offre plusieurs résultats de la recherche finale. La formation des ressources humaines hautement qualifiées pour l'industrie sucrière est l'objectif essentiel de ce programme.

PREPARACIÓN DE RECURSOS HUMANOS PARA LA CAÑA DE AZÚCAR EN MÉXICO

PALABRAS CLAVES: Caña de Azúcar, Recursos Humanos.

Resumen

LA UNIVERSIDAD Veracruzana (U.V.) es una institución pública, de reconocido prestigio en las artes y la literatura a nivel nacional e internacional, que al estar en el Estado con mayor producción azucarera en México y con el compromiso social, cultural y de desarrollo tecnológico que la sociedad le confiere, no es ajena a la problemática de la principal agroindustria del país. El Instituto para el Mejoramiento de la Producción de Azúcar (IMPA), fue fundado en 1949 y desarrolló durante muchos años importantes investigaciones de gran valor para este cultivo, pero fue cerrada en 1990. Dada esta situación la Universidad Veracruzana, en coordinación con otras instituciones, inició el programa de formación de recursos humanos en el campo de la agricultura cañera en México. En el país operan un total de 57 ingenios azucareros, distribuidos en 15 estados y producen mas de 5.5 millones de toneladas de azúcar anualmente. El estado de Veracruz contribuye con el 41% de la producción nacional. Once de estas fábricas están localizadas en la región de Córdoba, lugar donde funciona el Programa de la Maestría sobre el cultivo de la Caña de Azúcar y su impacto ambiental y socio-económico. Hasta el presente 40 alumnos de la Maestría en Manejo y Explotación de los Agro sistemas de la Caña de Azúcar han concluido sus tesis, 8 están por obtener el grado de Maestro en Ciencias de inmediato y el resto se espera que concluyan sus tesis el próximo año. En este momento están cursando el programa 9 alumnos, y todos ellos trabajan en ingenios azucareros de la región. En el presente trabajo se muestran las características generales del programa de la Maestría y su relación con la agro-industria azucarera mexicana, a través de proyectos de investigaciones aplicadas e introducción de tecnologías y se ofrecen varios resultados de las investigaciones finalizadas. La preparación de los recursos humanos para la agro-industria azucarera es el principal objetivo del presente programa.
TECHNOLOGY TRANSFER GROUPS AND THEIR IMPACT ON TECHNOLOGY INNOVATION IN THE SUGAR AGROINDUSTRY IN THE CAUCA VALLEY, COLOMBIA

Characterisation of Productive Units, Dynamic Monitoring.

Abstract

THE PURPOSE of this study was to measure the impact of the technology transfer strategy of forming groups of cane producers known as Technology Transfer Groups (GTT – Spanish acronym) in the process of technological innovation in the sugarcane agroindustry in the Cauca Valley, Colombia. The GTTs prioritised their needs for technical information and then implemented a program for outreach and exchange of the best cultural practices based on various group communication methods. Two years after the program started, a dynamic process of monitoring technological innovation in the production units began; and the changes in the process of technology adoption were characterised over time, focusing on the factors that were most influential in the process. The monitoring, which was done with a representative sample of cane producers, found that the greater exchange of best practices among them led to their faster adoption and increased levels of technology adoption (cane varieties and agronomic practices), as well as the productivity of their production units. In addition, it created a culture of agricultural practices based on site-specific agriculture and strengthened the interactions, communication and integration among the producers, sugar mill professionals and researchers. The greater adoption of technology, product of CENICAÑA’s research, has led to a dynamic process of technological innovation in the sugar agro-industry as the new agricultural practices generate higher returns for the producers, sustainability and competitiveness.

Introduction

CENICAÑA is a private, non-profit corporation, founded in 1977 by the Association of Sugarcane Growers of Colombia (ASOCAÑA). Its mission is to contribute to the development of the national sugar sector by means of research, technology transfer and the supply of specialised services so that the sector is competitive and can play an outstanding role in socioeconomic improvement and in the conservation of a productive, pleasant and healthy environment in the sugarcane production zones.

In 1995, the principles of social marketing were gradually incorporated into the CENICAÑA research and technology transfer system, given the low rate of adoption of the new technologies by the sugarcane productive units, particularly in the Cauca River Valley.

The project ‘Study of the clients for CENICAÑA’s new technology’ was begun. A census was taken of the cane producers and their productive units, which served as a basis for breaking down the clients for the technologies in order to design transfer and technical communication strategies. Two groups were identified according to their level of technology adoption with five subgroups ordered by level of schooling and crop ownership (Isaacs et al., 2000). Then a
behavioural characterisation of the potential adopters was prepared, based on personal characteristics (psychological, sociological and socioeconomic) that were expected to influence the process of technology innovation (M.J. Marrón in Puyol et al., 1995; Isaacs et al., 2002).

In 2001, together with the publication of the third approximation of the agro-ecological zoning for growing sugarcane in the Cauca River Valley (Carbonell et al., 2001), CENICAÑA strengthened its site-specific agriculture (SSA) initiative.

This initiative focuses on adapting and applying research and technology transfer of specific agricultural technologies to specific crop sites with unique soil and climate characteristics, and physical and socioeconomic infrastructure.

Its objective is to optimise the levels of productivity and profitability within the framework of sustainable development.

To disseminate SSA and promote the use of improved cultural practices from the technical, economic, environmental and quality control standpoint, among others, the project ‘Technology transfer groups (GTTs)’ was designed to link the cane suppliers of 11 sugar mills from 2001–2006 (Isaacs and Uribe, 2002; CENICAÑA, 2009a).

The strategic methodology applied successfully by the National Institute of Agricultural and Livestock Research (INIA, Chile) and by the Regional Consortia of Agricultural Experimentation (CREA, Argentina) (Isaacs, 1999; CREA, 2009; INIA, 2009) was adapted.

At the 455 events (293 field days, 104 conferences, 53 workshop-courses and five technical study tours) that the GTT program held during this time, 112 innovative cane growers presented their experiences related to technological management in their productive units. These have been documented and can be consulted on www.cenicana.org.

The objective of this study was to evaluate the influence of the GTT program on the process of technology innovation of the Colombian sugar agro-industry during the period 2001–2008.

Materials and methods

The GTT program has five components:

**Formation of groups and characterisation of the productive units**

In each sugar mill, groups were formed with a maximum of 25 cane suppliers with productive units of similar agro-ecological characteristics. (CENICAÑA, 2008).

A workshop was held with each group to characterise the technologies used in their productive units prior to the GTT program and characterise them using reference indicators to evaluate their management of technology transfer.

The producers filled out a formal survey on technology adoption, socioeconomic characteristics and the physical infrastructure of the productive units under their charge (CENICAÑA, 2009b)

The groups included three different types of producers: PV-1: suppliers with limited innovation and low productivity; PV-2: intermediate in innovation and productivity; and PV-3: the most innovative and with high productivity (Table 1 and Figure 1).

In Figure 1, each isoline represents points of equal productivity in tonnes of sugar per hectare; it means the combination of tonnes of cane per hectare per sugar content (%). All in all, 23 GTTs were formed with 900 suppliers.

**Identification of priorities regarding the groups’ needs for technical information**

In participatory workshops with each GTT, the needs for the groups’ technical information were prioritised by CENICAÑA using a Vester Matrix based on the technological problems that the producers perceived as production constraints (Table 2).

A program of transfer events was prepared, using the communication media preferred by the producers for obtaining technical information: primarily field days and roundtable discussions.
Table 1—Application of Marrón's model explaining innovative behaviour (In: Puyol et al., 1995, p. 339) with producers in Groups PV-1, PV-2 and PV-3 in relation to the adoption of new technologies.

Program of events and their implementation

The field days, as the principal medium of group communication, were preferably held on the farm of the producer identified by the group as being the most innovative and progressive in the
technical topic to be addressed. The program usually included three presentations: (1) The host producer presented the best practices for the topic in question and the results obtained; (2) The technical expert of the sugar mill explained the best practices implemented by the sugar mill; (3) The expert researcher from CENICAÑA discussed the progress made in the related research, with emphasis on the practical results for the producer. Each presentation addressed the technical aspects (application and use of technology), economic factors (profitability of new vs. conventional technologies), environmental aspects (sustainability), and quality control (correct utilisation of the technology). Finally a roundtable discussion was organised to share experiences, define needs for technological R&D, and identify technologies that should be validated under the production conditions in the GTTs’ agro-ecological zones of influence. The producers’ observations, requests, suggestions and recommendations to CENICAÑA were recorded for feedback into the processes of research, technology transfer and the GTT program (Table 3).

The proceedings of each event are published in CENICAÑA’s extranet for reference by registered users, who can also access the SSA information tools on line and consult structured databases that are regularly updated and designed to support the technical, economic and administrative decision-making in the productive units. The Web system also offers access to the library’s catalogues and publications, as well as to the bank of frequently asked questions and technological consultations, whereby the producer has the chance to interact with researchers and consult them about technical issues.

**Dynamic monitoring**

In order to measure the progress made in managing technology adoption, a process of systematic and participatory monitoring was carried out: first at two years after having begun the GTT program in each sugar mill and then at five years.

In this way, the progress in the adoption of the technologies in the short term was measured, and in the medium term the changes in the indicators of productivity and profitability of the productive units were evaluated, after which the impact of the communication strategy was determined. From 2001–2006, a total of 11 sugar mills were connected with the GTT program: Risaralda in 2001; Manueilita and Providencia in 2002; Castilla, Incauca, Mayagüez and Pichichí in 2003; Riopaila and Sancarlos in 2004; Cabaña and Carmelita in 2006. The monitoring analyses were done for the first eight mills.

The information was obtained by means of semi-structured interviews conducted by expert agronomists with a representative sample of the producer population, designed using simple random
sampling. The interviews were held in the productive units, using a guide for recording the current use of technology. The data were then recorded in a database created in Microsoft Excel©. The following analyses were performed:

- **Descriptive analyses** to synthesise the information and characterise the current use of the technologies through graphics, frequency distribution tables, indicators of central tendency and indicators of dispersion. The results obtained were broken down by producer; i.e. the cane provider or administrator of productive units with direct management of a sugar mill.
- **Multivariate analyses** for identifying possible associations between the characteristics of the adopters and non-adopters of the water balance methodology for programming crop irrigation schedules in the productive units.

These analyses were done with the SAS© statistical software v.9.1.3. They comprised:

- Multiple correspondence analysis in which the characteristics of the producers were associated on a Cartesian plane
- Analysis of conglomerates in which the characteristics of the associated producers were grouped in the multiple correspondence analysis, and segments of producers with similar characteristics and behaviours were created.

The results for each sugar mill were documented and then analysed with each GTT. For an example, consult Pino (2007).

**Results and discussion**

Examples are given of the results of the monitoring done in the productive units of cane suppliers participating in the GTT program in relation to the adoption of technologies such as cane varieties, SSA, water management, fertilisation and planting.

**Adoption of technology such as cane varieties**

In 2008, CENICAÑA varieties Colombia (CC) occupied 88% of the area planted with sugarcane in the Cauca River Valley, an increase of 40% with respect to 2001. In 2008, the most planted varieties were CC 85-92 (69%) and CC 84-75 (14%). Other new varieties in commercial validation trials have occupied 5% of the area since 2001 (Figures 2 and 3).

![Area harvested (% ha) vs Time (years)](image)

**Fig. 2**—CENICAÑA Colombia (CC) varieties in the Colombian sugar agro-industry from 2001–2006: Adoption of commercial varieties.

With respect to varietal adoption, the producers in the GTTs said that they decided to adopt a variety when it has:
• a high operating margin;
• sustainable production;
• productivity over 10 tonnes of cane per hectare per month (TCHM – Spanish acronym);
• production 10% higher with respect to the currently planted variety;
• results of commercial testing of 250 ha or more at their specific sugar mill.

Fig. 3—CENICAÑA Colombia (CC) varieties in the Colombian sugar agro-industry from 2001–2006: Semicommercial testing of varieties.

Adoption of the SSA approach for taking decisions about agronomic management

With the dissemination of the SSA approach, the number of cane suppliers that use the agro-ecological zoning developed by CENICAÑA to decide which cultural practices to use has increased by 51%; the cane suppliers that use it to decide which variety to plant has grown by 37%; and those who can identify the agro-ecological zones of influence in their productive units has increased by 15%. A total increment between sugar mills and cane suppliers of 33%, 21% and 8% to each technology.(Figure 4).

Fig 4—Adoption of the site-specific agriculture (SSA) approach for decision-making in the sugarcane crop by cane suppliers and sugar mills.
Adoption of agronomic management technologies with the SSA concept

The principal changes in the adoption of technology by the productive units of suppliers are summarised in Table 4. Some of them are commented on below.

Table 4—Changes in the adoption of technologies in the sugarcane production systems in the Cauca River Valley. Percent cane suppliers (GTTs per sugar mill) who confirmed their use of the technologies.

Table 4 cont.
Water management

The monitoring of the irrigation methods used by the cane suppliers shows that the irrigation events are characterised by continuous furrow and alternate ridge applications with irrigation channels and siphon tubes, followed by continuous furrow applications and the use of gated PVC pipes, alternate ridge applications and gated PVC pipes, and finally sprinkler irrigation.

Water balance

The descriptive analysis indicates increases in the level of adoption of the water balance methodology for programming the irrigation for both the alternate ridge applications and the use of gated PVC pipes, as well as in infrastructure for surface drainage. The principal reasons for the change are related to the benefits obtained with the use of water balance software (Cenicaña© WB v.3.0), reflected in a decrease in the number of irrigations (from 1–3 fewer irrigations per cut), the reduction in production costs, and better organisation of the productive unit. Those who are not using the WB program said that they were unfamiliar with its management.

The first two dimensions of the multiple correspondence analysis explained 92.1% of the total variability; the first dimension (Dim1) explained 82.8% and the second dimension (Dim2) explained 9.3% of the variability.

Dim1 is determined by the adoption or not of the water balance program so that low values of this dimension are associated with producers who do not adopt the program and high values with producers who adopt it. This dimension also presents a direct association with the education level and with the productive unit size; low values of Dim1 are associated with low or medium education level and areas of productive units ≤ 500 hectares. High values of Dim1 are associated with high education level and areas of productive units > 500 hectares. Besides, producers with age ≤ 45 years are associated with high values of Dim1, and producers with age > 46 years with low values.

Given the poor explanation of the variability for Dim2, it is not easy to interpret. Nevertheless, it was considered in the conglomerate analysis.

The statistical technique of conglomerate analysis uses software SAS 9.1 identified the possible associations between the adoption of the water balance methodology and the following variables: utilisation of the WB v.3.0, the producer’s age and schooling; schooling of the field supervisor, net area in cane group, source of the data on rapidly available water (LARA – Spanish acronym), source of information about the WB program, training in the WB program, owning a computer, owning the land and type of legal status. These analyses included information on cane suppliers and professionals from the sugar mills.

Four groups of producers were formed with similar characteristics, and a behaviour based on the adoption of the water balance methodology and the cause-effect relation of the adoption was determined (Figure 5).

Producers with aversion to technological change (Group 1): Characterised by having primary or secondary education (Pprim, Psecu), over 55 years of age, productive units under 50 ha, field supervisor with primary education (Mprim), do not own a computer (Noc), have not been trained in the use of the WB software and did not acquire the WB program (Nocp, Not).

Producers no adopters (Group 2): Characterised by having a technical education (Ptec), ages from 46–55 years, productive units with areas from 51–500 ha, do not use the WB program (Nobh), have not determined the LARA data (Nd), and all of them are cane suppliers (Prov).

Producers with a potential for adoption (Group 3): Characterised by being under 35 years of age, with a professional education (Pprof), manage from 501–1000 ha, trained in the use of the WB software and did not acquire the WB program (Sicp, Not).

Producers adopters (Group 4): Characterised by administering areas over 100 ha, ages from 36–45 years, graduate education (Ppost), obtained the LARA data from a specific study of the farm
Ef, of CENICAÑA’s table (TCc) or from the sugar mill (Ing), have field supervisor with technical education (Mtec), productive units directly managed by the sugar mill (mdi), and use the WB program (Sibh).

**Alternate ridges**

Among the main reasons for using alternate ridge irrigation, the producers mention the limited availability of water, decreased production costs, and optimised use of the water resource.

**Fertilisation**

The use of soil analyses to define the plan for fertilising the crop increased, as well as sending the samples to CENICAÑA’s Chemistry Lab for that purpose. Despite those increases, there was a noteworthy decrease in the number of suppliers that use the critical levels of NPK determined in the research carried out by CENICAÑA. The most frequent reason for this was that they do not use CENICAÑA’s lab service and therefore do not receive the recommendations that are given together with the results of the analysis.

The level of adoption of nitrogen fertilisation (just one application, not split) increased in the GTTs at some sugar mills; while in others there were no important changes. Those who split the nitrogen application explained that the main reason for doing so was the type of soil that they manage (sandy) and also because it is a traditional practice. On the other hand, those who applied nitrogen just once stated that by not splitting it, they also decreased their production costs. They also have knowledge of the positive results that have been obtained in commercial validation trials.

**Planting**

With respect to planting distances, there was a growing tendency for the percentage of suppliers who made the decision to use a distance greater than 12 m. The reasons include decreased production costs due to the use of less seed and the credibility of the experimental results. Those who use planting distances less than 12 m expressed their fear of having to replant and the subsequent increase in production costs.

Regarding the distance between furrows, there was no well-defined tendency of change. The most frequently used distances are 1.65 m and 1.75 m. The reasons indicate that with these distances the crop is favoured during the harvest because there is less damage to the stools from the machinery. Those who used smaller distances between furrows were afraid that the production would decline.
Use of the Web site

CENICAÑA’s Web site plays an active role in its technology transfer process. It offers the cane producers information and documentation services, as well as interactive consulting tools to support crop-related decision-making. Since it was launched in November 2003, the number of users registered on the Web site has increased progressively, as well as the number of users that consult the proceedings of the GTT program based on the statistics recorded by the AWStats© software (Figures 6 and 7).

![Fig. 6—Number of users registered on <www.cenicana.org> from November 2003 to April 2009.](image)

Technology innovation, productivity and profitability

In 2007, CENICAÑA contracted the Foundation for Higher Education and Development (FEDESARROLLO) to conduct an evaluation in order to learn what was the economic return on its investment in research and technology development. It was estimated that the additional net benefits coming from the use of varieties CC 85-92 and CC 84-75 reach US$46 million per year as compared with the use of the other varieties (CENICAÑA, 2008).

![Fig. 7—Number of visits by users with a code to enter the pages containing the proceedings from GTT events on www.cenicana.org.](image)
In experiments to validate the technology with the cane producers' participation, it was found that the use of reduced practices such as reduced tillage, fewer risks in accordance with water balance, lower plant density (seed) and minimum dose of fertiliser according to soil analysis, among others and practices with an SSA focus were good strategies for reducing production costs and increasing the levels of profitability vis-à-vis the conventional practices (Isaacs et al., 2009a, 2009b).

With respect to reducing production costs, the technologies for water management stand out, the use of which have contributed to decreasing up to 50% of the volume of water applied per unit of area.

Conclusions

- The GTT program has proven to be an effective strategy for group communication with the sugarcane producers and has promoted technology innovation in the productive units planted with sugarcane in the Cauca River Valley.
- The GTTs have strengthened the relations and communication among producers, researchers and field professionals from the sugar mills, facilitating the exchange of information on the best cultural practices.
- The exchange of information that is promoted in the GTTs has contributed to strengthening the knowledge of the sugarcane producers with emphasis on SSA applied to crop management.
- The increased levels of adoption of the new technologies promoted by CENICAÑA have impacted on both the productivity and the profitability of the cane productive units.
- The GTTs have been an effective mechanism for providing feedback to CENICAÑA about the needs that the sugarcane producers in the Cauca River Valley have for technological R&D.

Résumé

L'OBJECTIF de cette étude était de mesurer l'impact de la stratégie de transfert de technologie pour former des groupes de producteurs de canne appelés Groupes de Transfert de Technologie (GTT – acronyme espagnol) dans le processus d'innovation technologique dans l’agro-industrie de la canne à sucre dans la vallée du Cauca en Colombie. Les GTTs ont donné priorité à leurs besoins pour obtenir des informations techniques et ont ensuite mis en place un programme de sensibilisation et d'échange des meilleures pratiques culturelles selon différentes méthodes de communication du groupe. Deux ans après que le programme ait été lancé, un processus dynamique d'innovation technologique dans les unités de production a commencé; et les changements dans le processus d'adoption de la technologie ont été caractérisés au fil du temps, en se concentrant sur les facteurs les plus influents dans le processus. Le suivi qui a été effectué à partir d'un échantillon représentatif des producteurs de canne, a démontré que les échanges entre eux ont permis à une adoption plus rapide et à un niveau supérieur de technologie (variétés de canne à sucre et pratiques agronomiques), ainsi qu’une meilleure productivité de leurs unités de production. En plus de cela, les pratiques agricoles se sont améliorées, les interactions, la communication, l'intégration entre les producteurs, les techniciens d'usine et les chercheurs se sont renforcés. L'adoption de la technologie, produit de la recherche du CENICAÑA, a conduit à un processus dynamique de l'innovation technologique dans le secteur de l’agro-industrie sucrière, car les nouvelles pratiques agricoles génèrent plus de revenus pour les producteurs, et assurent la durabilité et la compétitivité.
GRUPOS DE TRANSFERENCIA DE TECNOLOGÍA Y SU IMPACTO EN LA INNOVACIÓN DE TECNOLOGÍA EN LA AGROINDUSTRIA AZUCARERA DEL VALLE DEL CAUCA, COLOMBIA

PALABRAS CLAVE: Grupos de Transferencia de Tecnología, Agroindustria Azucarera Colombiana, Innovación de Tecnología, Caracterización de Unidades de Producción, Monitoreo Dinámico.

Resumen
El objetivo de este estudio fue la medición del impacto de una estrategia de transferencia de tecnología basada en la formación de grupos de productores de caña denominados Grupos de Transferencia de Tecnología (GTT) en el proceso de innovación tecnológica en la agroindustria azucarera del Valle del Cauca en Colombia. Los GTTs priorizaron sus necesidades de información técnica y luego implementaron un programa para conseguir e intercambiar las mejores prácticas culturales, basados en varios métodos de comunicación de grupo. Dos años después de haber iniciado el programa, empezó un proceso dinámico de monitoreo de innovaciones tecnológicas en las unidades de producción; y los cambios en el proceso de adopción de tecnologías fueron caracterizados en el tiempo, enfocados en los factores que influenciaron más el proceso. En el monitoreo, que fue realizado con una muestra representativa de los productores de caña, se encontró que el mayor intercambio de las mejores prácticas entre ellos, condujo a la adopción más rápida y al incremento de los niveles de adopción de tecnologías (variedades de caña y prácticas agronómicas), así como la productividad en sus unidades de producción. Adicionalmente, creó una cultura de prácticas agrícolas basada en agricultura de sitios específicos y fortaleció las interacciones, comunicación e integración entre productores, profesionales de los ingenios e investigadores. La mayor adopción de tecnología, producto de la investigación de CENICAÑA, ha llevado a un proceso dinámico de innovación tecnológica en la agroindustria azucarera mientras las nuevas prácticas agrícolas generan retornos más altos para los productores, sostenibilidad y competitividad.

Abstract

AT THE ISSCT Management Commission Workshop in Townsville, Australia in May 2008, it was reported that, to a larger or lesser degree in most sugarcane producing countries, a ‘disconnect’ exists between research centres and their stakeholders. One reason for such a ‘disconnect’ is that research centres in many industries have already largely maximised productivity potential through cane variety breeding programs but stakeholders are not convinced of this, resulting in incongruent expectations. Another possible reason for the ‘disconnect’ is because productivity improvements are blurred by varying agro-climatic conditions and management practices. It has been suggested that research centres should better employ economic benchmarks to enable sugarcane growers to easily rank different research outcomes that compete for limited on-farm capital and management time. For non-financial experts, capital budgeting can be intimidating but spreadsheets take care of the complex mathematics and an economist or financial expert can be employed to source and disseminate generic costs. The capital budgeting methods described and adapted in this paper for the R&D context provide a powerful marketing tool for R&D outcomes in terms of attracting research funding and enhancing technology transfer to larger sugarcane growing firms in particular. Sugarcane farming is a business and research centres are increasingly required to communicate in the ‘language’ of business, notwithstanding the other environmental and social aspects of sustainable triple bottom line reporting. In an increasingly competitive global environment, this shift towards an improved understanding of economics is appropriate to all scales of sugarcane agriculture.

Introduction

At the ISSCT Management Commission Workshop in Townsville, Australia in May 2008, it was reported that, to a larger or lesser degree in most sugarcane producing countries, a ‘disconnect’ exists between research centres and their stakeholders (Wynne et al., 2008a). One reason for such a ‘disconnect’ is that research centres in many industries have already largely maximised productivity potential through cane variety breeding programs but stakeholders are not convinced of this, resulting in incongruent expectations. Breeding programs are indeed synonymous with maximising productivity potential and, although this rate of productivity increase has ‘slowed’ within commercial agriculture in recent times due to limitations associated with economic, environmental and management factors, active breeding programs must continue to ensure pests, disease, climate change, etc do not compromise productivity potential going forward and to create new economic opportunities through new products (e.g. energy cane) and farming systems (e.g. sustainably...
reducing input costs). This implies that relatively static productivity improvement benchmarks such as tonnes cane/sugar per hectare do not necessarily demonstrate that research and development (R&D) is ineffective; on the contrary, it may demonstrate its importance in preventing productivity declines.

Another possible reason for the ‘disconnect’ is because productivity improvements are blurred by varying agro-climatic conditions and management practices (Wynne et al., 2008b). Technology transfer plays an important role in facilitating the effective adoption of appropriate management practices for different agro-climatic conditions. Therefore, one of the technology transfer challenges is to convince industry participants of the economic value that will be derived from the implementation of a research outcome. Wynne et al. (2008a) suggest that research centres should better employ economic benchmarks to enable industry participants to easily rank different research outcomes that compete for limited on-farm capital and management time. This use of ‘business language’ should also aid research centres to compete more aggressively for investment funding for their future research programs; traditional physical benchmarks such as tonnes cane/sugar per hectare are less effective. The objective of this paper is to assist in providing this language; a glossary of the main economic terms used is presented at the end of the paper. While recognising the importance of environmental and social aspects of sustainable triple bottom line reporting (Christiansen, 2004), this paper will only explore the third economic component.

**Economic benchmarks for end users of R&D outcomes**

The underlying objective function of any sugarcane grower is to make a sustainable and preferably competitive economic return on their limited land, capital and management time. Increasing tonnes cane per hectare or sucrose percent cane are ‘derivatives’ of this underlying economic objective function. Therefore, ranking independent and/or mutually exclusive R&D outcomes in terms of economic worth, subject to environmental and social safeguards, should facilitate decision making and enhance technology transfer.

Governments typically evaluate large public sector projects in terms of the public's willingness to pay for them (benefits) or willingness to avoid them (costs), expressed in the form of a cost-benefit ratio. This is effectively achieved by listing all parties affected by an intervention where a monetary value or ‘welfare’ effect is assigned to each party. This welfare approach is not suited to the business environment of a sugarcane grower; capital budgeting techniques employed by business are more appropriate because they are aligned to optimising economic returns to limited land, capital and management time and therefore technically more robust. Capital budgeting techniques are well documented in the literature, where Brigham and Ehrhardt (2005) is the primary source in this paper. These capital budgeting techniques are explored with the view of applying or adapting them as economic benchmarks for R&D outcomes.

**Determining relevant cash flows**

Capital budgeting decisions are based on ‘free’ cash flows for the entire business, which is the cash flow generated by an economic activity that is available for distribution to investors. An accepted definition of incremental free cash flow for a specific business entity is as follows:

\[
\text{Incremental free cash flow} = \text{EBIT}^1 (1-\text{Tax}) + \text{Depreciation} - \text{Gross fixed asset expenditure} - \text{Change in net operating working capital}
\]

If an R&D outcome were to fully replace an existing on-farm operation, the cash flow difference between the existing and the new constitute the incremental free cash flow of this decision. Consequently, only the incremental cash flows pertinent to the R&D outcome are relevant; all other cash flows associated with other business activities cancel each other out. However, externalities associated with the adoption of an R&D outcome must be included in the

---

1 EBIT means earnings before interest and tax but inclusive of depreciation and amortisation.
incremental free cash flow calculation, whereby the earnings or cost structure of an existing operation might be enhanced or reduced; *i.e.* the net financial effect of the R&D outcome. Similarly, ‘opportunity costs’ must also be included as incremental free cash flows. This could be the market related cash flow that could be generated from an existing asset if it were made redundant by the adoption of the R&D outcome in question or the incremental free cash flows foregone if an existing asset becomes underutilised. The ‘opportunity cost’ approach is also a helpful tool in quantifying the value of costs and benefits that are difficult to otherwise express in financial terms.

Different businesses have different mixes of debt and equity capital (financial gearing) that have different tax implications, attracting different tax rates and possibly different tax laws that may require specialist skills. Furthermore, different businesses have different exposures to financial gearing or amortisation costs as well as working capital requirements. In instances where the implementation of an R&D outcome does not constitute a significant change to the existing financial status of a business, it can be assumed that tax implications and working capital requirements remain largely unaffected. It can also be assumed that 100% equity capital is used to finance fixed asset expenditure associated with the R&D outcome; *i.e.* amortisation costs are zero.

Consequently, the incremental free cash flow definition can be modified to cater for benchmarking R&D outcomes as follows:

\[
\text{Incremental free cash flow} = \text{EBITDA} - \text{Fixed asset expenditure}
\]

The challenges that remain are associated with qualifying fixed asset expenditure that will be incurred by a grower implementing the R&D outcome. A ‘sunk cost’ is fixed asset expenditure that has already been incurred and hence is not an incremental free cash flow and should therefore be excluded from the analysis. Conversely, the market value of an asset after its useful life, or ‘salvage value’, must be included. In terms of the incremental free cash flow timing, it is usually assumed that these occur at the end of each planning period (months or years). Where specialist accounting or economic skills are scarce, as in the scientific realms of research centres, this simplified and standardised approach to determining ‘generic’ incremental free cash flows has merit. Thereafter, adaptations can be made by industry participants or their agents to reflect ‘specific’ business entity operating environments.

**Determining relevant discount rates (finance costs)**

Incremental free cash flows arising from the implementation of an R&D outcome will accrue over a period of time into the future and because a dollar in hand today is worth more than a dollar received in future due to the interest it can earn. Future values (FV), therefore, need to be discounted to a present value (PV), which can easily be computed using a financial calculator or spreadsheet with the following underlying equation, where ‘r’ is the annual discount rate and ‘n’ the time period in years:

\[
PV = \frac{FV}{(1+r)^n}
\]

Inflation complicates matters because inflation erodes FVs; *i.e.* FVs are understated if ‘today’s’ values are used as a proxy for FVs. Therefore, in the presence of inflation, FVs must either be adjusted by an inflation factor or the annual discount rate (r) must be adjusted by an

---

2 In practice, most growers will utilise some debt financing but the extent is widely variable. The standardised 100% equity funding approach is both simple and reflective of the full value of the R&D outcome.

3 EBITDA means earnings before interest, tax, depreciation and amortisation; *i.e.* income generated by the R&D outcome less operating costs incurred by the R&D outcome, excluding depreciation and amortisation associated with the R&D outcome.
inflation factor. The latter approach is appropriate if it is assumed that a similar and consistent inflation factor will apply to all FVs and, because it is simple and robust, it is the preferred approach for research centres.

A business’s weighted average cost of capital (WACC) is the preferred annual discount rate but this varies between businesses and, therefore, from a generic benchmarking perspective, it is proposed that the national prime lending rate⁴ be used as the grower’s proxy annual discount rate (which is termed the nominal annual discount rate \( r_n \); i.e. before inflation is accounted for). A producer related inflation factor \( i \) is then used to adjust the nominal annual discount rate \( r_n \) to a real annual discount rate \( r_r \) as illustrated below, whereby FVs are expressed in ‘today’s’ nominal values (i.e. \( FV_n \) before inflation is accounted for):

\[
PV = \frac{FV_n}{(1 + r_r)^n} \text{ where } (1 + r_r) = \left(1 + \frac{r_n}{1+i}\right)
\]

**Discounted Payback Period (DPP)**

The simplest capital budgeting method is the ‘Discounted Payback Period’, defined as the expected number of years required by the grower to recover the initial capital investment, which is expressed as follows and illustrated in Table 1:

Discounted payback period = year before full recovery + \( \frac{\text{Unrecovered discounted cost in that year}}{\text{Discounted cash flow in subsequent year}} \)

<table>
<thead>
<tr>
<th>Annual Real Discount Rate ( (r_i) ) =</th>
<th>5%</th>
</tr>
</thead>
<tbody>
<tr>
<td>Period (years) =</td>
<td>0</td>
</tr>
<tr>
<td>Undiscounted Nominal Cash Flow =</td>
<td>-$1,000.00</td>
</tr>
<tr>
<td>Discounted NCF =</td>
<td>-$1,000.00</td>
</tr>
<tr>
<td>Cumulative Cash Flow =</td>
<td>-$1,000.00</td>
</tr>
<tr>
<td>Year before full recovery =</td>
<td>2</td>
</tr>
<tr>
<td>Unrecovered cost in above year =</td>
<td>$70.29</td>
</tr>
<tr>
<td>Cash flow during subsequent year =</td>
<td>$259.15</td>
</tr>
<tr>
<td>Pay back period =</td>
<td>2.27</td>
</tr>
</tbody>
</table>

R&D outcomes with shorter payback periods are preferred. This easy to understand ‘breakeven’ benchmark is also indicative of the R&D outcome’s liquidity, providing a helpful perspective of associated risk. Its downfall, however, is that no cognisance is given to neither cash flows received after the payback period nor the economic life of the R&D outcome.

**Net Present Value (NPV)**

The ‘Net Present Value’ method takes cognisance of all cash flows, which is expressed as follows and illustrated in Table 1 (assumes the R&D outcome has an economic life of four years).

---

⁴ Benchmarking research centres across international borders is complicated by exchange rate differentials. However, exchange rates, among other drivers, are influenced by nominal national prime lending rates. Therefore, if the use of nominal national prime lending rates becomes standard international practice for research centres, the international benchmarking of research centres becomes more meaningful.
Effectively, a NPV of zero means that the associated cash flows of the R&D outcome are sufficient to repay the initial capital investment over the expected life to the project. A positive NPV means the grower receives an economic return; i.e. wealth is created. NPV is arguably the best measure of absolute wealth creation but is unhelpful when R&D outcomes with varying capital investment requirements and unequal lives need to be compared and/or comparisons made to the opportunity cost of capital such as interest rates and/or competing off-farm investments.

**Profitability Index (PI)**

The ‘Profitability Index’ facilitates the comparison of R&D outcomes with varying capital investment requirements because it calculates the present value per dollar of initial cost, which is expressed as follows and illustrated in Table 2.

\[
PI = \frac{PV\text{ of future cash flows}}{Initial\ cost} = \frac{\sum_{t=0}^{n} \frac{CF_t}{(1 + r)^t}}{CF_0}
\]

**Table 2—Profitability Index example.**

<table>
<thead>
<tr>
<th>Annual Real Discount Rate ((r)) =</th>
<th>5%</th>
</tr>
</thead>
<tbody>
<tr>
<td>Period (years) =</td>
<td>0</td>
</tr>
<tr>
<td>Undiscounted Nominal Cash Flow =</td>
<td>-$1,000.00</td>
</tr>
<tr>
<td>NPV Period 1 =</td>
<td>$476.19</td>
</tr>
<tr>
<td>NPV Period 2 =</td>
<td>$453.51</td>
</tr>
<tr>
<td>NPV Period 3 =</td>
<td>$259.15</td>
</tr>
<tr>
<td>NPV Period 4 =</td>
<td>$246.81</td>
</tr>
<tr>
<td>Total NPV (excl initial outlay) =</td>
<td>$1,435.67</td>
</tr>
<tr>
<td>Profitability Index =</td>
<td>1.44</td>
</tr>
</tbody>
</table>

A ‘breakeven’ R&D outcome will have a PI of 1 and the higher the PI, the more attractive the R&D outcome becomes.

Using the PI approach to compare R&D outcomes with unequal lives or with the opportunity cost of capital, however, remains problematic.

**Internal Rate of Return (IRR)**

The ‘Internal Rate of Return’ is defined as the discount rate that equates the present value of the R&D outcomes future cash flows and the initial capital investment.

The IRR is the discount rate where the NPV is zero, which is expressed as follows and illustrated in Table 3.
PV (investment costs) = PV (cash flows) OR NPV = 0 = \sum_{t=0}^{n} \frac{CF_t}{(1 + IRR)^t}

Table 3—Internal Rate of Return example.

<table>
<thead>
<tr>
<th>Annual Real Discount Rate (r) =</th>
<th>5%</th>
</tr>
</thead>
<tbody>
<tr>
<td>Period (years) = 0 1 2 3 4</td>
<td></td>
</tr>
<tr>
<td>Undiscounted Nominal Cash Flow</td>
<td>-$1,000.00 $500.00 $500.00 $300.00 $300.00</td>
</tr>
<tr>
<td>NPV Period 1 =</td>
<td></td>
</tr>
<tr>
<td>NPV Period 2 =</td>
<td></td>
</tr>
<tr>
<td>NPV Period 3 =</td>
<td></td>
</tr>
<tr>
<td>NPV Period 4 =</td>
<td></td>
</tr>
<tr>
<td>Total NPV (incl initial outlay) = $0.00</td>
<td></td>
</tr>
<tr>
<td>Internal Rate of Return = 24.8%</td>
<td></td>
</tr>
</tbody>
</table>

If the IRR is greater than the grower’s debt interest rate, the grower is creating wealth and the adoption of the R&D outcome is considered beneficial. In theory, the IRR method solves the problems of comparing R&D outcomes with unequal lives and with the opportunity cost of capital. Unfortunately, the IRR method incorrectly assumes that all cash flows can be reinvested at the IRR rate, which means that projects with varying cash flows cannot be objectively compared; which includes R&D outcomes of unequal lives and/or with varying opportunity cost of capital.

**Modified Internal Rate of Return (MIRR)**

The ‘Modified Internal Rate of Return’ addresses the shortcomings of the IRR method by calculating the terminal value of each of the future cash flows using a known real discount rate and then solving for the discount rate that equates the present value of the combined terminal values with the initial capital investment. This definition is expressed as follows and illustrated in Table 4.

PV (investment costs) = PV (terminal cash flow value) OR NPV = 0 = \sum_{t=0}^{n} \frac{CF_t (1 + r_t)^{n-t}}{(1 + MIRR)^t}

Table 4—Modified Internal Rate of Return example.

<table>
<thead>
<tr>
<th>Annual Real Discount Rate (r) =</th>
<th>5%</th>
</tr>
</thead>
<tbody>
<tr>
<td>Period (years) = 0 1 2 3 4</td>
<td></td>
</tr>
<tr>
<td>Undiscounted Nominal Cash Flow</td>
<td>-$1,000.00 $500.00 $500.00 $300.00 $300.00</td>
</tr>
<tr>
<td>Terminal Value Period 4 =</td>
<td>@ (1+r_r) $300.00</td>
</tr>
<tr>
<td>Terminal Value Period 3 =</td>
<td>@ (1+r_r) $315.00</td>
</tr>
<tr>
<td>Terminal Value Period 2 =</td>
<td>@ (1+r_r) $551.25</td>
</tr>
<tr>
<td>Total NPV (incl initial outlay) = $0.00</td>
<td></td>
</tr>
<tr>
<td>Internal Rate of Return = 14.9%</td>
<td></td>
</tr>
</tbody>
</table>

There are several alternative definitions of MIRR; the differences primarily relate to how positive and negative cash flows are compounded. Most spreadsheets have a MIRR function that accommodates all options but, as most growers are indebted, it can be safely assumed that reinvestment is at the cost of capital or real national prime lending rate (r_r); i.e. positive and negative cash flows are compounded using the same discount rate. This avoids unnecessary financial complexity in the R&D context. Essentially, the MIRR method provides a standardised measure to compare different R&D outcomes of unequal economic lives as well as alternative investment options; i.e. if the MIRR is greater than the real national prime lending rate (r_r), the R&D outcome creates more wealth than a risk free investment at the bank. What the MIRR does not achieve is provide an indication of the total value add of the potential R&D outcome.

**Recommended capital budgeting approach for R&D outcomes**
Given that spreadsheets take care of the complex mathematics associated with capital budgeting with relative ease and that no single approach provides a panacea, it is recommended that three capital budgeting approaches be routinely computed for each R&D outcome and communicated with industry participants in the context of the unique insights each approach provides as described in Table 5. Other capital budgeting techniques can be ignored for reasons already given and/or because the insights they provide are already provided by those mentioned in Table 5.

In a study of 392 Chief Financial Officers employed by non-agricultural firms (Graham and Harvey, 2001), 74.9% and 75.7% evaluated new projects using the Net Present Value and Internal Rate of Return respectively, with 56.7% using the payback approach; i.e. most firms use more than one evaluation approach. This survey also found that smaller firms were more likely to rely on the payback approach, while larger firms were more likely to rely on the Net Present Value and Internal Rate of Return, which is consistent with earlier studies by Brierman (1993) and Walker et al. (1993). The three most cited reasons why smaller firms focus on the payback approach are:

(1) smaller firms preoccupation with liquidity, which is best indicated by payback;
(2) a lack of familiarity with capital budgeting techniques; and
(3) a belief that small projects do not warrant the effort of a capital budget.

Large sugarcane growing firms, such as those found in South and Central America, may already use capital budgeting techniques to evaluate new projects. Such practices are expected to be less common in Australia and South Africa where cane growing firms are much smaller and absent altogether from industries that are populated by very small firms like India and Thailand. From a research centre perspective, the use of capital budgeting as an extension and marketing tool is expected to have the highest uptake and to be most effective among larger firms. This does not negate the use of capital budgeting at research centres that service smaller firms because capital budgeting provides:

(1) an invaluable tool for the internal evaluation of projects; and
(2) improves stakeholders’ understanding of economic terms and business sense.

Research centres, therefore, need to tailor their initial capital budgeting approach to their immediate circumstances. Striving for economic perfection at the outset will be a misguided approach. Instituting an economic focus or ‘culture’ is as much about change management as it is about economics.

**Economic benchmarks for research centres generating R&D outcomes**

Researchers generally have limited exposure to economics and therefore may be reticent to employ economic benchmarks, particularly if this approach is burdensome. Ensuring ‘buy-in’ from researchers may require the compilation of generic costing sheets that are updated and disseminated for researchers to use in their own R&D outcome capital budgets. Training would also need to be provided to maintain robust and reliable results.
The most meaningful incentive to employ economic benchmarks, however, is for researchers to demonstrate the value of their research, particularly to attract funding resources. This is also true for the research centre as a whole, creating an incentive for the research centre to consolidate all its independent capital budgeting models. This has the advantage of facilitating a measure of standardisation and providing a ‘checking step’ for all the capital budgets for independent R&D outcomes. These composite measures for the research centre are expressed as follows (superscripts RC and RO stand for research centre and research outcome respectively):

\[
\text{Weighted average } \text{DPP}^{\text{RC}} = \frac{\sum_{i=1}^{n} \text{DPP}_{i}^{\text{RO}} \cdot \text{NPV}_{i}^{\text{RO}}}{\sum_{i=1}^{n} \text{NPV}_{i}^{\text{RO}}}
\]

\[
\text{Weighted average } \text{MIRR}^{\text{RC}} = \frac{\sum_{i=1}^{n} \text{MIRR}_{i}^{\text{RO}} \cdot \text{NPV}_{i}^{\text{RO}}}{\sum_{i=1}^{n} \text{NPV}_{i}^{\text{RO}}}
\]

A research centre cannot sum the NPV of each research outcome to determine its absolute wealth creation because there are often numerous parallel research outcomes that would result in double counting. The annual budget of the research centre provides an indication of the scale of the research centre and its associated operations. In terms of a research centre’s attention to liquidity, risk and return on investment, the weighted average DPP\textsuperscript{RC} and the weighted average MIRR\textsuperscript{RC} provide a clear enough picture.

**Implementation**

Cost estimates are the basis of capital budgeting and therefore need to be reliable. Research centres that embrace capital budgeting therefore must also implement measures to collate cost estimates. There are numerous ways this can be done, which include:

1. subsidising a book keeping service for farmers from which costs can be extracted;
2. forging relationships with farmers and their accountants to share costs on a confidential basis;
3. conduct statistically sound economic surveys; and
4. establish costs from a zero base by contacting market participants directly.

With the advent of computers and increasing uptake of computerised accounting, all of these approaches are becoming more robust. In practice, a combination of approaches is usually required, the emphasis being determined by local conditions.

An *ex-ante* evaluation should be conducted prior to or at the start of a project to aid in project planning, but these often suffer from a dearth of information and potential biases in data and analyses, examples of which include:

1. reliance on past projects that may differ markedly in function, size and certainty in the skill levels of the researchers;
2. reliance on crude heuristics (‘rules of thumb’) to estimate free cash flows, particularly of intangible elements; and
3. an inability to dispel biases (often unconscious) of researchers who often have a vested interest in a ‘go ahead’ outcome or a ‘think positive’ psychological tendency.

*Ex-post* evaluations of R&D outcomes, therefore, are equally important; *i.e.* economic
evaluations after implementation to test assumptions and accuracy.

An example best illustrates how the economic benchmarks described can be employed by a research centre: A research centre breeds and develops cane variety A followed by cane variety B. When variety B is released, sugarcane growers need to decide whether to continue with variety A or replant with variety B, where the yields are 100 and 90 tonnes cane per hectare respectively and ratooning ability of 3 and 4 years respectively, as illustrated in Table 6.

At first glance, a grower might be tempted to retain variety A because of its higher annual undiscounted nominal cash flow and shorter discounted payback period arising from its higher yield.

However, once the ratooning cycles have been accommodated, variety B shows greater economic promise with a higher net present value and modified internal rate of return.

The grower might nevertheless retain variety A for environmental reasons such as susceptibility to pests and diseases (although the researcher could discount the yield to accommodate this impact in conjunction with probability scenarios) or social reasons whereby a contractor that undertakes both harvesting and planting for the grower threatens to withdraw completely if the planting schedule is altered.

The composite measures for the research centre’s breeding program are also presented.

Table 6—Illustrative example of a sugarcane grower selecting a cane variety.

Discussion and conclusion

For non-financial experts, capital budgeting can be intimidating. However, given that spreadsheets take care of the complex mathematics and an economist or financial expert can be employed to source and disseminate generic costs, the skill of constructing a capital budget can be developed on a broad scale within a research centre, particularly if economics becomes engrained in the organisation’s culture. Such a culture should be the end goal of research centres but this can only be achieved incrementally over a period of time; striving for economic perfection is an unrealistic goal. However, researchers must be urged to identify and qualitatively explain their capital budgeting results because the results of capital budgeting are only as good as their assumptions and inputs.

Every effort must be made to ensure that data inputs have integrity. In this regard, it is recommended that updated generic costing sheets are regularly disseminated to researchers to input
into their own capital budgets, that random capital budgeting audits are conducted and that training is provided to maintain robust and reliable results on a consistent basis.

The capital budgeting methods described and adapted in this paper for the R&D context provide a powerful marketing tool for R&D outcomes in terms of attracting research funding and enhancing technology transfer to larger sugarcane growing firms in particular.

Sugarcane farming is a business and research centres are increasingly required to communicate in the ‘language’ of business, not withstanding the other environmental and social aspects of sustainable triple bottom line reporting.

In an increasingly competitive global environment, this shift towards an improved understanding of economics is appropriate to all scales of sugarcane agriculture.

ECONOMIC GLOSSARY

**Amortisation**—a loan repaid in fixed equal periodic amounts that comprise principal and interest components.

**Cash flow**—all the cash transactions relating to a firm that occur during a defined period.

**Discounting**—the process of finding the present value of a single payment or series of payments.

**Equity capital**—financial contribution by the owners of a firm as opposed to debt finance.

**Externalities**—an indirect consequence of a project, where prices do not reflect the full costs or benefits in production or consumption of a product or service.

**Liquidity**—refers to a firm’s cash position and its ability to make maturing payments. A liquid asset can be sold quickly and converted to cash.

**National prime lending rate**—the average interest rate payable to banks for debt finance on a project of average risk.

**Nominal**—the effects of inflation are not accounted for.

**Opportunity cost**—a cash flow that a firm must forego to accept a project, or alternatively the next best cash flow that a firm will accrue in the absence of a project.

**Producer related inflation**—the loss of purchasing power over time calculated using a basket of goods representative of producers’ inputs. Consumer related inflation is associated with a basket of goods representative of consumers’ purchases.

**Real**—the effects of inflation are accounted for.

**Terminal value**—at the end of a project, assets may have a terminal or residual value that can be realised.

Resume

A L’ATELIER de Gestion de l’ISSCT tenu en mai 2008 à Townsville, Australie, il fut rapporté que dans plus ou moins tous les pays producteurs de canne à sucre, une incompréhension existait entre les centres de recherches et les producteurs. Une des raisons de cette incompréhension est que la recherche avait déjà optimisé la productivité à travers les programmes de croisement variétal tandis que les producteurs n’étaient pas convaincus de cela et s’attendaient à de meilleurs résultats. Une autre raison de cette incompréhension, est le fait que les conditions agro climatiques et les pratiques culturales masquent souvent le gain de productivité. Il a été suggéré que les centres de recherches fassent des études économiques pour permettre aux producteurs de cannes de comparer les différents projets de recherche qui sont en compétition. Pour les experts non financiers, les budgets capitaux peuvent être décourageants, mais les chiffres peuvent être expliqués et un économiste ou un expert financier peut être employé pour identifier et ventiler les coûts des projets. Les méthodes de Budgets Capitaux décrits et adaptés dans cette présentation dans le contexte de R & D nous donne un puissant outil de marketing pour attirer des fonds pour la Recherche et accélérer le transfert de technologie au gros producteur de cannes en particulier. L’exportation de canne à sucre est un business, et les centres de recherches doivent aujourd’hui communiquer dans des termes financiers, sans oublier les autres aspects sociaux et environnementaux. Avec une augmentation de compétitivité dans l’environnement global, ce changement vers une amélioration de la rentabilité est approprié à tous les niveaux de la culture de la canne.

Resumen

EN EL TALLER de la Comisión de Gerencia de ISSCT que se llevó a cabo en Townsville, Australia en mayo de 2008, se reportó que en mayor o menor grado en la mayoría de países productores de caña de azúcar existe una ‘desconexión’ entre los centros de investigación y sus actores principales. Una de las razones para esta ‘desconexión’ es que los centros de investigación en varias industrias han maximizado el potencial de productividad a través de los programas de mejoramiento de variedades, pero los actores principales no están convencidos de esto, resultando en incongruencias en sus expectativas. Otra posible razón para la ‘desconexión’ es que las mejoras en productividad son opacadas por varias condiciones agro-climáticas y por algunas prácticas gerenciales. Se ha sugerido que los centros de investigación mejor deberían emplear comparativos económicos para permitir que los productores de caña puedan calificar los distintos productos de la investigación que compiten por el limitado capital y el tiempo gerencial del productor. Para los no-expertos en finanzas, el presupuesto de capital puede ser intimidante pero las hojas electrónicas se encargan de la matemática compleja y un experto en finanzas o en economía puede contratarse para direccionar o diseminar los costos genéricos. Los métodos de presupuesto de capitales descritos y adaptados en este trabajo para el contexto de I+D proveen una herramienta poderosa para el mercadeo de los productos de I+D, en términos de atraer financiamiento para investigación y el mejoramiento de la transferencia de tecnología particularmente para industrias azucareras más grandes y en crecimiento. La producción de caña de azúcar es un negocio y cada vez se requiere más que los centros de investigación se comuniquen en el ‘lenguaje’ de los negocios, sin dejar de lado los otros aspectos de los reportes de sostenibilidad o sea los ambientales y sociales. En un ambiente global en el que crece la competitividad, este giro que procura entender mejor la economía es apropiado en todas las escalas de la agricultura de la caña.
RESEARCH AND EXTENSION NEEDS TO MITIGATE CONSTRAINTS LIMITING THE PRODUCTIVITY OF SMALL-SCALE SUGARCANE FARMERS IN MAURITIUS

KEYWORDS: Small-Scale Farmers, Improved Productivity, Competitiveness, Sustainability.

Abstract

The issue of low productivity on small farmers’ lands is a matter of concern in many sugarcane producing countries. In Mauritius, some 25 000 small-scale farmers are involved in sugarcane cultivation which is a major source of income for 200 000 rural families. Yield differences as high as 40% exist between the small-scale and large commercial farmers and their causes are often taken for granted. This paper presents part of the findings of a project to better understand, with farmers’ participation, the functioning of the existing small farming systems and their information-seeking behaviours, a study financed by the French government through the Southern African Development Community (SADC). A survey, based on a formal questionnaire, was carried out among 800 farmers in Mauritius. Analysis of the data collected has enabled the prioritisation of factors and constraints affecting productivity, namely, increasing costs of inputs, availability and costs of labour and transport and access to finance and credit facilities. The conditions limiting adoption of good management practices have been identified to be the small-sized farms, low adoption rate of improved technologies and limited contact with advisory and support services. The elaboration of decision support tools to assist these farmers to increase production levels through sustainable and environment friendly production systems will now be generated. There is a need to pursue specific research on cost-cutting farming operations and new production techniques, adopting extension strategies favouring targeted and grouped extension interventions for some categories of small-scale sugarcane farmers. It is believed that the research and extension interventions will ensure the long-term survival of this producer category and will enhance ability to achieve productivity levels that will render the agricultural activities of the small-farmers economically and environmentally sustainable.

Introduction

In the context of world trade globalisation and the reform of the European Union sugar regime, whereby a reduction of 36% in price is imposed on sugar exported to the European Union by countries of the African-Caribbean-Pacific regions including Mauritius, sugar industries in those countries are compelled to adopt various strategies to improve their competitiveness and sustainability.

Strategies in Mauritius are embodied in the 2006–2015 Multi Annual Adaptation Strategic Plan prepared by the Government of Mauritius in partnership with all the stakeholders of the sugar industry (MAAS, 2006).
The Multi-Annual Adaptation Strategy Plan highlighted the absence of economies of scale in the operations of small-farmers. These coupled with poor financial resources at their level have made the small-farmers vulnerable to the decrease in sugar price if urgent measures are not taken to safeguard their interests.

The sugarcane planting community in Mauritius can be classified into three categories as shown in Table 1.

Source: Sugar Insurance Fund Board, 2008

From 2005 to 2007, an average of 4.6 million tonnes canes were harvested, with the small-farmers harvesting around 30.1% of the area under cane, but contributing to only 26.0% of total cane harvested. Average yield was approximately 60.4 tonnes per hectare while the larger producers (large and corporate) averaged 71.1 tonnes per hectare. The yield differential for the period 1996 to 2007 is illustrated in Figure 1.

Scope for enhancing the productivity of the small-farmers in Mauritius therefore exists and, with the financial support of the French government through the Southern African Development Community (SADC), a participatory study was initiated with the objectives of better understanding the functioning of the existing small farming systems and their information-seeking behaviours. It is anticipated that this improved understanding of farmer needs would enable more effective research to be initiated and enhanced advisory services to be dispensed to this category of sugarcane farmers.
Conditions and factors limiting adoption of improved technologies can be addressed through targeted interventions. The elaboration of decision-making models based on farmers’ strategies and factors that restrict their ability to progress are envisaged to enable them to make well-informed decisions. This paper reports the main findings of the study in Mauritius.

Methodology

A comprehensive literature review was undertaken to assess different methodologies used in conducting similar studies in other sugarcane growing countries. No evidence was found of small-scale farmer surveys in the sugarcane growing countries around the world. In fact, there was scant evidence of similar studies in the SADC region.

The following methodology was subsequently developed for the study:

Data collection

A combination of quantitative and qualitative methodologies was used for the study. This paper reports only on the quantitative methodology opted for, namely, a formal survey questionnaire. Using the formal questionnaire and the traditional pen and paper approach, the survey was conducted by twenty enumerators among a stratified random sample of 800 small-farmers selected on four criteria; namely farm size, agro-climatic zones, ownership and rainfed / irrigated conditions.

Questionnaire design and information to be collected

Cognisance was taken of outcomes from previous participatory workshops and working sessions where some preliminary key aspects had been identified. Furthermore, the problem tree technique was used to investigate the possible relationships between low productivity and four major aspects, namely, growers’ practices, land potential and utilisation issues, availability and utilisation of resources, and research, extension and services.

A 15-page questionnaire with six sections was developed to enable data collection on the following:

- Socio-demographic profile (geographic and personal details)
- General information on the sugarcane farming environment
- Resource base (land, sugarcane fields, land ownership, labour, finance, etc.)
- Sugarcane husbandry and use of technology (choice of planting method, land preparation and planting, fertilisation, choice of variety, weed control, etc.)
- Communication facilities and
- Decision making

Data management

A relational database was designed using Microsoft Access software for data entry. A user-friendly GUI (graphical user interface) with the use of drop down menus was developed to provide first level validation for data entry. This facilitated data capture and minimised errors in the keying of data, which was done only for open-ended questions. Data retrieval and analysis were done either directly through query to the database in Access or by using the Statistical Package for Social Sciences (SPSS).

Results

Socio-demographic profile

Nearly 75% of the respondents were male and married, with the great majority (80.1%) being both the head of the family and the farmer. They formed an ageing population, with 47.8% of them between 41 and 60 and 41% above 60 years old (Figure 2).
Among the 70% of the respondents who had at least a full primary education and could be considered as literate, some 30% had a partial secondary education, 10.5% completed the secondary curriculum with only 6% having studied up to tertiary level.

The majority of the farmers (65%) were cultivating sugarcane on a part-time basis, with only 30% doing it as a full-time activity. Very few (5.5%) of the respondents were simultaneously engaged in other farming activities.

Sugarcane farming system

The great majority of the respondents (83%) had a minimum of ten years experience in sugarcane farming. The main reason for being involved in sugarcane farming was mostly because of tradition or on account of a family business they had inherited, with sugar proceeds representing an important source of income.

Regarding succession planning, 54% mentioned that another family member would take over their sugarcane business, while some 41% of the respondents had no opinion on this issue. However, only one respondent replied that he would sell his land.

Parents or family members were the main source of knowledge in sugarcane farming and production for 81.9% of the respondents and 71.7% of these farmers claimed that it was also self-acquired. Formal education and training in sugarcane farming, found to be most useful, was received by only 6.8% of respondents and was provided mainly by the Farmers Service Corporation (FSC) and the Mauritius Sugar Industry Research Institute (MSIRI). Some 20% of the respondents expressed the need for further knowledge or agricultural training in cultural operations and/or sugarcane agronomy in general.

The majority of the respondents were aware of the existence of advisory services, be it FSC, MSIRI or Agricultural Research and Training Unit (AREU), but their perception of the role/function of the extension officer varied from provision of advice only (30% of the respondents), provision of services only (30%), acting as a facilitator for them with other service providers (13%) to provision of training in sugarcane husbandry (6%). It was worth noting that some 22% of the respondents were of the opinion that extension was doing very little or nothing at all. When asked about their expectations of extension, most of the respondents (69%) replied that provision of advice and services should be more available. Acting as a facilitator and conducting training, meetings and seminars should be the major roles of the extension officer and the remaining 31% had no idea or opinion on what extension should be doing for them. A point worth noting is
that some 66% of the respondents did rely on the assistance and support of extension for their farming operations but they stressed that they themselves made the final decision with regards to those operations.

**Sugarcane husbandry practices**

**Date of planting**

An analysis of the responses obtained indicated that short season planting (July to August) was believed to be ideal for over 53% of the respondents in the rainfed regions. For 63% of those in the subhumid (< 1500 mm annual rainfall) to humid (between 1500 to 2500 mm) regions, long to intermediate season planting (from January to May) was favoured (Figure 3).

![Fig. 3—Ideal months of planting by agro-climatic regions.](image)

As for the months that they usually replant, the responses were more or less similar to those mentioned above, suggesting that a slight majority of the farmers usually replant at the appropriate period. A significant number of the respondents stated that they could not replant their fields in the ideal months mainly due to the unavailability of tractors and planting material and to the dry conditions which prevailed at that moment.

**Land preparation and planting**

Apart from some who had recently acquired their cane fields, most of the respondents had replanted their fields at least once since acquisition. About 42% of respondents had done so before the 7th ratoon, about 49% after the 8th to 10th ratoons and the remaining 9% after the 10th ratoon. A majority (91%) had adopted the conventional mechanical land preparation (raking, ploughing and furrowing) while the rest practised minimum tillage or manual land preparation.

**Crop nutrition**

Soil analysis prior to replanting, a service free of charge, was practised by only 25% of the respondents. Of this 25% group, 75% adopted the recommendations for soil amendment and fertilisation which were given to them, based on soil analysis results. For those not doing soil analysis, 80% of them did not use soil amendment and some 75% fertilised their fields on the basis of their past experience or on their neighbour’s practice.

The timing of fertilisation is also a matter of concern. It has been found that more than 80% of the respondents still practised split application of fertilisers either in plant cane or ratoons, a practice which is no longer recommended.
Choice of sugarcane variety

Information on sugarcane varieties, influencing the choice of the variety planted, came from Extension officers for 40% of the respondents, from own/self knowledge for 30% of them and from other farmers for the remaining 22%. The majority of the respondents considered good adaptation and performance as the major criteria for their choice of variety.

Weed control

Chemical weed control, sometimes supplemented with manual weeding, was a common practice among 89% of the respondents. They were aware that weeds directly compete with sugarcane and might be responsible for yield losses. Some 32% of these farmers were not satisfied with their weeding practice due to persisting unfavourable climatic conditions and inappropriate herbicide mixtures for problem weeds.

Major constraints to production.

An important component of the study was to obtain from the respondents what they believed to be the major constraints limiting their sugarcane production, ranking them in order of importance and suggesting appropriate methods on how to minimise the effect of these constraints on productivity. The responses obtained are summarised below.

Increasing cost of inputs

Fertilisers and herbicides are the most commonly used inputs in sugarcane cultivation. The cost of these inputs has been constantly on the increase during the past few years. Figure 4 shows the evolution of nutrient prices for the period 2003 to 2008, where increases of up to 700% were noted.

It was expected that a large majority of the respondents would highlight increasing cost of inputs, mainly fertilisers and herbicides as the most important constraint limiting production. As to how to minimise the effect of this constraint, most of the respondents were of opinion that the authorities, mainly the central government, should intervene through subsidy.

Availability and costs of labour and transport

The availability and cost of labour and transport were reported as being the second most important constraint to sugarcane production (nearly 30% of respondents answered lack of labour,
19% indicating transport and quota problems and 10% mentioned high cost of labour). This has also been observed in past studies, and the labour and transport survey undertaken in 1990 revealed that more than 70% of the small-planters interviewed were facing labour problems, especially during harvesting operations.

Among the solutions proposed by the respondents to counteract these constraints were grouping smaller units into larger blocks to allow for partial or total mechanisation of farming operations and/or recourse to contractors.

**Finance and credit facilities**

The third problem in importance was low profitability resulting from high cost of production coupled with lack of finance and credit facilities. Low profitability as a constraint limiting production is perfectly understandable because if profit is constantly decreasing and if finance and credit facilities are lacking, there will be no further investments, and this will affect productivity. It is important to mention that the authorities have put in place a range of measures in terms of government sponsored loans, subsidies or other soft loans offered by commercial banks to assist sugarcane farmers to stay in business. Lack of information on these measures and difficult access to the facilities offered might in fact be the real cause.

**Discussions and conclusion**

This section highlights the major implications of the above findings for research and extension and eventually the strategies to be developed to meet the needs of the small-scale sugarcane farmers.

**Farmer profile**

The sugarcane farmers in Mauritius are predominantly male. They form an ageing population, with at least a primary schooling tending toward literate part-time farmers. This understanding has some bearing on extension policy and strategy.

A rethinking of extension is necessary to target and to serve a larger farmer population. In particular, specific strategies should be devised to make extension services more accessible to part-time farmers allowing them to benefit from existing new technologies and improved cultural operations.

It is urgent for the extension officers to be more available even if they have to work at odd hours. The judicious use of new communication and IT facilities for effective exchange and dissemination of information is another avenue to be fully explored. It is worth noting that, in this context, the provision of e-services to the small-sugarcane planters in the form of an online system facilitating requests for certain services; for example, a soil analysis service is being offered by the MSIRI in collaboration with the FSC.

**Farming system**

In general, the small sugarcane farmer typically cultivates his own field(s) or fields belonging to the family. Monocropping is a most salient feature of the cropping system and the farmers have a tendency to cultivate only one variety. The fields are usually small in size (0.1 to 2.0 ha) and managed on an individual basis by the farmers themselves. Farmers stated that the final decision regarding their husbandry and production aspects remains theirs.

A vast majority of the respondents have acquired a vast experience in sugarcane farming and they have valid reasons to continue their sugarcane business, justifying why research and extension need to continue developing cost-cutting and innovative strategies to keep this vulnerable group of small-farmers in production.

A good majority of the farmers have not received formal training in sugarcane husbandry and many of them would wish to adopt good management practices to improve their production
levels. This is an area where research and extension may develop tailor-made training programs to meet the aspirations of the small-farmers.

The grouping of small-sized farms into larger units, which is already in progress, apart from enabling the small-farmers to benefit from economies of scale, will also provide a good opportunity for extension, through group techniques, to reach a larger number of farmers through more frequent and regular contacts.

**Husbandry practices**

The major prerequisites for good crop establishment are ideal planting date, elimination of resistant weeds, good land preparation, soil amendment, optimum nutrition, and choice of the most appropriate variety.

If ‘off-the-shelf’ technologies are already in a position to cater for most of these issues, research is still required to continue to develop and seek cost-cutting farming operations or practices and new production techniques that will maintain the competitiveness of small-scale sugarcane farming.

Consequently, where concern by extension is apparent is that nearly 50% of the respondents are not replanting at the appropriate moment, which in most cases would result in a poor crop establishment. The farmers need to be aware of that consequence. Some 75% are not making use of the free soil analysis service available, representing a lost opportunity as farmers could have been practising optimal/sound nutrition.

**Reported constraints**

The increasing costs of inputs, mainly fertilisers, herbicides and labour, coupled with low profitability have been reported to be the major constraints limiting sugarcane production. Research is already adapting new cropping systems which have been successful in other sugarcane producing countries such as Australia for the local sugarcane industry. Through more innovative extension strategies, small-farmers need to be kept informed of these new opportunities and must be encouraged to adopt practices that will enable them to increase their cane yields while at the same time reducing or optimising their production costs.

**Acknowledgements**

The contribution of the French government, which supported the study financially through the Southern African Development Community, is gratefully acknowledged. The authors are also very thankful to the 800 small-scale sugarcane farmers and to all participating institutions for their invaluable collaboration.

Resumé

La faible productivité chez les petits exploitants canniers préoccupe beaucoup les pays producteurs de sucre. A Maurice, environ 25 000 petits planteurs cultivent la canne à sucre qui est une source de revenu pour quelques 200 000 familles des régions rurales. Des écarts de rendement atteignant 40% existent entre les gros producteurs et les petits planteurs et les causes sont souvent considérées comme admises. Ce papier présente une partie des conclusions d’un projet initié avec la participation des planteurs pour mieux comprendre le fonctionnement des petits systèmes agricoles et de leurs démarches dans la recherche de l’information agricole. Une enquête, basée sur un questionnaire formel, a été réalisée auprès de 800 petits planteurs à Maurice. Cette étude a été financée par le gouvernement français, à travers la ‘South African Development Community’ (SADC). Une analyse des données recueillies a permis la hiérarchisation des facteurs et des contraintes affectant la productivité, notamment l’augmentation des coûts des intrants, la disponibilité et les coûts de main-d’œuvre, les facilités de transport pendant la récolte et l’accès au financement et au crédit. Les raisons limitant l’adoption des bonnes pratiques de gestion ont été identifiées, à savoir, la petite superficie des exploitations, le faible niveau d’adoption des technologies de pointe et le contact restreint avec les services de vulgarisation et de logistique. Des outils visant à aider les planteurs dans la prise de décisions afin d’accroître leur productivité à travers des systèmes d’exploitations durables et respectueux de l’environnement vont être développés. Une recherche visant à réduire les coûts associés aux opérations culturelles et les nouvelles techniques de production et l’adoption de stratégies vulgarisation favorisant des interventions ciblées pour certains groupes de petits exploitants sont nécessaires. Les interventions de la recherche et de la vulgarisation vont, sans nul doute, assurer la survie de cette catégorie de producteurs dans le long terme, tout en améliorant leur capacité d’atteindre des niveaux de productivité qui vont permettre à leur activité d’être économiquement et écologiquement durable.

PALABRAS CLAVE: Productores a Pequeña Escala, Mejora de la Productividad, Competitividad, Sostenibilidad.

Resumen

EL PROBLEMA de baja productividad de los pequeños agricultores es un tema preocupante en muchos países productores de azúcar. En Mauricio, unos 25 000 productores a pequeña escala están involucrados en el cultivo de la caña de azúcar como la principal fuente de ingresos para unas 200 000 familias rurales. Diferencias en la productividad de hasta el 40% existen entre los productores de pequeña escala y los grandes productores comerciales y las causas muchas veces se toman como algo normal. Este trabajo presenta algunos de los resultados de un proyecto encaminado a entender mejor la forma en que funcionan los pequeños sistemas agrícolas y sus comportamientos de búsqueda de la información, un estudio realizado con la participación de los pequeños productores y financiado por el gobierno francés a través de la Comunidad de Desarrollo Sudafricana (SADC, en inglés). Una encuesta, basada en un cuestionario formal, se realizó entre 800 productores de caña de Mauricio. El análisis de los datos ha permitido la priorización de los factores y limitantes que afectan la productividad, incrementando los costos de producción, la disponibilidad y costos de la mano de obra y transporte y el acceso a financiamiento y crédito. Se identifican las condiciones que limitan la adopción de prácticas adecuadas de manejo tales como el tamaño pequeño de las fincas, el bajo índice de adopción de tecnologías mejoradas y el poco contacto con servicios de asesoría y apoyo. La elaboración de herramientas para la toma de decisiones para ayudar a estos productores a mejorar sus niveles de producción a través de sistemas de producción sostenibles y amigables con el ambiente serán generadas. Existe una necesidad de realizar investigación específica sobre las operaciones que permitan reducir costos en el cultivo y nuevas técnicas de producción, la adopción de estrategias de extensión que favorecerán grupos específicos y tendrán intervenciones conjuntas para algunas categorías de productores de caña a pequeña escala. Se cree que las intervenciones de investigación y extensión asegurarán la sobrevivencia a largo plazo de esta categoría de productores y mejorará la habilidad para alcanzar niveles de productividad que resultarán en sostenibilidad de las actividades agrícolas de los pequeños productores, las cuales serán amigables con el ambiente.
EXTENSION AND ADOPTION OF THE ‘SIX EASY STEPS’ NUTRIENT MANAGEMENT PROGRAM IN SUGARCANE PRODUCTION IN NORTH QUEENSLAND

KEYWORDS: Nutrient Management, SIX EASY STEPS, Reef.

Abstract

In tropical north Queensland, the need for accelerated adoption of best-practice nutrient management has become more urgent because of increasing pressures for profitable cane production to be achieved in combination with environmental awareness. The latter of these contributory factors is driven primarily by the proximity of sugarcane-producing areas to the World Heritage-listed Great Barrier Reef. The SIX EASY STEPS program was developed to enable easy adoption of best-practice nutrient management principles on-farm and to promote sustainable nutrient use in the Australian sugar industry. This system, aimed at sustainable sugarcane production, encourages growers to use knowledge of soils, nutrients and the sugarcane crop to make informed decisions about their fertiliser inputs. Although growers usually have an inherent understanding of these concepts, a short-course program is being used to promote the development and use of appropriate nutrient management plans for targeting nutrient inputs. This paper reports on an assessment of this educational process which is linked to specific follow-up and grower-interactive activities. In general, it has been found that growers and their advisers value the opportunity to attend the short-course program. However, development of individual nutrient management plans will probably not be progressed by growers without further input from extension officers. The use of participative on-farm strip trials that compare usual grower nutrient management practices to those promoted by the SIX EASY STEPS, is a useful and practical means of demonstrating the worth of best-practice nutrient management to growers.

Introduction

During the past 15 years, Australian sugar industry scientists have been modifying nutrient management guidelines for sugarcane production. Led by BSES Limited, the Australian sugar industry’s principal research, development and extension (RD&E) organisation, the changes have included refined nutrient application rates and tighter recommendations on timing and placement of nutrient applications.

The impetus for revamping nutrient management recommendations arose from the increasingly narrow profit margins of sugarcane production and rising environmental awareness by the industry. No longer could nutrient advice concentrate only on sugarcane yields but would also have a very strong focus on sustainability which includes aims at profitable cane production in combination with minimal impact on the agricultural and wider environments.

The new sustainability guidelines, therefore, encompass optimising sugarcane production and profitability while minimising nutrient losses due to volatilisation, denitrification, leaching and soil erosion.
The new sustainability guidelines have been encompassed in the SIX EASY STEPS strategy (Schroeder et al., 2010) which is being rolled out to Australian sugarcane growers under a one-day short-course extension program called ‘Accelerating the adoption of best-practice nutrient management’. The course provides canegrowers with the information and tools on how to develop sustainable nutrient management plans for each block on their farms.

This paper provides an historical summary of nutrient use within the Australian sugar industry and describes the concept of sustainable nutrient management in the context of environmental and government pressures to limit nutrients into the Great Barrier Reef Lagoon.

It also provides a summary of the development, operation, attendance and impact of the SIX EASY STEPS program.

**History of nutrient use**

Early BSES Limited sugarcane technologists recognised the need to devise balanced nutrition strategies (Maxwell, 1901). The BSES Limited fertiliser advisory service to growers commenced in about 1940. An upsurge in sugarcane nutrition research began in the 1970s (Schroeder et al., 1998) resulting in a set of broad, generalised recommendations across regions and soil types (Calcino 1994, Wood et al., 1997, Calcino et al., 2000).

While useful, the recommendations afforded little recognition of differences in soil type, and in particular the nitrogen (N) mineralisation potential of soils. The need to refine nutrient recommendations to minimise adverse environmental impacts while maintaining profitability and soil fertility was recognised in the late 1990s.

The resulting SIX EASY STEPS nutrient recommendations are now standards accepted by industry and government.

In the past, canegrowers have generally over-fertilised especially with N. Schroeder et al. (2002) showed that on average across the industry:

- 80% of growers surveyed applied rates of N fertiliser on fallow plant cane in excess of BSES Limited recommendations. The majority of these applied more than 50 kg N/ha above the recommended rates.
- 45% applied rates of N on replant cane (cane planted soon after the destruction of the previous crop without an intervening fallow) in excess of recommendations.
- 44% applied rates of N on ratoon cane in excess of recommendations.

These percentages did not vary much between mill areas, with the exception of Innisfail and Babinda. Most growers in these areas applied recommended rates or lower.

Risk aversion has been a major factor motivating growers to apply nutrients, especially N, above recommended rates (Thorburn et al., 2003). Extra N was seen as economical insurance to protect profits against unforeseen environmental impacts during the 12- to 14-month growing period.

This type of approach was not sustainable, as N and phosphorus (P) are the two agricultural nutrients that have the potential to adversely impact on water quality and, ultimately, coral reefs.

However, data supplied by Incitec Pivot Limited (the major manufacturer and supplier of fertilisers to the Australian sugar industry), indicate that N and P application rates have shown a downward trend over the last decade (Tables 1 and 2).

The company compiles annual estimates of nitrogen and phosphorus use in Australia’s main sugarcane districts. While imperfect, these figures provide possibly the most reliable picture of temporal and spatial fertiliser usage by Australian canegrowers.

Since 1996, the average nitrogen application rate across the Australian industry has fallen by 20% (Table 1). During the same period, the average phosphorus application rate across the Australian industry has fallen by 30% (Table 2).
Table 1—Nitrogen application rates (kg N/ha) across Australian sugarcane growing regions 1996–2007.

Source: Garry Kuhn, Product Stewardship Manager, Incitec Pivot.

The accuracy of the data is supported by regional surveys by BSES Limited such as the Wet Tropics Tully/Murray River catchment application figures (Mahon and Hurney, 2008). That survey found that growers are currently applying, on average, 141 kg N/ha, 22 kg P/ha and 107 kg K/ha. These rates are consistent with current BSES Limited recommendations based on the SIX EASY STEPS program (Schroeder et al., 2009). The survey also revealed that nutrient application methods take into consideration potential losses from the soil that include leaching, run-off and gaseous losses (such as volatilisation and denitrification). The majority of the survey respondents were also aware of, and actively implementing, sustainable farm-management practices on-farm.

Unfortunately, in some catchments and on some individual farms throughout the industry, the average N and P application rates are still above industry recommendations. Additionally, in some locations, the timing and placement of nutrient applications needs to be improved to reduce adverse off-site impacts. The nutrient management practices outlined in the SIX EASY STEPS program are regarded by authorities and industry as the best way to achieve these targets. (Anon., 2009)

Sustainable nutrient use, the environment and government

As indicated above, BSES Limited and its partners (CSR Sugar and the previous Queensland Department of Natural Resources and Water (NRW)) working within projects funded by the Sugar Research and Development Corporation (SRDC) and the Cooperative Research Centre for Sustainable Sugar Production (Kingston and Lawn, 2003) undertook research aimed at enhancing the sustainability of the Australian sugar industry well before two recent key government initiatives. In January 2009, the Australian Government commenced its $200 million Reef Rescue Plan, and in mid-2009 the Queensland State Government introduced legislation to control the use of nutrients in sugarcane production in areas adjacent to the Great Barrier Reef ecosystems. Although applied in different ways, both initiatives are designed primarily to improve the quality of water draining into the Great Barrier Reef lagoon.
The Great Barrier Reef was officially listed as a World Heritage Site in 1981 as an example of superlative natural phenomena. The Great Barrier Reef World Heritage Area is the world’s largest coral reef ecosystem and one of the most complex natural systems on earth. The Reef extends 2000 km along the Queensland coast, comprises 2900 individual reefs including 760 fringing reefs (Johnson and Marshall, 2007), and covers an area of 35 million hectares. It directly contributes over $5.8 billion annually to the gross domestic product of the Australian economy and supports approximately 63000 jobs (Jones, 2009; Rudd et al., 2007; Anon, 2005). Many coastal communities which evolved as the sugar industry developed in the late 19th century colonisation of Queensland rely heavily on the sugar industry and Great Barrier Reef tourism for their future.

Sugarcane cropping has been identified as posing a high risk of nutrient transport in Reef catchments primarily due to the area under production (Furnas, 2003) and the location of the industry adjacent to the Reef. CSIRO, Great Barrier Reef Marine Park Authority and James Cook University have conducted modelling which has identified run-off hot spots and determines the temporal and spatial aspects of the delivery of pollution to the Reef. These include areas of high fertiliser use (Maughan et al., 2007) particularly in the Wet Tropics region of north Queensland.

Along the Queensland coast, 31 river catchments drain into the Great Barrier Reef. Sugarcane is grown in approximately half the catchments comprising seven in the Wet Tropics (Mossman to Tully), one in the Herbert (Ingham), three in the Burdekin (Ayr), four in central Queensland (Proserpine to Sarina) and one in south Queensland. Very little cane production occurs in the south Queensland catchment.

In October 2007, 14 months before being elected to government, the Federal Australian Labor Party issued a policy document titled ‘Labor’s Reef Rescue Plan’ whose aim was to ‘tackle climate change and improve water quality in the Reef through a range of activities’ (Rudd et al., 2007). The policy document stated there was a growing body of scientific evidence linking the declining health of the Great Barrier Reef to poor water quality. Following Labor’s election, the five-year Reef Rescue Plan was implemented on 1 January 2009 to improve farming practices in the Great Barrier Reef catchment. Included in those practices was improved nutrient management on sugarcane farms.

At the Queensland state government level, the Great Barrier Reef Protection Bill which took effect from 1 January 2010 aims to reduce the levels of farm fertiliser, pesticide and sediment harming the Reef (Jones 2009).

Given the pressure and incentives from State and Commonwealth governments and the sugar industry’s desire and commitment to reduce its environmental footprint, the SIX EASY STEPS nutrient management program is having a major role in improving the industry’s sustainability while satisfying the community’s expectations of the industry.

**Development of the SIX EASY STEPS workshops**

The SIX EASY STEPS workshop program (Schroeder et al., 2010) was developed as a district-specific, interactive, practical and interesting short course specifically for canegrowers (Schroeder et al., 2006a). This integrated nutrient management tool incorporates the recent refinements to nutrient recommendations for the Australian industry and has been strongly supported by the industry.

The program consists of the following six components:

1. Knowing and understanding your soils
2. Understanding and managing nutrient process and losses
3. Regular soil testing
4. Adopting soil-specific nutrient management guidelines
5. Checking on the adequacy of nutrient inputs (e.g. leaf analyses)
6. Keeping good records to modify nutrient inputs when and where necessary
The program provides:

- guidelines for the implementation of balanced sugarcane nutrition to optimise productivity and profitability without adversely affecting soil fertility or the environment i.e. sustainable sugarcane production
- skills for growers to develop their farm nutrient management plans

A key message of the workshops is that soil test analyses are crucial to providing the necessary information on which to develop the most appropriate nutrient management strategy for individual farms.

The new nutrient recommendations focus on regional environments and soil characteristics. Management guidelines are soil specific by recognising soil attributes such as colour, texture, chemical properties and position in the landscape.

The SIX EASY STEPS program also promotes the development and implementation of fertiliser strategies for a full crop cycle. The ‘whole of crop cycle’ fertiliser recommendation approach is compatible with a more strategic, longer-term attitude to nutrient management promoted by industry research, development and extension organisations.

Before rolling out the SIX EASY STEPS program to the industry, BSES Limited sought input from extension staff and growers. The final product incorporated suggestions to enhance the program and improve its effectiveness to grower stakeholders.

With the extension of the SIX EASY STEPS nutrient management program, Australian canegrowers are now in a far better position to better understand their soils, their nutritional requirements and techniques to avoid adverse off-site impacts.

**Operation of SIX EASY STEPS workshops**

A SIX EASY STEPS workshop lasts for approximately six hours. Attendance numbers are restricted to maximise interaction between the workshop presenters and the usual nine to 15 attendees. Each participant receives a workshop manual to keep for future reference. The manual provides detailed information on all the material covered during the workshop including a laminated, one-page nutrient recommendation sheet which lists advised inputs based on soil analyses.

The cornerstone of the workshop is a computer-based presentation that comprehensively covers all aspects of the SIX EASY STEPS approach to nutrient best management practice. The workshop is designed to be as interactive as possible. Attendees are strongly encouraged to ask questions and offer observations relating to their own experiences for discussion by the group. Working in small sub-groups with the assistance of the presenters, participants work through several exercises to reinforce information presented earlier in the workshop. Participants are given a certificate of attendance upon completion of the workshop. The certificate is regarded favourably when the grower applies for funding to adopt strategies to reduce off-site environmental impacts.

The first SIX EASY STEPS workshop was held in south Queensland in 2005. With the introduction of the Commonwealth Government’s Reef Rescue Program on 1 January 2009, the roll-out of the workshops across all catchments adjacent to the Great Barrier Reef became a priority for BSES Limited extension officers and scientists.

Funding to conduct the workshops is being provided by the Australian Government under the Reef Rescue Plan. Operating in conjunction with these workshops, partial funding is also being provided by the government to enable growers to implement on-farm activities that will lead to improved water quality on the Great Barrier Reef by reducing the run-off of nutrients, pesticides and sediments from agricultural land. (Rudd et al., 2007).

**Attendance and impact of the SIX EASY STEPS workshops**

A total of 3842 growers from north to central Queensland produce sugarcane in the catchments that drain into the Great Barrier Reef (CANEGROWERS Brisbane, pers. comm. 2009).
The South Queensland contribution to Reef run-off is very small and is not included in the following discussion.

To 30 June 2009, approximately 630 growers had voluntarily attended a SIX EASY STEPS workshop. This 16% of the total grower number is estimated to represent approximately 30% of the area producing cane. In addition, about 100 extension staff, natural resource management representatives, sugar industry productivity officers and agribusiness advisers also attended workshops.

SIX EASY STEPS workshops were rolled out across north Queensland in February 2008, one to two years later than in the rest of the industry. Detailed records of attendance at north Queensland workshops show that 40625 ha or 31% of the area under sugarcane cropping has been represented at SIX EASY STEPS workshops (Table 3).

When participants at the last ten workshops were asked to provide an overall assessment of the workshop, the average score of the 119 respondents was 9.1 out of 10. Forty per cent of respondents rated the workshop at the maximum score of 10.

In 2009, a survey of 88 cane growers in all regions across Queensland who had completed a SIX EASY STEPS workshop was conducted (RWUEI 2009, T Anderson pers. comm.). The survey
assessed on-farm practical changes that had been implemented as a result of attendance at a workshop. The survey results confirmed that the initial positive impact of the workshops translated into the adoption of sustainable practices. Some of the survey results include:

- Ninety-five per cent of growers had taken a soil test in the previous two years to determine the most appropriate nutrient management program for a particular cane field or area of the farm.
- Sixty-one per cent changed the type of fertiliser they used to a more economical or nutritionally appropriate product.
- Fifty-eight per cent reduced fertiliser rates. The confidence they gained from the course to reduce fertiliser rates without fear of loss of productivity was stated as a significant factor in the decision to reduce nutrient inputs.
- Almost all growers who grew an alternative crop reduced fertiliser inputs in the following plant cane crop.

The reasons for the success of the workshops are believed to be due to several factors. Canegrowers are increasingly aware of the environmental issues due to over-fertilising and inappropriate timing and placement of fertiliser applications. The sugar industry understands that government and community pressure on the industry, whether warranted or not, has to be addressed through appropriate nutrient management strategies. The workshops were developed in close cooperation with growers and extension staff to produce a product that is relevant, interactive, interesting and useful. Active participation in the workshops is seen as the key to their success.

**Training program support**

The SIX EASY STEPS training program is supported by a range of initiatives that are currently under way or planned (Schroeder et al., 2010). These include:

- a workshop reference manual
- regional soil reference booklets (Wood et al., 2003, Schroeder et al., 2006b, Schroeder et al., 2007a, Schroeder et al., 2007b) which include soil-specific nutrient management guidelines for cane production in each district
- nutrient management plans which will include farm maps with soil overlays
- replicated on-farm strip trials (Salter et al., 2008) to compare SIX EASY STEPS nutrient recommendations with growers’ own current fertiliser strategies
- the NutriCalc calculator to determine nutrient requirements based on soil test results
- two new decision support tools for minimising off-site movement of nutrients (Moody et al., 2008): ‘Soils Constraint and Management Package’ (SCAMP) that utilises soil analytical data to identify soil constraints to long-term sustainability and ‘SafeGauge for Nutrients’.
- trials to determine the nutrient requirements of new farming systems (Wood et al., 2008)

**Conclusion**

The development and delivery of the SIX EASY STEPS program and implementation of the program’s nutrient recommendations and management practices have been significant achievements for the Australian sugar industry. The program is successfully addressing industry, community and government targets relating to sustainable nutrient use in the sugarcane production system.

**Acknowledgements**

The SIX EASY STEPS program forms part of the nutrient management initiative involving BSES Limited, CSR Ltd and the Queensland Department of the Environment and Resource Management (DERM). It is supported by CANEGROWERS and receives funding from the Sugar Research and Development Corporation (SRDC), Queensland Primary Industries & Fisheries
(QPIF) and the Australian Department of the Environment, Water, Heritage and the Arts (DEWHA). Under the Reef Rescue Program, the Australian Government provided partial funding through Terrain Natural Resource Management to assist with the delivery of some of the SIX EASY STEPS workshops.

MOTS-CLES: Gestion des Engrais, SIX ETAPES FACILES, Récif.

Résumé

DANS LE NORD du Queensland tropical, la nécessité d’adopter une meilleure pratique pour accélérer la gestion des engrais est encore plus urgente en raison des pressions exercées pour atteindre une production de canne rentable tout en prenant compte de l’environnement. Ce dernier facteur dépend principalement de la proximité des planteurs de cannes avec la Grande Barrière de Corail reconnue par le Patrimoine Mondial. Le programme de SIX ETAPES FACILES a été développé pour permettre l’adoption de meilleures pratiques de gestion en éléments nutritifs sur les fermes et pour
promouvoir l’utilisation durable d’engrais dans l’industrie sucrière australienne. Ce système vise à une production durable de la canne, encourage les planteurs à mieux connaître les sols, les éléments nutritifs et la culture de la canne afin de prendre des décisions en toute connaissance de cause sur leurs apports d’engrais. Bien que les producteurs ont généralement une connaissance inhérente de ces principes, un cours de courte durée est proposé pour promouvoir le développement et l’utilisation des plans de gestion appropriés des éléments nutritifs afin de cibler les apports d’engrais. Cette présentation rapporte l’évaluation de cette méthode d’éducation qui est liée à des activités spécifiques et encourage des interactions entre les planteurs. En général, il a été constaté que les planteurs et leurs conseillers ont apprécié la possibilité de suivre ce cours de courte durée. Toutefois, la gestion individuelle ne va probablement pas progresser sans une aide supplémentaire des officiers de vulgarisation. La mise en place d’essais par bande sur les fermes avec la participation des planteurs qui comparent les pratiques de gestion des éléments nutritifs habituels à celles qui sont préconisées par les SIX ETAPES FACILES, est un moyen utile et pratique de démontrer une meilleure gestion des engrais aux planteurs.

EXTENSIÓN Y ADOPCIÓN DEL PROGRAMA DE MANEJO DE NUTRIENTES ‘SIX EASY STEPS’ (SEIS PASOS FÁCILES) EN LA PRODUCCIÓN DE CAÑA DE AZÚCAR EN EL NORTE DE QUEENSLAND

Por

D.V. CALCINO1, B.L. SCHROEDER2 y A.P. HURNEY3

dcalcino@bses.org.au

PALABRAS CLAVE: Manejo de Nutrientes, SIX EASY STEPS, Arrecife.

Resumen

EN EL NORTE tropical de Queensland, se ha hecho urgente la necesidad de adoptar rápidamente las mejores prácticas para el manejo de nutrientes debido a las presiones crecientes en cuanto a la producción rentable de caña de azúcar en combinación con el cuidado del ambiente. El último de estos factores se debe a la proximidad de las áreas de producción de caña con la Gran Barrera del Arrecife que ha sido declarada Patrimonio Mundial. El programa de los ‘Seis Pasos Fáciles’, Six Easy Steps, en inglés, se desarrolló para permitir la fácil adopción de los principios de las mejores prácticas de manejo de nutrientes en el campo y para promover el uso sostenible de los nutrientes en la agroindustria azucarera australiana. Este sistema, orientado a la producción sostenible de caña, insta a los productores a usar el conocimiento de los suelos, nutrientes y el cultivo de caña para tomar decisiones documentadas sobre el uso de sus fertilizantes. Aunque los productores de caña generalmente tienen un conocimiento básico de estos conceptos, se está utilizando un curso corto para promover el desarrollo y uso apropiado de planes de manejo de nutrientes. Este trabajo reporta un estudio que se hizo de este proceso educativo que tiene un seguimiento específico y actividades interactivas para los productores de caña. En general, se ha encontrado que los productores y sus asesores valoran la oportunidad de atender este programa. Sin embargo, el desarrollo de los programas individuales de manejo de nutrientes no progresará sin el apoyo de los oficiales extensionistas. El uso de ensayos de franjas demostrativas donde se compara la práctica usual del productor y las prácticas promovidas por el programa Six Easy Steps, es un medio práctico y útil para demostrar el valor de un programa de mejor manejo de nutrientes a los productores.
LIVER:BODY MASS$^1$ RATIOS OF LAB RATS DRINKING WATER WITH CALORIC AND HYPO-CALORIC SWEETENERS ADDED

KEYWORDS: Sucrose, Fructose, Aspartame, Sucralose, Liver Tissue.

Abstract

CARBOHYDRATES are metabolised in the livers of mammals. In order to determine the effect of consumption of sweeteners on the liver, mass ratios of the mass of the liver to total body mass were assessed in experiments carried out in laboratory animals. Weaned male Wistar rats were fed daily with a solid diet ad libitum (Global Teklad), and given water with: 1) Fructose, 15%; 2) Sucrose, 10%; 3) Aspartame, 0.3%; 4) Sucralose, 0.19%, and 5) Control, unsweetened water. After 73 days, the animals were sacrificed, and hepatic tissues were removed. Daily water volume consumption, amount of ingested food, and body mass gain were assessed. Results were statistically compared (p<0.05), showing that fructose in water promoted the highest mass gain in the rats. Rats that consumed sucrose had the lowest food consumption and the lowest final mass gain, statistically similar to those of the control lot. Study animals that had water with hypo-caloric artificial sweeteners, aspartame and sucralose, ingested the same amount of food as the control counterparts but were fatter than control and sucrose lots, but lower than the fructose-drinking specimens. The fructose-consuming lot showed a tendency to greater liver mass:body mass ratio even though it did not have statistically-significant values with respect to the other lots evaluated. A contrary tendency of liver:body mass ratios, smaller than the other three lots, was produced in the lots ingesting the two hypo-caloric sweeteners, although they did not reach statistically-significant values. These results should be further studied in a longer term experiment (250–300 days).

Introduction

The prevalence of obesity is increasing around the world, and is a significant public health problem in many countries. Consumers are increasingly concerned about the quality and safety of

$^1$ In the sciences, mass and weight are different properties. Mass is a measure of the amount of matter in the body while weight is a measure of the force on the object caused by a gravitational field. For example, a person with 60 kg mass, weighs 60 kg-force in Earth’s surface; but, the same person, in the Moon surface would only weigh around 10 kg-force; however, his/her mass will be 60 kg. In common language, the term ‘weight’ is wrongly used as a synonym of ‘mass’. The mass unit in the IS is the kilogram, kg
many products present in the diets of industrialised countries, in particular, the use of artificial sweeteners and dietary supplements.

General apprehension also exists regarding the possible long-term health effects. Of particular concern are the potential carcinogenic effects of these products (Vermunt et al., 2003; Soffritti et al., 2006). Fructose is a monosaccharide found in fruits and honey that in recent decades has been enzymatically obtained from starch hydrolysis, mainly from maize (Bray et al., 2004). Some authors have suggested that the ingestion of fructose syrups may be responsible for much of the obesity problem seen in today’s world (Aeberli et al., 2007; Gaby, 2005; Johnson et al., 2007).

Fructose is directly transported to the liver without increasing insulin in blood plasma, mobilising fats, and at a higher rate than glucose, which is controlled by phosphofructokinase (Voet and Voet, 1992). The liver, kidneys, and small intestine are the main metabolic utilisation sites for sugar (Murray et al., 1994). Aspartame and sucralose, some of the most commonly-added artificial sweeteners to foods and drinks, have also been studied, but still no conclusive data are available (Jürgens et al., 2005, Teff et al., 2004).

To corroborate the effects that these sweeteners have in liver when chronically consumed, especially in infancy and adolescence, these sweeteners were added daily to the drinking water of male Wistar rats after they were weaned, using them as models, until they reached ‘adulthood’. Both food and water were given *ad libitum*.

**Materials and methods**

The investigation protocol was approved by the Institutional Program for the Care and Use of Animals from the Animal Experimentation Unit, Complex E, Faculty of Chemistry, UNAM (*Universidad Nacional Autónoma de México*, National Autonomous University of Mexico in Spanish). Male Wistar rats were used with an average initial body mass of 39.2± 0.4 g.

Rats were placed in individual boxes and acclimated for seven days in a controlled environment at a temperature of 23±1°C and a 12 hour cycle of light/dark and fed with the same solid diet *ad libitum* (Global Teklad) and tap drinking water. At the end of the inuring week, they were randomly distributed in five groups of 9 rats each one. Four groups had different sweeteners in their drinking water.

Two treatments were with natural sugars comparable to those found in soft drinks:

1) Fructose solution, 15% (Jürgens et al., 2005), and
2) Sucrose solution, 10% (González, 2006).

Two other treatments utilised hypocaloric sweeteners:

3) Aspartame solution, 0.3% (González, 2006), and
4) Sucralose solution, 0.19% (González, 2006).

Finally, the fifth group received

5) Unsweetened drinking water (control).

Sweeteners were dissolved in drinking water. After daily intake was measured, residual water was discarded and freshly-prepared solutions were placed after water troughs were perfectly washed in order to avoid bacterial contamination. Body mass gain was individually measured for each of the nine rats of the five groups by means of an analytical weighing scale (OHAUS model Scout II), three times per week; the average was calculated by group/day. In the same way, food and liquid were measured daily for each rat.

After 73 days of feeding, the animals were sacrificed and their livers removed for histological analysis (Genneser, 1989; Ross et al., 1992). Experimental data obtained were statistically processed with analysis of variance (ANOVA, p≤0.05), between: a) Body mass gained by specimens and lots for the duration of the experiment, and b) Differences in the mass ratios of the amounts of food ingested by specimens and lots for the duration of the experiment. Once it was

corroborated that statistically-significant differences existed, a comparison between groups, using a student's $t$-distribution ($p \leq 0.05$), was performed (Pedrero and Pangborn, 1996).

**Results and discussion**

Figure 1 presents the average values of liver mass with respect to total mass gain from the nine rats of each group. A tendency towards higher liver:body mass ratios was observed in the animals that ingested fructose. Even though these data were not statistically different ($p<0.05$), this finding will have to be studied in a longer term experiment (250–300 days) to establish its possible meaning.

Results obtained in this research show that drinking fructose water solutions promoted the highest mass gain in Wistar rats in comparison to other caloric and hypo-caloric sweeteners (Figure 2). Statistical differences were found among the rat group that ingested water containing caloric sweeteners (fructose, with respect to sugar and control), with the highest mass gain for the fructose-consuming group and the lowest for the sugar-consuming group.

There were no statistically-significant differences in mass gain between the sugar-consuming and control lots ($p<0.05$). When a comparison was made between both groups consuming hypo-caloric sweeteners, there were no significant differences. However, they were statistically different with respect to the other three groups (sucrose, fructose, and control).

The highest body mass gain from these two groups consuming hypo-caloric sweeteners was observed in the aspartame-consuming group. Once the rats reached adulthood, daily water consumption was up to 110 mL for the sugar group whereas for the control and aspartame-consuming groups, it was only 30 mL, with the fructose-consuming group ca. 90 mL, and the sucralse-consuming group around 55 mL (Figure 3).

Daily food intake was on average 19 g for the groups consuming hypo-caloric sweeteners and controls, and 12 g for the groups consuming caloric sweeteners (Figure 4). As had been expected, a preference was observed on the part of the animals for the liquid containing caloric sweeteners, along with a reduction of the ingestion of solids, where the daily caloric ingestion was concerned. Histological analysis showed that the hepatic tissue of the rats that drank fructose solution showed a greater accumulation and concentration of extracellular lipids.
It is interesting to observe that in spite of the similar daily consumption of water, and food with similar caloric intake (Martínez-Tinajero et al., 2009), the animals that consumed hypo-caloric sweeteners are statistically fatter than those of the control group. A recent paper suggests that metabolic alterations might indeed be occurring after ingestion of these artificial sweeteners (Dyer et al., 2007).

On the other hand, the groups ingesting hypo-caloric sweeteners showed a tendency to lower liver:body mass ratio, even though this did not reach statistically-significant values. (Figure 1). Rats that consumed hypo-caloric sweeteners had similar solid food intakes to that of the control group.

Nevertheless, when the liquid intake was analysed, it was observed that the animals receiving the hypo-caloric sweeteners showed a statistical difference where the sucralose-consuming lot was concerned (p<0.05). This behaviour should also be evaluated in a longer term experiment (250–300 days) to establish its possible meaning.

**Conclusions**

Caloric sweeteners promote water intake. However, fructose promotes a higher mass gain than sugar. Moreover, ingestion of fructose brings about an accumulation of extracellular lipids in liver tissue, as well as a slightly higher liver:body mass ratio when it is compared to sugar-ingesting and control groups.

Although hypo-caloric sweeteners did not contribute to caloric intake, they promoted greater mass gain than sugar-ingesting and control groups. Additionally, a slight tendency to a lower liver:body mass ratio was found among the sucralose- and aspartame-ingesting group when compared to the sugar-ingesting and control groups. These effects on liver:body mass ratios for both natural and hypo-caloric sweeteners should be studied further.

Résumé

LES CARBOHYDRATES sont métabolisés dans le foie des mammifères. Afin de déterminer l'effet de la consommation d'édulcorants sur le foie, les rapports de la masse du foie et la masse du corps total ont été évalués lors des expériences menées sur des animaux de laboratoire. Des rats adultes mâles Wistar ont été nourris quotidiennement avec une alimentation solide ad libitum et de l'eau contenant (1) 15% de fructose, (2) 10% de saccharose, (3) 0.3% d'aspartame, (4) 0.19% de sucralose, et (5) de l'eau non sucré, comme contrôle. Après 73 jours, les animaux ont été sacrifiés et les tissus hépatiques retirés. La consommation journalière du volume d'eau, la quantité des aliments ingérés et le gain de poids corporel ont été évalués. Les résultats ont été comparés statistiquement (p<0.05), montrant que le fructose dans l'eau favorise le gain de poids le plus élevé chez les rats. Les rats consommant du saccharose avaient la plus faible consommation alimentaire et le gain de poids le plus bas, statistiquement similaire au contrôle. L’étude des animaux qui avaient bu de l'eau avec les édulcorants hypo caloriques artificiels, l'aspartame et le sucralose, ont consommé la même quantité de nourriture que ceux du contrôle mais étaient plus gros que les lots de contrôle et de saccharose, et inférieur à ceux qui avaient consommé du fructose. Ces derniers ont montré une tendance à un plus grand rapport entre la masse du foie et du corps, même si les différences n’étaient pas statistiquement significatives. Une tendance contraire au ratio foie:poids corporel, plus faible que les trois autres lots, a été noté dans les lots avec les deux édulcorants hypo-caloriques, bien qu’ils n'ont pas atteint des valeurs statistiquement significatives. Ces résultats devraient être étudiés plus profondément dans une expérience à long terme (250–300 jours).

Palabras Clave: Sacarosa, Fructosa, Aspartame, Sucralosa, Tejido Hepático.

Resumen

LOS CARBOHIDRATOS son metabolizados en el hígado de los mamíferos. Con el propósito de determinar el efecto que tiene en el hígado el consumo de edulcorantes, se llevó un a cabo un estudio de las razones de la masa del hígado y la masa corporal total de un grupo de animales de laboratorio. Ratas macho Wistar destetadas fueron alimentadas diariamente con una dieta sólida ad libitum (Global Teklad) y se les dio a beber agua que contenía uno de los siguientes edulcorantes: 1) Fructosa, 15%; 2) Sacarosa, 10%; 3) Aspartame, 0.3%; 4) Sucralosa, 0.19%, y 5) Control, agua sin edulcorante. Después de 73 días, los animales fueron sacrificados y el tejido hepático fue removido. Se tenía información del volumen de agua consumido por día, cantidad de alimento y ganancia en masa corporal. Los resultados fueron comparados estadísticamente (p<0.05), mostrando que la fructosa en agua provocó la mayor ganancia de masa en las ratas. Las ratas que consumieron sacarosa tuvieron la menor ingesta de alimento y la ganancia de masa más baja, estadísticamente similar a los animales del grupo control. Los animales bajo estudio que tomaron agua con edulcorantes artificiales hipo-calóricos, aspartame y sucralosa, consumieron la misma cantidad de comida que los animales en el grupo control pero estaban más gordos que el control y que el grupo que consumió sacarosa, aunque menos pesados que los animales que tomaron agua con fructosa. El grupo que consumió fructosa mostró una tendencia a tener un radio masa hepática:masa corporal más alto aunque los resultados no fueron estadísticamente significativos respecto a los otros grupos. Una tendencia contraria en cuanto al radio masa hepática:masa corporal se notó en los grupos de ratas consumiendo los dos edulcorantes hipo-calóricos, aunque los valores tampoco fueron estadísticamente significativos. Estos resultados deben estudiarse más a fondo en experimentos de más largo plazo (250–300 días).
SUGARCANE PRODUCTION AND RESEARCH IN CHINA

By

CHEN RUKAI and ZHAONIAN YUAN

Key Lab of Genetic Improvement for Sugarcane, Ministry of Agriculture, Fuzhou 350002

yzn05@sina.com

KEYWORDS: Industry, History, China, Research, Production.

Abstract

This paper describes the progress of the sugarcane industry in China, as well as the major characteristics of sugarcane production systems and R&D. Over the past 8 years, production area expanded by 47.87%, total sugarcane production increased by 79.54%, cane yield per hectare by 21.26% and annual sugar production by 83.12%. Sugar consumption in China has also grown steadily. Sugarcane was mainly grown in Central-South Guangxi, Southwest Yunnan, West of Guangdong and Northern Hainan. For energy production from sugarcane, national research projects have been carried out. Pilot study showed that the cost of ethanol production from sugarcane could be reduced to US$0.50/L, which was more economic than gasoline at US$70 per barrel. The problems facing the industry and their possible solutions are also discussed.

The history of sugarcane production in China

China is one of the original producers of sugarcane. Bamboo Cane (Saccharum sinense) and wild species (S. spontaneum) are widely distributed, from the North Qinling Mountains to the South Hainan Island. Sugarcane cultivation has a long history; since the late 4th century BC, China has used sugarcane to produce syrup.

Since the establishment of new China, sugarcane production has increased significantly. From 1949 to 2008, the total area of sugarcane plantation extended from 0.108 million to 1.475 million ha, cane production from 2.643 million to 113.0 million tonnes, cane yield per ha from 24 to 75 tonnes and total sugar production from 0.15 million to 13.697 million tonnes.

Sugarcane status of China

Major statistics for sugarcane production from 1997 to 2008 are listed in Table 1, and similar information for major production provinces from 2001 to 2008 in Table 2. In 2008, sugarcane plantation area was 1.521 million ha, which accounted for 71.4% of the total area for sugar plantations.

Total sugarcane production was 110.711 million tonnes, which produced 13.697 million tonnes of cane sugar. Compared with the 2001/2002 crushing season, production area expanded by 47.87%, total sugarcane production increased by 79.54%, cane yield per hectare by 21.26%, and annual sugar by 83.12% (Tables 1 and 2).

In December 2001, the State Council launched the Food and Nutrition Development Plan in China (2001–2010). This Plan aimed to increase sugar intake by 9 kg per person by 2010, which was equivalent to a total of 12 million tonnes of white sugar.

Before 2000, Chinese sugar consumption averaged about 8 Mt/y. It then increased to 10 Mt in 2003 and 11.4 Mt in 2004.

The average consumption of sugar per person per year in China was about 8.4 kg, which was among the lowest in the world. For sugar consumed in China, 72.6% was used in the food industry, 26.2% by households, and less than 1.2% for export. Sugar consumption has been increasing steadily due to the rapid development in the food, restaurant and catering industry (Table 1).
Table 1—Sugarcane industry in China from 1997–2008.

Sugarcane growing areas in China

The major sugarcane production area in China is located between latitude 18.5° to 32°N and longitude 92° to 122°E that includes Guangxi, Yunnan, Guangdong, Hainan, Fujian, Taiwan, Zhejiang, Sichuan, Guizhou, Hunan and Jiangxi provinces (or Autonomous Regions). Before the late 1980s, coastal areas in southeastern China such as Guangdong and Fujian were the main sugarcane producing areas. Since then, sugarcane production gradually shifted to the west to more sustainable production. So the current major production areas include Guangxi, Yunnan, Guangdong and Hainan provinces. In 2007/2008 season, 9.37 million tonnes of sugar was produced in Guangxi, which was equal to 68.5% of total sugar production, the largest producer in China. Yunnan produced 2.163 million tonnes, or 15.8% of the total production, which made it the second largest. Sugar production in western Guangdong was 1.454 million tonnes per year, the third largest. The combined sugar production from these three provinces accounted for 94.8% of the total production in China. Dominant production regions in these provinces were central-south in Guangxi, southwest in Yunnan, western in Guangdong and northern in Hainan (Figure 1).

Fig. 1—Major sugar producing areas (shaded) in China
Main features of sugarcane production systems

There were about 5 million farms. The average farm size was only about 0.27 ha and produced an average of 18 t cane. Planting, weeding, cultivation, fertilising, spraying and harvesting were still done by hand. Fertiliser was used excessively, especially nitrogen, at three times the world average, while the usage efficiency was low. It resulted in soil acidification and degradation as well as pollution. Most of the sugarcane fields were dry slopes with infertile soil. The average available irrigation was below 20 percent irrigation. Rainfall distribution was uneven and seasonal natural disasters such as drought and frost happened frequently. All these had an adverse impact on sugarcane production. For example, the frost in 1998–1999 and the drought in 2005–2006 caused serious damage to sugar production. Sugarcane smut, ratoon stunting disease, mosaic and other diseases caused more than a 20 percent reduction in production. Borers and soil-borne pests (e.g. Dorysthenes granulosus, grub) were found in over 60% of sugarcane plantations, which caused the loss of sugar content of over 0.5%. Improper usage of pesticides polluted the environment. Varieties from Taiwan Sugar were grown in more than 70% of the total sugarcane plantation area, varieties bred in mainland China less than 30%.

In 2006–2007, China had 212 sugar mills, of which 90% were in Guangdong, Guangxi and Yunnan. They were able to process 780 000 tonnes of cane per day, 18.2% higher than the capacity at the beginning of this century. There were 17 sugar enterprises with daily processing capacity exceeding 10 000 t cane, such as South China Sugar Co., Guangxi Farming Co., Fengtang Biochemistry Co., Yingmao Sugar Co. and Zhanjiang Farming Co. Energy consumption for processing 100 t cane was equivalent to 4.97 t standard coal, which was 20.5% less than 2002 or the lowest in history. Processing of 1 tonne of cane consumed 30.86 kWh of power, 2.7% less than 2002. Ratio of white sugar to cane was 12.23%, 1.28% higher than the beginning of this century. The sugar industry saved energy and increased efficiency remarkably. The major statistics of the industry are presented in Tables 2 and 3.

Main institutes doing sugarcane R&D in China

In China, the major sugarcane research institutes are the Sugarcane Synthetic Institute of Fujian Agriculture and Forestry University, Guangzhou Sugarcane Industry Research Institute, Guangxi Sugarcane Institute and the Sugarcane Institute of Yunnan Academy of Agricultural Science.

The institute of Fujian Agriculture and Forestry University has undertaken sugarcane research and development for 54 years. It established the first Sugarcane Branch of the National Sugar Crop Improvement Centre and managed a number of research laboratories and organisations; notably, the Key Laboratory of Sugarcane Genetics and Improvement of the Ministry of Agriculture, Cane Sugar Inspection Centre of the Ministry of Agriculture, Sugarcane Society of the Chinese Crop Society and National Sugarcane Variety Accreditation Committee. The Institute had the authority to award masters and PhD degrees and also hosted post-doctoral workers.

Professor Chen Rukai, the discipline leader, is a member of the Science and Technology Commission of the Ministry of Agriculture, and a chief scientist in sugarcane. In his institute, there are 6 professors who are national-level scientists in sugarcane research and 13 associate professors. The Institute has 30 staff and 30 to 40 graduates, and it is engaged in sugarcane research and development including genetics and improvement for sugar and energy sugarcane, nutrition management, pest control, agricultural mechanisation and industrial economy.

Guangzhou Sugarcane Industry Research Institute has undertaken sugarcane research and development for 50 years. It was under the former Ministry of Light Industry, and now it is the National Centre for Sugar Quality Inspection, Guangdong Branch of National Sugarcane Improvement Centre, and National Sugarcane Hybridisation Station in Hainan.

Source: Chinese Sugar Industry Association

Director Li Qiwei is engaged in sugarcane breeding and cultivation and is responsible for the Guangdong Sugarcane Society. He is also the executive member of China's Sugarcane Special Committee.

The institute has 4 national-level scientists, 30 researchers and associate researchers, and a staff of 120 members who work in sugarcane genetics and breeding, cultivation, plant protection, sucrose and ethanol processing, and sugar quality inspection. It is an assistant institute for the national projects undertaken by Fujian Agriculture and Forestry University.

Guangxi Sugarcane Institute is the Sugarcane Research Centre of the Chinese Academy of Agricultural Sciences, Sugarcane Variety Inspection Centre of Ministry of Agriculture, and Guangxi Branch of National Sugar Improvement Centre. It has 3 national-level experts, 20 researchers and associate researchers, and a staff of 160 members engaged in sugarcane breeding, cultivation and pest control. It is also in charge of two prepared projects for the National Science and Technology support plan, as an assistant institute for national projects undertaken by Fujian Agriculture and Forestry University.

The Institute of Yunnan Academy of Agricultural Sciences is the Yunnan Branch of National Sugar Crop Improvement Centre, and National Sugarcane Germplasm Resources Base is an assistant institute for national projects undertaken by Fujian Agriculture and Forestry University. Director Zhang Yuebin is engaged in sugarcane cultivation research. The institute has 3 national-level experts, 20 researchers and associate researchers, and a staff of 60 members.

To centralise the management of scientific research and prevent repetition at a low level, the Ministry of Agriculture and Ministry of Finance has appointed a number of scientists nationwide to build a national sugarcane industrial technology system under the guarantee of retaining the current administrative relationship.

The system is divided into two layers, including one national sugarcane industrial technology research and development centre and 15 extension stations. Based on the Fujian Agriculture and Forestry University, the research and development centre consists of 5 programs.

They are: sugarcane genetics and improvement with 6 scientists, nutrition and cultivation with 4 scientists, plant protection with 5, facilities and equipments with 3, and the processing and industrial economy with 2. Major participants are the Fujian Agriculture and Forestry University, Guangzhou Sugarcane and Sugar Industry Institute, Guangxi Sugarcane Institute, Yunnan Sugarcane Research Institute and South China Agricultural University.

Professor Chen Rukai has been appointed as the chief scientist. Lin Yanquan, Li Qiwei, Huang Chenghua, Ou Yinggang and Zheng Chuanfang have been appointed as program leaders. Meanwhile, 15 extension stations have been established based on provincial and district level that are based on Nanning, Chongzuo, Laibin, Liuzhou, Bose, Beihai, Nongken of Guangxi; Suixi, Zhanjiang of Guangdong; Kaiyuan, Lincang, Baoshan of Yunnan; Zhangzhou of Fujian; Nankang of Jiangxi; Zhanzhou of Hainan.

Fifteen directors have been appointed for the stations for a 5-year term with funds from government. In the current administration system, the projects are structured in a vertical fashion. The cooperation among different sectors of the industry, regions and disciplines should accelerate sugarcane industrial technology progress.

Prospects for future: further expansion

From 1996 to 2007, China’s sugar consumption increased from 7.8 million to 13.4 million tonnes, with an annual increase of 0.46 million tonnes. Based on this rate, the domestic sugar demand will reach 17 million tonnes by 2015, of which 13 million tonnes will come from cane sugar, 2.5 from corn, and 1.5 from sugar beet. This requires an extra 2 million tonnes of cane sugar based on the 10.75 million tonnes of cane sugar production in 2007. It is predicted that by 2015 total sugarcane area would be around 1.6 million hectares, cane yield 75 tonnes per hectare and total cane yield 12 million tonnes. With this prediction, the targeted sugar production could be met.

In China, the ‘Renewable Energy Law’ has come into effect, and the standards of ‘Denaturalised Fuel Ethanol’ and ‘Gasoline Alcohol’ have been established. The 863 Nation High Technology Project on energy sugarcane and sugarcane ethanol has started and is making progress. The concept of diversified ethanol materials has been extremely popular. The cost of ethanol is $0.25/L in Brazil, $0.50/L in USA, also $0.50 /L in China. Ethanol at $0.50/L is more cost-effective than gasoline at $70 per barrel in the market. In South China, sugarcane does not compete with grain crops for land and water. In Yunnan, Guangxi, Guangdong, Fujian and Hainan, there are still about
0.67 million ha of land that can be used to grow energy sugarcane, and it could produce 5.88 million tonnes of sucrose or 3.84 million tonnes of ethanol. It is beneficial to the environment because it will reduce pollution caused by automobiles. The development of the sugarcane ethanol industry will optimise the production structure of the sugarcane industry, stabilise the sugarcane growing areas, and increase farmers’ job opportunities and incomes.

The Chinese sugar industry produces 4.40 million tonnes of molasses annually, which can be used to produce 800,000 tonnes of fuel ethanol. It also produces 26.57 million tonnes of bagasse with 50% water content. Bagasse can be used to produce 8 million tonnes of paper pulp or a 1600 MW power plant to produce 11.2 billion kWh of green power per year. The cellulose and hemicellulose of bagasse are high quality raw materials for future industrial use to produce fuel ethanol.

In the coming 5 years, the major tasks in China sugarcane research and development will be as follows:

- Selection of new sugarcane varieties with high yield, optimal quality, resistance to diseases and pests, strong ratooning ability for the dominant sugarcane growing areas; this is necessary in order to solve present problems in production such as few varieties, same maturity periods, low sugar yield, deficiencies in rural labour forces, lack of machinery, severe diseases and pests, effects of toxic pesticides on environment, high production costs.

- A system of production technologies including mechanisation, water-fertiliser management, intercropping, diseases and pest control, along with more varieties with a wide range of maturing periods. Production trials and demonstrations in large areas of these technologies should be conducted in different ecological regions, from which to form a practical production system with high efficiency and low cost.

- Development and demonstration of techniques on water use efficiency, intercropping systems (sugarcane and leguminous), harvest machinery systems, and the integration of cultivation and varieties

- Research from the viewpoint of the sugarcane industry facing the challenge of growing population, resource and environmental pressures.
RECHERCHE ET PRODUCTION DE LA CANNE À SUCRE EN CHINE

Par

CHEN RUKAI et ZHAONIAN YUAN
Laboratoire de l’Amélioration Génétique de la canne à Sucre,

Mots Clés: Industrie, Histoire, Chine, Recherche, Production.

Résumé
Cet article décrit l'état d'avancement de l'industrie de la canne à sucre en Chine, les principales caractéristiques des systèmes de production, ainsi que la Recherche et le Développement. Au cours des 8 dernières années la superficie de production s’est étendu par 47.87 %, la production totale de la canne à sucre a augmenté de 79.54 %, le rendement de canne à l'hectare de 21.26 % et la production de sucre annuelle de 83.12 %. La consommation de sucre en Chine a également connu une croissance constante. La canne à sucre a été principalement cultivée au Centre-Sud Guangxi, au Sud-Ouest de Yunnan, à l’Ouest de Guangdong et au Nord de Hainan. Pour la production d'énergie à partir de la canne à sucre, les projets nationaux de recherche ont été effectués. Une étude pilote a montré que le coût de production de l’éthanol à partir de la canne à sucre pourrait être réduit à 0,50 $ US/L, qui était plus économique que l'essence à US$ 70 le baril. Les problèmes auxquels fait face l'industrie et les solutions possibles sont également abordées.

PRODUCCION E INVESTIGACIÓN DE CAÑA DE AZÚCAR EN CHINA

Resumen
Este trabajo describe el progreso de la industria azucarera en China, así como las principales características de los sistemas de producción y de investigación y desarrollo (R&D en inglés). Durante los últimos 8 años, el área total de producción se expandió en 47.87%, la producción total de azúcar se incrementó en 79.54%, el rendimiento de caña por hectárea mejoró en un 21.26% y la producción anual de azúcar en 83.12%. El consumo de azúcar en China también ha tenido un crecimiento estable. Los cultivos de caña de azúcar estaban principalmente en la Región Centro-Sur de Guangxi, al suroeste de Yunnan, al Oeste de Guangdong y el norte de Hainan. Se han realizado proyectos de investigación a nivel nacional para la producción de energía proveniente de la caña. Un estudio piloto demostró que el costo de la producción de etanol de caña podía reducirse a USD 0.50/L, lo que es más económico que el precio de la gasolina a USD 70 por barril. Los problemas que enfrenta la industria y sus posibles soluciones también son discutidos.
